If C^*D^* is $\perp^r$ to both L_1 and L_2, we get two equations for the two unknowns r_1 and r_2. Solving and knowing r_1 and r_2, the coordinates of C and D are determined. Then the magnitude of CD is obtained by length formula, and equation of CD by two point formula.

Parallel planes: Shortest distance CD = perpendicular distance from any point on L_1 to the plane parallel to L_1 and containing L_2.

WORKED OUT EXAMPLES

Example 1: Find the magnitude and equation of the line of shortest distance between the lines

$$\frac{x-1}{2} = \frac{y-2}{3} = \frac{z-3}{4},$$

$$\frac{x-2}{3} = \frac{y-4}{4} = \frac{z-5}{5}.$$

Solution: Point $A(x_1, y_1, z_1)$ on first line is $(1, 2, 3)$ and $B(x_2, y_2, z_2)$ on second line is $(2, 4, 5)$. Also (l_1, m_1, n_1) are $(2, 3, 4)$ and $(l_2, m_2, n_2) = (3, 4, 5)$. Then

$$\begin{aligned} k^2 &= (m_1 n_2 - m_2 n_1)^2 + (n_1 l_2 - n_2 l_1)^2 + (l_1 m_2 - l_2 m_1)^2 \\ &= (15-16)^2 + (12-10)^2 + (8-9)^2 \\ &= 1 + 4 + 1 = 6 \quad \text{or} \quad k = \sqrt{6}. \end{aligned}$$

So DR's is of line of shortest of distance: $-\frac{1}{\sqrt{6}}, \frac{2}{\sqrt{6}}, -\frac{1}{\sqrt{6}}$.

$$\text{Shortest distance} = \frac{1}{k}\begin{vmatrix} x_2 - x_1 & y_2 - y_1 & z_2 - z_1 \\ l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \end{vmatrix}$$

$$\begin{aligned} &= \begin{vmatrix} 1 & 2 & 2 \\ 2 & 3 & 4 \\ 3 & 4 & 5 \end{vmatrix} \frac{1}{\sqrt{6}} \\ &= \frac{(15-16) - 2(10-12) + 2(8-9)}{\sqrt{6}} \\ &= \frac{-1+4-2}{\sqrt{6}} = \frac{1}{\sqrt{6}}. \end{aligned}$$

Equation of shortest distance line:

$$\begin{vmatrix} x-1 & y-2 & z-3 \\ 2 & 3 & 4 \\ -\frac{1}{\sqrt{6}} & \frac{2}{\sqrt{6}} & -\frac{1}{\sqrt{6}} \end{vmatrix} = 0 \quad \text{or} \quad 11x + 2y - 7z + 6 = 0$$

and

$$\begin{vmatrix} x-1 & y-4 & z-5 \\ 2 & 3 & 4 \\ -\frac{1}{\sqrt{6}} & \frac{2}{\sqrt{6}} & -\frac{1}{\sqrt{6}} \end{vmatrix} = 0 \quad \text{or} \quad 7x + y - 5z + 7 = 0.$$

Example 2: Determine the points of intersection of the line of shortest distance with the two lines

$$\frac{x-3}{3} = \frac{y-8}{-1} = \frac{z-3}{1}; \ \frac{x+3}{-3} = \frac{y+7}{2} = \frac{z-6}{4}.$$

Also find the magnitude and equation of shortest distance.

Solution: Any general point C^* on first line is $(3 + 3r_1, 8 - r_1, 3 + r_1)$ and any general point D^* on the second line is $(-3 - 3r_2, -7 + 2r_2, 6 - 4r_2)$. DR's of C^*D^* are $(6 + 3r_1 + 3r_2, 15 - r_1 - 2r_2, -3 + r_1 - 4r_2)$. If C^*D^* is $\perp^r$ to both the given lines, then

$$3(6+3r_1+3r_2) - 1(15-r_1-2r_2) + 1(-3+r_1-4r_2) = 0$$

$$-3(6+3r_1+3r_2) + 2(15-r_1-2r_2) + 4(-3+r_1-4r_2) = 0$$

Solving for r_1 and r_2, $11r_1 - 7r_2 = 0, +7r_1 + 29r_2 = 0$ so $r_1 = r_2 = 0$. Then the points of intersection of shortest distance line CD with the given two lines are $C(3, 8, 3)$, $D(-3, -7, 6)$.

$$\begin{aligned} \text{Length of } CD &= \sqrt{(-6)^2 + (-15)^2 + (3)^2} \\ &= \sqrt{270} = 3\sqrt{30} \end{aligned}$$

$$\text{Equation } CD\text{:} \quad \frac{x-3}{-3-3} = \frac{y-8}{-7-8} = \frac{z-3}{6-3}$$

$$\text{i.e.,} \quad \frac{x-3}{-6} = \frac{y-8}{-15} = \frac{z-3}{3}.$$

Example 3: Calculate the length and equation of line of shortest distance between the lines

$$5x - y - z = 0, \quad x - 2y + z + 3 = 0 \qquad (1)$$

$$7x - 4y - 2z = 0, \quad x - y + z - 3 = 0 \qquad (2)$$

Solution: Any plane containing the second line (2) is

$$(7x - 4y - 2z) + \mu(x - y + z - 3) = 0$$

$$\text{or } (7 + \mu)x + (-4 - \mu)y + (-2 + \mu)z - 3\mu = 0 \quad (3)$$

DR's of first line (1) are $(l, m, n) = (-3, -6, -9)$ obtained from:

$$\begin{array}{ccc} l & m & n \\ 5 & -1 & -1 \\ l & -2 & 1 \end{array}$$

The plane (3) will be parallel to the line (1) with $l = -3, m = -6, n = -9$ if

$$-3(7 + \mu) + 6(4 + \mu) + 9(2 - \mu) = 0 \quad \text{or} \quad \mu = \frac{7}{2}$$

Substituting μ in (3), we get the equation of a plane containing line (2) and parallel to line (1) as

$$7x - 5y + z - 7 = 0 \quad (4)$$

To find an arbitrary point on line (1), put $x = 0$. Then $-y - z = 0$ or $y = -z$ and $-2y + z + 3 = 0$, $z = -1$, $y = 1$. $\therefore$ $(0, 1, -1)$ is a point on line (1). Now the length of the shortest distance = perpendicular distance of $(0, 1, -1)$ to plane (4)

$$= \frac{0 - 5(1) + (-1) - 7}{\sqrt{49 + 25 + 1}} = \left|\frac{-13}{\sqrt{75}}\right| = \frac{13}{\sqrt{75}} \quad (5)$$

Equation of any plane through line (1) is

$$5x - y - z + \lambda(x - 2y + z + 3) = 0$$

$$\text{or } (5 + \lambda)x + (-y - 2\lambda)y + (-1 + \lambda)z + 3\lambda = 0 \quad (6)$$

DR's of line (2) are $(l, m, n) = (2, 3, 1)$ obtained from

$$\begin{array}{ccc} l & m & n \\ 7 & -4 & -2 \\ 1 & -1 & 1 \end{array}$$

plane (6) will be parallel to line (2) if

$$2(5 + \lambda) + 3(-y - 2\lambda) + 1(-1 + \lambda) = 0 \quad \text{or} \quad \lambda = 2.$$

Thus the equation of plane containing line (1) and parallel to line (2) is

$$7x - 5y + z + 6 = 0 \quad (7)$$

Hence equation of the line of shortest distance is given by (6) and (7) together.

Aliter: A point on line (2) is $(0, -1, 2)$ obtained by putting $x = 0$ and solving (2). Then the length of shortest distance = perpendicular distance of $(0, -1, 2)$ to the plane (7) $= \frac{0+5+2+6}{\sqrt{75}} = \frac{13}{\sqrt{75}}$

Note: By reducing (1) and (2) to symmetric forms

$$\frac{x - \frac{1}{3}}{1} = \frac{y - \frac{5}{3}}{2} = \frac{z}{3}$$

$$\frac{x + 4}{1} = \frac{y + 7}{\frac{3}{2}} = \frac{z}{\frac{1}{2}}$$

The problem can be solved as in above worked Example 1.

Example 4: Show that the lines $\frac{x-1}{2} = \frac{y-2}{3} = \frac{z-3}{4}; \frac{x-2}{3} = \frac{y-3}{4} = \frac{z-4}{5}$ are coplanar.

Solution: Shortest distance between the two lines is

$$\begin{vmatrix} 2-1 & 3-2 & 4-3 \\ 2 & 3 & 4 \\ 3 & 4 & 5 \end{vmatrix} = \begin{vmatrix} 1 & 1 & 1 \\ 2 & 3 & 4 \\ 3 & 4 & 5 \end{vmatrix} \begin{aligned} &= (-1) - (-2) + (-1) \\ &= 0 \end{aligned}$$

$\therefore$ Lines are coplanar.

Example 5: If a, b, c are the lengths of the edges of a rectangular parallelopiped, show that the shortest distance between a diagonal and an edge not meeting the diagonal is $\frac{bc}{\sqrt{b^2+c^2}} \left(\text{or} \frac{ca}{\sqrt{c^2+a^2}} \text{ or } \frac{ab}{\sqrt{a^2+b^2}}\right)$.

Solution: Choose coterminus edges *OA*, *OB*, *OC* along the X, Y, Z axes. Then the coordinates are $A(a, 0, 0)$, $B(0, b, 0)$, $C(0, 0, c)$, $E(a, b, 0)$, $D(0, b, c)$, $G(a, 0, c)F(a, b, c)$ etc. so that $OA = a$, $OB = b$, $OC = c$.
To find the shortest distance between a diagonal *OF* and an edge *GC*. Here *GC* does not interest *OF*

$$\text{Equation of the line } OF\text{: } \frac{x - 0}{a - 0} = \frac{y - 0}{b - 0} = \frac{z - 0}{c - 0}$$

$$\text{or} \quad \frac{x}{a} = \frac{y}{b} = \frac{z}{c} \quad (1)$$

$$\text{Equation of the line } GC\text{: } \frac{x - 0}{a - 0} = \frac{y - 0}{b - 0} = \frac{z - c}{c - c}$$

$$\text{or} \quad \frac{x}{1} = \frac{y}{0} = \frac{z - c}{0} \quad (2)$$

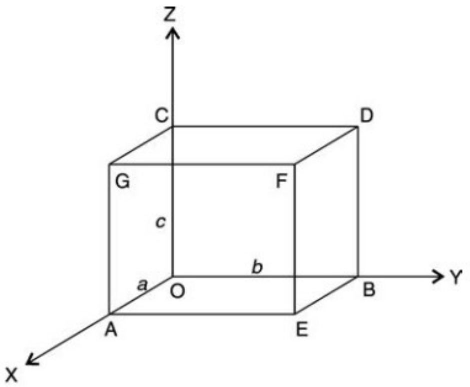

Fig. 36.17

Equation of a plane containing line (1) and parallel to (2) is

$$\begin{vmatrix} x & y & z \\ a & b & c \\ 1 & 0 & 0 \end{vmatrix} = 0 \qquad \text{or} \qquad cy - bz = 0 \qquad (3)$$

Shortest distance = Length of perpendicular drawn from a point say $C(0, 0, c)$ to the plane (3)

$$= \frac{c \cdot 0 - b \cdot c}{\sqrt{0^2 + c^2 + b^2}} = \frac{bc}{\sqrt{c^2 + b^2}}.$$

In a similar manner, it can be proved that the shortest distance between the diagonal OF and non-intersecting edges AN and AM are respectively $\frac{ca}{\sqrt{c^2+a^2}}$, $\frac{ab}{\sqrt{a^2+b^2}}$.

EXERCISE

1. Determine the magnitude and equation of the line of shortest distance between the lines. Find the points of intersection of the shortest distance line, with the given lines

   $\frac{x-8}{3} = \frac{y+9}{-16} = \frac{z-10}{7}$, $\quad \frac{x-15}{3} = \frac{y-29}{8} = \frac{z-5}{-5}$.

Ans. $14, 117x + 4y - 41z - 490 = 0, 9x - 4y - z = 14$, points of intersection $(5, 7, 3)$, $(9, 13, 15)$.

2. Calculate the length, points of intersection, the equations of the line of shortest distance between the two lines

   $\frac{x+1}{2} = \frac{y+1}{3} = \frac{z+1}{4}$, $\quad \frac{x+1}{3} = \frac{y}{4} = \frac{z}{5}$.

Ans. $\frac{1}{\sqrt{6}}, \frac{x-\frac{5}{3}}{\frac{1}{6}} = \frac{y-3}{-\frac{1}{2}} = \frac{z-\frac{15}{2}}{\frac{1}{6}}, \left(\frac{5}{3}, 3, \frac{13}{3}\right),$ $\left(\frac{3}{2}, \frac{10}{3}, \frac{25}{6}\right)$.

3. Find the magnitude and equations of shortest distance between the two lines

   $\frac{x-1}{2} = \frac{y-2}{3} = \frac{z-3}{4}$, $\quad \frac{x-2}{3} = \frac{y-4}{4} = \frac{z-5}{5}$.

Ans. $\frac{1}{\sqrt{6}}, 11x + 2y - 7z + 6 = 0, 7x + y - 5z + 7 = 0$.

4. Show that the shortest distance between the lines $\frac{x}{2} = \frac{y}{-3} = \frac{z}{1}$ and $\frac{x-2}{3} = \frac{y-1}{-5} = \frac{z+2}{2}$ is $\frac{1}{\sqrt{3}}$ and its equations are $4x + y - 5z = 0, 7x + y - 8z = 31$.

5. Determine the points on the lines $\frac{x-6}{3} = \frac{y-7}{-1} = \frac{z-4}{1}$, $\frac{x}{-3} = \frac{y+9}{2} = \frac{z-2}{4}$ which are nearest to each other. Hence find the shortest distance between the lines and find its equations.

Ans. $(3, 8, 3)$, $(-3, -7, 6)$, $3\sqrt{30}$, $\frac{x-3}{2} = \frac{y-8}{5} = \frac{z-3}{-1}$.

6. Prove that the shortest distance between the two lines $\frac{x-1}{3} = \frac{y-4}{2} = \frac{z-4}{-2}$, $\frac{x+1}{2} = \frac{y-1}{-4} = \frac{z+2}{1}$ is $\frac{120}{\sqrt{341}}$

   Hint: Equation of a plane passing through the first lines nad parallel to the second line is $6x + 7y + 16z = 98$. A point on second line is $(-1, 1, -2)$. Perpendicular distance $= \frac{6(-1)+7(1)+16(-2)}{\sqrt{6^2+7^2+16^2}}$.

7. Find the length and equations of shortest distance between the lines $x - y + z = 0, 2x - 3y + 4z = 0$; and $x + y + 2z - 3 = 0, 2x + 3y + 3z - 4 = 0$.

   Hint: Equations of two lines in symmetric form are $\frac{x}{1} = \frac{y}{2} = \frac{z}{1}$, $\frac{x-5}{-3} = \frac{y+2}{1} = \frac{z}{1}$.

Ans. $\frac{13}{\sqrt{66}}, 3x - y - z = 0, x + 2y + z - 1 = 0$.

8. Determine the magnitude and equations of the line of shortest distance between the lines $\frac{x-3}{2} = \frac{y+15}{-7} = \frac{z-9}{5}$ and $\frac{x+1}{2} = \frac{y-1}{1} = \frac{z-9}{-3}$.

Ans. $4\sqrt{3}$, $-4x + y + 3z = 0$, $4x - 5y + z = 0$ (or $x = y = z$).

9. Obtain the coordinates of the points where the line of shortest distance between the lines $\frac{x-23}{-6} = \frac{y-19}{-4} = \frac{z-25}{3}$ and $\frac{x-12}{-9} = \frac{y-1}{4} = \frac{z-5}{2}$ meets them. Hence find the shortest distance between the two lines.

Ans. $(11, 11, 31), (3, 5, 7), 26$

10. Find the shortest distance between any two opposite edges of a tetrahedron formed by the planes $x + y = 0$, $y + z = 0$, $z + x = 0$, $x + y + z = a$. Also find the point of intersection of three lines of shortest distances.

    Hint: Vertices are $(0, 0, 0)$, $(a, -a, a)$, $(-a, a, a)$, $(a, a, -a)$.

Ans. $\frac{2a}{\sqrt{6}}, (-a, -a, -a)$.

11. Find the shortest distance between the lines PQ and RS where $P(2, 1, 3)$, $Q(1, 2, 1)$, $R(-1, -2, -2)$, $S(-1, 4, 0)$.

Ans. $3\sqrt{2}$

36.6 THE RIGHT CIRCULAR CONE

Cone

A **cone** is a surface generated by a straight line (known as **generating line or generator**) passing through a fixed point (known as **vertex**) and satisfying a condition, for example, it may intersect a given curve (known as **guiding curve**) or touches a given surface (say a sphere). Thus cone is a set of points on its generators. Only cones with second degree equations known as quadratic cones are considered here. In particular, quadratic cones with vertex at origin are homogeneous equations of second degree.

Equation of cone with vertex at (α, β, γ) and the conic $ax^2 + 2hxy + by^2 + 2gx + 2fy + c = 0$, $z = 0$ as the guiding curve:

The equation of any line through vertex (α, β, γ) is

$$\frac{x-\alpha}{l} = \frac{y-\beta}{m} = \frac{z-\gamma}{n} \qquad (1)$$

(1) will be generator of the cone if (1) intersects the given conic

$$ax^2 + 2hxy + by^2 + 2gx + 2fy + c = 0, \; z = 0 \qquad (2)$$

Since (1) meets $z = 0$, put $z = 0$ in (1), then the point $\left(\alpha - \frac{l\gamma}{n}, \beta - \frac{m\gamma}{n}, 0\right)$ will lie on the conic (2), if

$$a\left(\alpha - \frac{l\gamma}{n}\right)^2 + 2h\left(\alpha - \frac{l\gamma}{n}\right)\left(\beta - \frac{m\gamma}{n}\right) + b\left(\beta - \frac{m\gamma}{n}\right)^2 + \\ + 2g\left(\alpha - \frac{l\gamma}{n}\right) + 2f\left(\beta - \frac{m\gamma}{n}\right) + c = 0 \qquad (3)$$

From (1)

$$\frac{l}{n} = \frac{x-\alpha}{z-\gamma}, \qquad \frac{m}{n} = \frac{y-\beta}{z-\gamma} \qquad (4)$$

Eliminate l, m, n from (3) using (4),

$$a\left(\alpha - \frac{x-\alpha}{z-\gamma}\cdot\gamma\right)^2 + \\ + 2h\left(\alpha - \frac{x-\alpha}{z-\gamma}\cdot\gamma\right)\left(\beta - \frac{y-\beta}{z-\gamma}\cdot\gamma\right) + \\ + b\left(\beta - \frac{y-\beta}{z-\gamma}\cdot\gamma\right)^2 + 2g\left(\alpha - \frac{x-\alpha}{z-\gamma}\cdot\gamma\right) + \\ + 2f\left(\beta - \frac{\gamma-\beta}{z-\gamma}\cdot\gamma\right) + c = 0$$

or

$$a(\alpha z - x\gamma)^2 + 2h(\alpha z - x\gamma)(\beta z - y\gamma) + \\ + b(\beta z - y\gamma)^2 + 2g(\alpha z - x\gamma)(z - \gamma) + \\ + 2f(\beta z - y\gamma)(z - \gamma) + c(z - \gamma)^2 = 0$$

or

$$a(x-\alpha)^2 + b(y-\beta)^2 + c(z-\gamma)^2 + \\ + 2f(z-\gamma)(y-\beta) + 2g(x-\alpha)(z-\gamma) + \\ + 2h(x-\alpha)(y-\beta) = 0 \qquad (5)$$

Thus (5) is the equation of the quadratic cone with vertex at (α, β, γ) and guiding curve as the conic (2).

Special case: Vertex at origin $(0, 0, 0)$. Put $\alpha = \beta = \gamma = 0$ in (5). Then (5) reduces to

$$ax^2 + by^2 + cz^2 + 2fzy + 2gxz + 2hxy = 0 \qquad (6)$$

Equation (6) which is a homogeneous and second degree in x, y, z is the equation of cone with vertex at origin.

Right circular cone

A right circular cone is a surface generated by a line (**generator**) through a fixed point (**vertex**) making a constant angle θ (**semi-vertical angle**) with the fixed line (**axis**) through the fixed point (**vertex**). Here the guiding curve is a circle with centre at c. Thus every section of a right circular cone by a plane perpendicular to its axis is a circle.

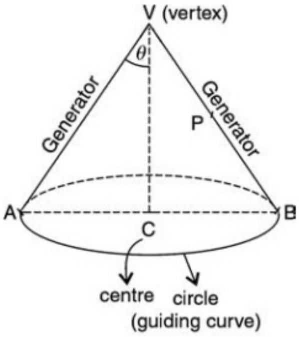

Fig. 36.18

Equation of a right circular cone: with vertex at (α, β, γ), semi vertical angle θ and equation of axis

$$\frac{x-\alpha}{l} = \frac{y-\beta}{m} = \frac{z-\gamma}{n} \tag{1}$$

Let $P(x, y, z)$ be any point on the generating line VB. Then the DC's of VB are proportional to $(x-\alpha, y-\beta, z-\gamma)$. Then

$$\cos\theta = \frac{l(x-\alpha)+m(y-\beta)+n(z-\gamma)}{\sqrt{(l^2+m^2+n^2)}\sqrt{(x-\alpha)^2+(y-\beta)^2+(z-\gamma)^2}}$$

Rewriting, the required equation of cone is

$$\left[l(x-\alpha)+m(y-\beta)+n(z-\gamma)\right]^2 =$$

$$= (l^2+m^2+n^2)\left[(x-\alpha)^2+(y-\beta)^2+(z-\gamma)^2\right]\cos^2\theta \tag{2}$$

Case 1: If vertex is origin $(0, 0, 0)$ then (2) reduces

$$(lx+my+nz)^2 = (l^2+m^2+n^2)(x^2+y^2+z^2)\cos^2\theta \tag{3}$$

Case 2: If vertex is origin and axis of cone is z-axis (with $l = 0, m = 0, n = 1$) then (2) becomes

$$z^2 = (x^2+y^2+z^2)\cos^2\theta \quad \text{or} \quad z^2\sec^2\theta = x^2+y^2+z^2$$

$$z^2(1+\tan^2\theta) = x^2+y^2+z^2$$

i.e.,
$$x^2+y^2 = z^2\tan^2\theta \tag{4}$$

Similarly, with y-axis as the axis of cone

$$x^2+z^2 = y^2\tan^2\theta$$

with x-axis as the axis of cone

$$y^2+z^2 = x^2\tan^2\theta.$$

If the right circular cone admits sets of three mutually perpendicular generators then the semi-vertical angle $\theta = \tan^{-1}\sqrt{2}$ (since the sum of the coefficients of x^2, y^2, z^2 in the equation of such a cone must be zero i.e., $1+1-\tan^2\theta = 0$ or $\tan\theta = \sqrt{2}$).

WORKED OUT EXAMPLES

Example 1: Find the equation of cone with base curve $\frac{x^2}{a^2}+\frac{y^2}{b^2} = 1, z = 0$ and vertex (α, β, γ). Deduce the case when base curve is $\frac{x^2}{16}+\frac{y^2}{9} = 1, z = 0$ and vertex at $(1, 1, 1)$.

Solution: The equation of any generating line through the vertex (α, β, γ) is

$$\frac{x-\alpha}{l} = \frac{y-\beta}{m} = \frac{z-\gamma}{n} \tag{1}$$

This generator (1) meets $z = 0$ in the point

$$\left(x = \alpha - \frac{l\gamma}{n}, \qquad y = \beta - \frac{m\gamma}{n}, \qquad z = 0\right) \tag{2}$$

Point (2) lies on the generating curve

$$\frac{x^2}{a^2}+\frac{y^2}{b^2} = 1 \tag{3}$$

Substituting (2) in (3)

$$\frac{\left(\alpha - \frac{l\gamma}{n}\right)^2}{a^2} + \frac{\left(\beta - \frac{m\gamma}{n}\right)^2}{b^2} = 1 \tag{4}$$

Eliminating l, m, n from (4) using (1),

$$\frac{\left[\alpha - \left(\frac{x-\alpha}{z-\gamma}\right)\gamma\right]^2}{a^2} + \frac{\left[\beta - \left(\frac{y-\beta}{z-\gamma}\right)\gamma\right]^2}{b^2} = 1$$

$$b^2\left[\alpha(z-\gamma)-\gamma(x-\alpha)\right]^2 + a^2\left[\beta(z-\gamma)-\gamma(y-\beta)\right]^2$$

$$= a^2b^2(z-\gamma)^2$$

Deduction: When $a=4, b=3, \alpha=1, \beta=1, \gamma=1$,

$$9\Big[(z-1)-(x-1)\Big]^2+16\Big[(z-1)-(y-1)\Big]^2$$
$$=144(z-1)^2$$
$$9x^2+16y^2-119z^2-18xz-32yz+288z-144=0.$$

Example 2: Find the equation of the cone with vertex at (1, 0, 2) and passing through the circle $x^2+y^2+z^2=4$, $x+y-z=1$.

Solution: Equation of generator is

$$\frac{x-1}{l}=\frac{y-0}{m}=\frac{z-2}{n} \qquad (1)$$

Any general point on the line (1) is

$$(1+lr, \quad mr, \quad 2+nr). \qquad (2)$$

Since generator (1) meets the plane

$$x+y-z=1 \qquad (3)$$

substitute (2) in (3)

$$(1+lr)+(mr)-(2+nr)=1$$

or $$r=\frac{2}{l+m-n}. \qquad (4)$$

Since generator (1) meets the sphere

$$x^2+y^2+z^2=4 \qquad (5)$$

substitute (2) in (5)

$$(1+lr)^2+(mr)^2+(2+nr)^2=4$$

or $$r^2(l^2+m^2+n^2)+2r(l+2n)+1=0 \qquad (6)$$

Eliminate r from (6) using (4), then

$$\frac{4}{(l+m-n)^2}(l^2+m^2+n^2)+2\frac{2}{(l+m-n)}(l+2n)+1=0$$
$$9l^2+5m^2-3n^2+6lm+2ln+6nm=0 \qquad (7)$$

Eliminate l, m, n from (7) using (1), then

$$9\left(\frac{x-1}{r}\right)^2+5\left(\frac{y}{r}\right)^2-3\left(\frac{z-2}{r}\right)^2+6\left(\frac{x-1}{r}\right)\left(\frac{y}{r}\right)+$$
$$+2\left(\frac{x-1}{r}\right)\left(\frac{z-2}{r}\right)+6\left(\frac{z-2}{r}\right)\left(\frac{y}{r}\right)=0$$

or $$9(x-1)^2+5y^2-3(z-2)^2+6y(x-1)+$$
$$+2(x-1)(x-2)+6(z-2)y=0$$

Vertex (0, 0, 0):

Example 3: Determine the equation of a cone with vertex at origin and base curve given by

a. $ax^2+by^2=2z, \qquad lx+my+nz=p$

b. $ax^2+by^2+cz^2=1, \qquad lx+my+nz=p$

c. $x^2+y^2+z^2=25, \qquad x+2y+2z=9$

Solution: We know that the equation of a quadratic cone with vertex at origin is a homogeneous equation of second degree in x, y, z. By eliminating the non-homogeneous terms in the base curve, we get the required equation of the cone.

a. $2z$ is the term of degree one and is non homogeneous. Solving

$$\frac{lx+my+nz}{p}=1$$

rewrite the equation

$$ax^2+by^2=2\cdot z(1)=2z\left(\frac{lx+my+nz}{p}\right)$$
$$apx^2+bpy^2-2nz^2-2lxz-2myz=0$$

which is the equation of cone.

b. Except the R.H.S. term 1, all other terms are of degree 2 (and homogeneous). Rewriting, the required equation of cone as

$$ax^2+by^2+cz^2=(1)^2=\left(\frac{lx+my+nz}{p}\right)^2$$
$$(ap^2-l^2)x^2+(bp^2-m^2)y^2+(cp^2-n^2)z^2-$$
$$-2lmxy-2mnyz-2lnxz=0$$

c. On similar lines

$$x^2+y^2+z^2=25=25(1)^2=25\left(\frac{x+2y+2z}{9}\right)^2$$
$$56x^2-19y^2-19z^2-100xy-200yz-100xz=0$$

Right circular cone:

Example 4: Find the equation of a right circular cone with vertex at (2, 0, 0), semi-vertical angle $\theta=30°$ and axis is the line $\frac{x-2}{3}=\frac{y}{4}=\frac{z}{6}$.

Solution: Here $\alpha = 2, \beta = 0, \gamma = 0, l = 3, m = 4, n = 6$

$$\frac{\sqrt{3}}{2} = \cos 30 = \cos\theta$$

$$= \frac{l(x-\alpha) + m(y-\beta) + n(z-\gamma)}{\sqrt{(l^2+m^2+n^2)[(x-\alpha)^2+(y-\beta)^2+(z-\gamma)^2]}}$$

$$\frac{\sqrt{3}}{2} = \frac{3(x-2)+4y+6z}{\sqrt{9+16+36}\sqrt{(x-2)^2+y^2+z^2}}$$

$$183[(x-2)^2+y^2+z^2] = 4[3(x-2)+4y+6z]^2$$

$$147x^2 + 119y^2 + 39z^2 - 192yz - 144zx - 96xy -$$

$$-588x + 192y + 288z + 588 = 0$$

Vertex (0, 0, 0):

Example 5: Find the equation of the right circular cone which passes through the line $2x = 3y = -5z$ and has $x = y = z$ as its axis.

Solution: DC's of the generator $2x = 3y = -5z$ are $\frac{1}{2}, \frac{1}{3}, -\frac{1}{5}$. DC's of axis are $\frac{1}{\sqrt{3}}, \frac{1}{\sqrt{3}}, \frac{1}{\sqrt{3}}$. Point of intersection of the generator and axis is (0, 0, 0). Now

$$\cos\theta = \frac{\frac{1}{2}\cdot\frac{1}{\sqrt{3}}+\frac{1}{3}\cdot\frac{1}{\sqrt{3}}-\frac{1}{5}\cdot\frac{1}{\sqrt{3}}}{\sqrt{\frac{1}{3}+\frac{1}{3}+\frac{1}{3}}\sqrt{\frac{1}{4}+\frac{1}{9}+\frac{1}{25}}} = \frac{\frac{19}{30}}{\sqrt{\frac{361}{900}}}\cdot\frac{1}{\sqrt{3}} = \frac{1}{\sqrt{3}}$$

Equation of cone with vertex at origin

$$\frac{1}{\sqrt{3}} = \cos\theta = \frac{\frac{1}{\sqrt{3}}(x+y+z)}{1\sqrt{x^2+y^2+z^2}}$$

$$x^2+y^2+z^2 = (x+y+z)^2$$

$$xy + yz + zx = 0.$$

Example 6: Determine the equation of a right circular cone with vertex at origin and the guiding curve circle passing through the points (1, 2, 2), (1, −2, 2)(2, −1, −2).

Solution: Let l, m, n be the DC's of OL the axis of the cone. Let θ be the semi- vertical angle. Let $A(1, 2, 2)$, $B(1, -2, 2)$, $C(2, -1, -2)$ be the three points on the guiding circle. Then the lines OA, OB, OC make the same angle θ with the axis OL. The DC's of OA, OB, OC are proportional to (1, 2, 2)(1, −2, 2)(2, −1, −2) respectively. Then

$$\cos\theta = \frac{l(1)+m(2)+n(2)}{\sqrt{1}\cdot\sqrt{1+4+4}} = \frac{l+2m+2n}{3} \qquad (1)$$

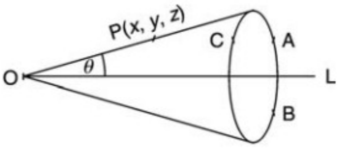

Fig. 36.19

Similarly,

$$\cos\theta = \frac{l(1)+m(-2)+n(2)}{\sqrt{1}\sqrt{1+4+4}} = \frac{l-2m+2n}{3} \qquad (2)$$

$$\cos\theta = \frac{2l-m-2n}{3} \qquad (3)$$

From (1) and (2), $4m = 0$ or $m = 0$.
From (2) and (3), $l + m - 4n = 0, l - 4n = 0$ or $l = 4n$.

DC's $\quad \frac{l}{4} = \frac{m}{0} = \frac{n}{1}$ or $\frac{l}{\frac{4}{\sqrt{17}}} = \frac{m}{0} = \frac{n}{\frac{1}{\sqrt{17}}}$.

From (1) $\quad \cos\theta = \dfrac{\frac{4}{\sqrt{17}}+2\cdot 0+2\frac{1}{\sqrt{17}}}{3} = \dfrac{2}{\sqrt{17}}$.

Equation of right circular cone is

$$(l^2+m^2+n^2)(x^2+y^2+z^2)\cos^2\theta = (lx+my+nz)^2$$

$$\left(\frac{16}{17}+0+\frac{1}{17}\right)(x^2+y^2+z^2)\frac{4}{17} = \left(\frac{4}{\sqrt{17}}x+0+\frac{1}{\sqrt{17}}z\right)^2$$

$$4(x^2+y^2+z^2) = (4x+z)^2$$

$$12x^2 - 4y^2 - 3z^2 + 8xz = 0$$

is the required equation of the cone.

EXERCISE

1. Find the equation of the cone whose vertex is (3, 1, 2) and base circle is $2x^2 + 3y^2 = 1$, $z = 1$.

Ans. $2x^2 + 3y^2 + 20z^2 - 6yz - 12xz + 12x + 6y$
$-38z + 17 = 0$

2. Find the equation of the cone whose vertex is origin and guiding curve is $\frac{x^2}{4}+\frac{y^2}{9}+\frac{z^2}{1}=1, x+y+z=1$.

Ans. $27x^2+32y^2+72(xy+yz+zx)=0$.

3. Determine the equation of the cone with vertex at origin and guiding curve $x^2+y^2+z^2-x-1=0, x^2+y^2+z^2+y-z=0$.

   Hint: Guiding curve is circle in plane $x+y=1$. Rewrite $x^2+y^2+z^2-x(x+y)-(x+y)^2=0$.

Ans. $x^2+3xy-z^2=0$

4. Show that the equation of cone with vertex at origin and base circle $x=a, y^2+z^2=b^2$ is $a^2(y^2+z^2)=b^2x^2$. Further prove that the section of the cone by a plane parallel to the XY-plane is a hyperbola.

Ans. $b^2x^2-a^2y^2=a^2c^2, z=c$ (put $z=c$ in equation of cone)

5. Find the equation of a cone with vertex at origin and guiding curve is the circle passing through the X, Y, Z intercepts of the plane $\frac{x}{a}+\frac{y}{b}+\frac{z}{c}=1$.

Ans. $a(b^2+c^2)yz+b(c^2+a^2)zx+c(a^2+b^2)xy=0$

6. Write the equation of the cone whose vertex is $(1, 1, 0)$ and base is $y^2+z^2=9, x=0$.

   Hint: Substitute $\left(0, 1-\frac{m}{l}, -\frac{n}{l}\right)$ in base curve and eliminate $\frac{m}{l}=\frac{y-1}{x-1}, \frac{n}{l}=\frac{z}{z-1}$.

Ans. $x^2+y^2+z^2-2xy=0$

Right circular cone (R.C.C.)

7. Find the equation of R.C.C. with vertex at $(2, 3, 1)$, axis parallel to the line $-x=\frac{y}{2}=z$ and one of its generators having DC's proportional to $(1, -1, 1)$.

   Hint: $\cos\theta=\frac{-1-2+1}{\sqrt{6}\sqrt{3}}, l=-1, m=2, n=1, \alpha=2, \beta=3, \gamma=1$.

Ans. $x^2-8y^2+z^2+12xy-12yz+6zx-46x++36y+22z-19=0$

8. Determine the equation of R.C.C. with vertex at origin and passes through the point $(1, 1, 2)$ and axis line $\frac{x}{2}=\frac{-y}{4}=\frac{z}{3}$.

   Hint: $\cos\theta=\frac{2-4+6}{\sqrt{6}\sqrt{29}}$, DC's of generator: 1, 1, 2, axis: 2, −4, 3

Ans. $4x^2+40y^2+19z^2-48xy-72yz+36xz=0$

9. Find the equation of R.C.C. whose vertex is origin and whose axis is the line $\frac{x}{1}=\frac{y}{2}=\frac{z}{3}$ and which has semi- vertical angle of 30°

   Hint: $\cos 30=\frac{\sqrt{3}}{2}=\frac{x(1)+y(2)+z(3)}{\sqrt{(x^2+y^2+z^2)}\sqrt{1+4+9}}$

Ans. $19x^2+13y^2+3z^2-8xy-24yz-12zx=0$

10. Obtain the equation of R.C.C. generated when the straight line $2y+3z=6, x=0$ revolves about z-axis.

    Hint: Vertex (0, 0, 2), generator $\frac{x}{0}=\frac{y}{3}=\frac{z-2}{-2}, \cos\theta=-\frac{2}{\sqrt{13}}$.

Ans. $4x^2+4y^2-9z^2+36z-36=0$

11. Lines are drawn from the origin with DC's proportional to $(1, 2, 2), (2, 3, 6), (3, 4, 12)$. Find the equation of R.C.C.

    Hint: $\cos\alpha=\frac{l+2m+2n}{3}=\frac{2l+3m+6n}{7}=\frac{3l+4m+12n}{13}$ $\frac{l}{-1}=\frac{m}{1}=\frac{n}{1}, \cos\alpha=\frac{1}{\sqrt{3}}$, DC's of axis: −1, 1, 1.

Ans. $xy-yz+zx=0$

12. Determine the equation of the R.C.C. generated by straight lines drawn from the origin to cut the circle through the three points $(1, 2, 2), (2, 1, -2)$, and $(2, -2, 1)$.

    Hint: $\cos\alpha=\frac{l+2m+2n}{3}=\frac{2l+m-2n}{3}=\frac{2l-2m+n}{3}$ $\frac{l}{5}=\frac{m}{1}=\frac{n}{1}, \cos\alpha=\frac{5+2+2}{3\sqrt{27}}=\frac{1}{\sqrt{3}}$.

Ans. $8x^2-4y^2-4z^2+5xy+5zx+yz=0$

36.7 THE RIGHT CIRCULAR CYLINDER

A cylinder is the surface generated by a straight line (known as **generator**) which is parallel to a fixed straight line (known as **axis**) and satisfies a condition; for example, it may intersect a fixed curve (known as the **guiding curve**) or touch a given surface. A **right circular cylinder** is a cylinder whose surface is generated by revolving the generator at a fixed distance (known as the **radius**) from the axis; i.e., the guiding curve in this case is a circle. In fact, the intersection of the right circular cylinder with any plane perpendicular to axis of the cylinder is a circle.

Equation of a cylinder with generators parallel to the line $\frac{x}{l}=\frac{y}{m}=\frac{z}{n}$ and guiding curve conic $ax^2+by^2+2hxy+2gx+2fy+c=0, z=0$.

Let $P(x_1, y_1, z_1)$ be any point on the cylinder. The equation of the generator through $P(x_1, y_1, z_1)$ which is parallel to the given line

$$\frac{x}{l}=\frac{y}{m}=\frac{z}{n} \tag{1}$$

is
$$\frac{x-x_1}{l}=\frac{y-y_1}{m}=\frac{z-z_1}{n} \tag{2}$$

Since (2) meets the plane $z=0$,

$$\therefore \quad \frac{x-x_1}{l}=\frac{y-y_1}{m}=\frac{0-z_1}{n}$$

or
$$x=x_1-\frac{l}{n}z_1,\ y=y_1-\frac{m}{n}z_1 \tag{3}$$

Since this point (3) lies on the conic

$$ax^2+by^2+2hxy+2gx+2fy+c=0 \tag{4}$$

substitute (3) in (4). Then

$$a\left(x_1-\frac{l}{n}z_1\right)^2+b\left(y_1-\frac{m}{n}z_1\right)^2+$$
$$+2h\left(x_1-\frac{l}{n}z_1\right)\left(y_1-\frac{m}{n}z_1\right)+2g\left(x_1-\frac{l}{n}z_1\right)+$$
$$+2f\left(y_1-\frac{m}{n}z_1\right)+c=0.$$

The required equation of the cylinder is

$$a(nx-lz)^2+b(ny-mz)^2+2h(nx-lz)(ny-mz)+$$
$$+2ng(nx-lz)+2nf(ny-mz)+cn^2=0 \tag{5}$$

where the subscript 1 is droped because (x_1, y_1, z_1) is any general point on the cylinder.

Corollary 1: The equation of a cylinder with axis parallel to z-axis is obtained from (5) by putting $l=0, m=0, n=1$ which are the DC's of z-axis: i.e.,

$$ax^2+by^2+2hxy+2gx+2fy+c=0$$

which is **free** from z.

Thus the equation of a cylinder whose axis is paralle to x-axis (y-axis or z-axis) is obtained by eliminating the variable x(y or z) from the equation of the conic.

Equation of a right circular cylinder:

a. Standard form: with z-axis as axis and of radius a. Let $P(x, y, z)$ be any point on the cylinder. Then M the foot of the perpendicular PM has $(0, 0, z)$ and $PM=a$ (given). Then

$$a=PM=\sqrt{(x-0)^2+(y-0)^2+(z-z)^2}$$
$$x^2+y^2=a^2$$

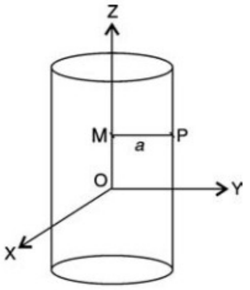

Fig. 36.20

Corollary 2: Similarly, equation of right circular cylinder with y-axis is $x^2+z^2=a^2$, with x-axis is $y^2+z^2=a^2$.

b. General form with the line $\frac{x-\alpha}{l}=\frac{y-\beta}{m}=\frac{z-\gamma}{n}$ as axis and of radius a.

Axis AB passes through the point (α, β, γ) and has DR's l, m, n. Its DC's are $\frac{l}{k}, \frac{m}{k}, \frac{n}{k}$ where $k=\sqrt{l^2+m^2+n^2}$.

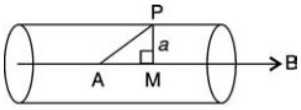

Fig. 36.21

From the right angled triangle APM

$$AP^2=PM^2+AM^2$$
$$(x-\alpha)^2+(y-\beta)^2+(z-\gamma)^2$$
$$=a^2+\left[l(x-\alpha)+m(y-\beta)+n(z-\gamma)\right]^2$$

which is the required equation of the cylinder (Here AM is the projection of AP on the line AB is equal to $l(x-\alpha)+m(y-\beta)+n(z-\gamma)$).

Enveloping cylinder of a sphere is the locus of the tangent lines to the sphere which are parallel to a given line. Suppose

$$x^2+y^2+z^2=a^2 \tag{1}$$

is the sphere and suppose that the generators are parallel to the given line

$$\frac{x}{l}=\frac{y}{m}=\frac{z}{n} \tag{2}$$

Then for any point $P(x_1, y_1, z_1)$ on the cylinder, the equation of the generating line is

$$\frac{x-x_1}{l}=\frac{y-y_1}{m}=\frac{z-z_1}{n} \tag{3}$$

Any general point on (3) is

$$(x_1+lr, \qquad y_1+mr, \qquad z_1+nr) \tag{4}$$

By substituting (4) in (1), we get the points of intersection of the sphere (1) and the generating line (3) i.e.,

$$(x_1+lr)^2+(y_1+mr)^2+(z_1+nr)^2=a^2$$

Rewriting as a quadratic in r, we have

$$(l^2+m^2+n^2)r^2+2(lx_1+my_1+nz_1)r+ +(x_1^2+y_1^2+z_1^2-a^2)=0 \tag{5}$$

If the roots of (5) are equal, then the generating line (3) meets (touches) the sphere in a single point i.e., when the discriminant of the quadratic in r is zero.

or $$4(lx_1+my_1+nz_1)^2-4(l^2+m^2+n^2)\times \times(x_1^2+y_1^2+z_1^2-a^2)=0$$

Thus the required equation of the enveloping cylinder is

$$(lx+my+nz)^2=(l^2+m^2+n^2)(x^2+y^2+z^2-a^2)$$

where the subscript 1 is droped to indicate that (x, y, z) is a general point on the cylinder.

WORKED OUT EXAMPLES

Example 1: Find the equation of the quadratic cylinder whose generators intersect the curve $ax^2+by^2+cz^2=k$, $lx+my+nz=p$ and parallel to the y-axis. Deduce the case for $x^2+y^2+z^2=1$ and $x+y+z=1$ and parallel to y-axis

Solution: Eliminate y between

$$ax^2+by^2+cz^2=k \tag{1}$$

and $$lx+my+nz=p \tag{2}$$

Solving (2) for y, we get

$$y=\frac{p-lx-nz}{m} \tag{3}$$

Substitute (3) in (1), we have

$$ax^2+b\left(\frac{p-lx-nz}{m}\right)^2+cz^2=k.$$

The required equation of the cylinder is

$$(am^2+l^2)x^2+(bn^2+m^2c)z^2-2pblx -2npbz+2blnxz+(bp^2-m^2k)=0.$$

Deduction: Put $a=1, b=1, c=1, k=1, l=m=n=p=1$

$$2x^2+2z^2-2x-2z+2xz=0$$

or $$x^2+z^2+xz-x-z=0.$$

Example 2: If l, m, n are the DC's of the generators and the circle $x^2+y^2=a^2$ in the XY-plane is the guiding curve, find the equation of the cylinder. Deduce the case when $a=4, l=1, m=2, n=3$.

Solution: For any point $P(x_1, y_1, z_1)$ on the cylinder, the equation of the generating line through P is

$$\frac{x-x_1}{l}=\frac{y-y_1}{m}=\frac{z-z_1}{n} \tag{1}$$

Since the line (1) meets the guiding curve $x^2+y^2=a^2, z=0$,

$$\frac{x-x_1}{l}=\frac{y-y_1}{m}=\frac{0-z_1}{n}$$

or $$x=x_1-\frac{lz_1}{n}, \qquad y=y_1-\frac{mz_1}{n} \tag{2}$$

This point (2) lies on the circle $x^2+y^2=a^2$ also. Substituting (2) in the equation of circle, we have

$$\left(x_1-\frac{lz_1}{n}\right)^2+\left(y_1-\frac{mz_1}{n}\right)^2=a^2$$

or $$(nx-lz)^2+(ny-mz)^2=n^2a^2$$

is the equation of the cylinder.

Deduction: Equation of cylinder whose generators are parallel to the line $\frac{x}{1}=\frac{y}{2}=\frac{z}{3}$ and pass through the curve $x^2+y^2=16, z=0$. With $a=4, l=1, m=2, n=3$, the required equation of the cylinder is

$$(3x-z)^2+(3y-2z)^2=9(16)=144$$

or $$9x^2+9y^2+5z^2-6zx-12yz-144=0.$$

Example 3: Find the equation of the right circular cylinder of radius 3 and the line $\frac{x-1}{2}=\frac{y-3}{2}=\frac{z-5}{-1}$ as axis.

Solution: Let $A(1, 3, 5)$ be the point on the axis and DR's of AB are $2, 2, -1$ or DC's of AB are $\frac{2}{3}, \frac{2}{3}, -\frac{1}{3}$. Radius $PM=3$ given. Since AM is the projection of AP on AB, we have

$$AM=\frac{2}{3}(x-1)+\frac{2}{3}(y-3)-\frac{1}{3}(z-5)$$

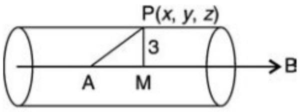

Fig. 36.22

From the right angled triangle APM

$$AP^2=AM^2+MP^2$$
$$(x-1)^2+(y-3)^2+(z-5)^2$$
$$=\left[2\frac{(x-1)}{3}+2\frac{y-3}{3}-1\frac{(z-5)}{3}\right]+9$$
$$9[x^2+1-2x+y^2+9-6y+z^2+25-10z]$$
$$=[2x+2y-z-3]^2+81$$
$$9[x^2+y^2+z^2-2x-6y-10z+35]$$
$$=[4x^2+4y^2+z^2+9+8xy-4xz-12x$$
$$-4yz-12y+6z]+81$$

is the required equation of the cylinder.

Example 4: Find the equation of the enveloping cylinder of the sphere $x^2+y^2+z^2-2y-4z-11=0$ having its generators parallel to the line $x=-2y=2z$.

Solution: Let $P(x_1, y_1, z_1)$ be any point on the cylinder. Then the equation of the generating line through P and parallel to the line $x=-2y=2z$ or $\frac{x}{1}=\frac{y}{-\frac{1}{2}}=\frac{z}{\frac{1}{2}}$ is

$$\frac{x-x_1}{1}=\frac{y-y_1}{-\frac{1}{2}}=\frac{z-z_1}{\frac{1}{2}} \qquad (1)$$

Any general point on (1) is

$$\left(x_1+r, \quad y_1-\frac{1}{2}r, \quad z_1+\frac{1}{2}r\right) \qquad (2)$$

The points of intersection of the line (1) and the sphere

$$x^2+y^2+z^2-2y-4z-11=0 \qquad (3)$$

are obtained by substituting (2) in (3).

$$(x_1+r)^2+\left(y_1-\frac{1}{2}r\right)^2+\left(z_1+\frac{1}{2}r^2\right)^2-2\left(y_1-\frac{1}{2}r\right)$$
$$-4\left(z_1+\frac{1}{2}r\right)-11=0$$

Rewriting this as a quadratic in r

$$\frac{3}{2}r^2+(2x_1-y_1+z_1-1)r$$
$$+(x_1^2+y_1^2+z_1^2-2y_1-4z_1-11)=0 \qquad (4)$$

The generator touches the sphere (3 if (4) has equal roots i.e., discriminant is zero or

$$(2x_1-y_1+z_1-1)^2$$
$$=4\cdot\frac{3}{2}\cdot(x_1^2+y_1^2+z_1^2-2y_1-4z_1-11).$$

The required equation of the cylinder is

$$2x^2+5y^2+5z^2+4xy-4xz+2yz$$
$$+4x-14y-22z-67=0.$$

EXERCISE

1. Find the equation of the quadratic cylinder whose generators intersect the curve
   a. $ax^2+by^2=2z, lx+my+nz=p$ and are parallel to z-axis.
   b. $ax^2+by^2+cz^2=1, lx+my+nz=p$ and are parallel to x-axis.
   Hint: Eliminate z

Ans. **a.** $n(ax^2+by^2)+2lx+2my-2p=0$

Hint: Eliminate x.

Ans. **b.** $(bl^2+am^2)y^2+(cl^2+an^2)z^2+2amnyz$ $-2ampy-2anpz+(ap^2-l^2)=0$

2. If l, m, n are the DC's of the generating line and the circle $x^2+z^2=a^2$ in the zx-plane is the guiding curve, find the equation of the sphere.

Ans. $(mx-ly)^2+(mz-ny)^2=a^2m^2$

Find the equation of a right circular cylinder (4 to 9)

4. Whose axis is the line $\frac{x-1}{2}=\frac{y+3}{-1}=\frac{z-2}{5}$ and radius is 2 units.

Ans. $26x^2+29y^2+5z^2+4xy+10yz-20zx+150y+30z+75=0$

5. Having for its base the circle $x^2+y^2+z^2=9, x-y+z=3$.

Ans. $x^2+y^2+z^2+xy+yz-zx-9=0$

6. Whose axis passes through the point (1, 2, 3) and has DC's proportional to (2, −3, 6) and of radius 2.

Ans. $45x^2+40y^2+13z^2+36yz-24zx+12xy-42x-280y-126z+294=0.$

7. Whose axis is the line $\frac{x-1}{2}=\frac{y-2}{1}=\frac{z-3}{2}$ and radius 2 units.

Ans. $5x^2+8y^2+5z^2-4yz-8zx-4xy+22x-16y-14z-10=0$

8. The guiding curve is the circle through the three points (1, 0, 0), (0, 1, 0)(0, 0, 1).

Ans. $x^2+y^2+z^2-xy-yz-zx=1$

9. The directing curve is $x^2+z^2-4x-2z+4=0$, $y=0$ and whose axis contains the point (0, 3, 0). Also find the area of the section of the cylinder by a plane parallel to xz-plane.

Hint: Centre of circle (2, 0, 1) radius: 1

Ans. $9x^2+5y^2+9z^2+12xy+6yz-36x-30y-18z+36=0, \pi$

10. Find the equation of the enveloping cylinder of the sphere $x^2+y^2+z^2-2x+4y=1$, having its generators parallel to the line $x=y=z$.

Ans. $x^2+y^2+z^2-xy-yz-zx-2x+7y+z-2=0.$

Chapter 12

Introduction to trigonometry

***Why it is important to understand:* Introduction to trigonometry**

There are an enormous number of uses of trigonometry and trigonometric functions. Fields that use trigonometry or trigonometric functions include astronomy (especially for locating apparent positions of celestial objects, in which spherical trigonometry is essential) and hence navigation (on the oceans, in aircraft, and in space), music theory, acoustics, optics, analysis of financial markets, electronics, probability theory, statistics, biology, medical imaging (CAT scans and ultrasound), pharmacy, chemistry, number theory (and hence cryptology), seismology, meteorology, oceanography, many physical sciences, land surveying and geodesy (a branch of earth sciences), architecture, phonetics, economics, electrical engineering, mechanical engineering, civil engineering, computer graphics, cartography, crystallography and game development. It is clear that a good knowledge of trigonometry is essential in many fields of engineering.

At the end of this chapter, you should be able to:

- state the theorem of Pythagoras and use it to find the unknown side of a right-angled triangle
- define sine, cosine, tangent, secant, cosecant and cotangent of an angle in a right-angled triangle
- evaluate trigonometric ratios of angles
- solve right-angled triangles
- understand angles of elevation and depression
- use the sine and cosine rules to solve non-right-angled triangles
- calculate the area of any triangle
- solve practical problems involving trigonometry

12.1 Trigonometry

Trigonometry is the branch of mathematics which deals with the measurement of sides and angles of triangles, and their relationship with each other. There are many applications in engineering where knowledge of trigonometry is needed.

12.2 The theorem of Pythagoras

With reference to Fig. 12.1, the side opposite the right angle (i.e. side b) is called the **hypotenuse**. The **theorem of Pythagoras*** states:

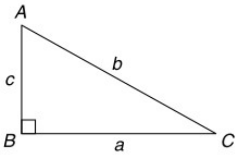

Figure 12.1

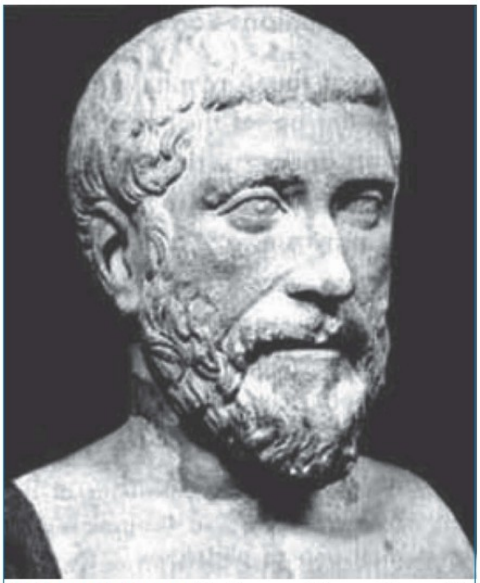

[*] **Who was Pythagoras**? **Pythagoras of Samos** (Born c. 570 BC and died about 495 BC) was an Ionian Greek philosopher and mathematician. He is best known for the Pythagorean theorem, which states that in a right-angled triangle $a^2+b^2=c^2$. To find out more go to **www.routledge.com/cw/bird**

'In any right-angled triangle, the square on the hypotenuse is equal to the sum of the squares on the other two sides.'

Hence $\boldsymbol{b^2 = a^2 + c^2}$

Problem 1. In Fig. 12.2, find the length of EF.

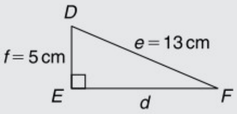

Figure 12.2

By Pythagoras' theorem:

$$e^2 = d^2 + f^2$$

Hence $\quad 13^2 = d^2 + 5^2$

$$169 = d^2 + 25$$

$$d^2 = 169 - 25 = 144$$

Thus $\quad d = \sqrt{144} = 12\,\text{cm}$

i.e. $\quad \boldsymbol{EF = 12\,\text{cm}}$

Problem 2. Two aircraft leave an airfield at the same time. One travels due north at an average speed of 300 km/h and the other due west at an average speed of 220 km/h. Calculate their distance apart after four hours.

After four hours, the first aircraft has travelled $4 \times 300 = 1200$ km, due north, and the second aircraft has travelled $4 \times 220 = 880$ km due west, as shown in Fig. 12.3. Distance apart after four hours = BC.

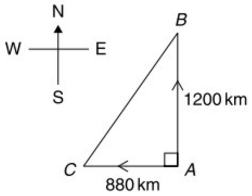

Figure 12.3

From Pythagoras' theorem:

$$BC^2 = 1200^2 + 880^2 = 1\,440\,000 + 774\,400$$

and $BC = \sqrt{(2\,214\,400)}$

Hence distance apart after four hours = 1488 km

Now try the following Practice Exercise

Practice Exercise 51 The theorem of Pythagoras (Answers on page 863)

1. In a triangle *CDE*, $D = 90°$, $CD = 14.83$ mm and $CE = 28.31$ mm. Determine the length of *DE*.
2. Triangle *PQR* is isosceles, *Q* being a right angle. If the hypotenuse is 38.47 cm find (a) the lengths of sides *PQ* and *QR*, and (b) the value of $\angle QPR$.
3. A man cycles 24 km due south and then 20 km due east. Another man, starting at the same time as the first man, cycles 32 km due east and then 7 km due south. Find the distance between the two men.
4. A ladder 3.5 m long is placed against a perpendicular wall with its foot 1.0 m from the wall. How far up the wall (to the nearest centimetre) does the ladder reach? If the foot of the ladder is now moved 30 cm further away from the wall, how far does the top of the ladder fall?
5. Two ships leave a port at the same time. One travels due west at 18.4 km/h and the other due south at 27.6 km/h. Calculate how far apart the two ships are after four hours.
6. Figure 12.4 shows a bolt rounded off at one end. Determine the dimension *h*.

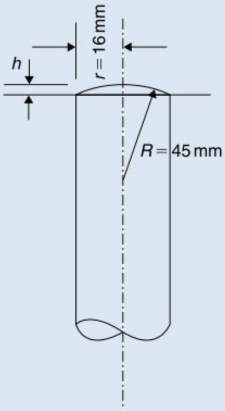

Figure 12.4

7. Figure 12.5 shows a cross-section of a component that is to be made from a round bar. If the diameter of the bar is 74 mm, calculate the dimension *x*.

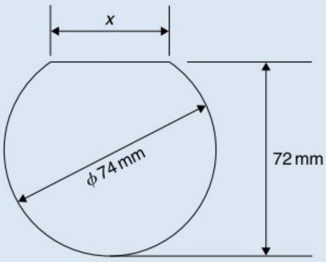

Figure 12.5

12.3 Trigonometric ratios of acute angles

(a) With reference to the right-angled triangle shown in Fig. 12.6:

(i) $$\text{sine}\,\theta = \frac{\text{opposite side}}{\text{hypotenuse}}$$

i.e. $$\boldsymbol{\sin\theta = \frac{b}{c}}$$

(ii) $$\text{cosine}\,\theta = \frac{\text{adjacent side}}{\text{hypotenuse}}$$

i.e. $$\boldsymbol{\cos\theta = \frac{a}{c}}$$

(iii) $$\text{tangent}\,\theta = \frac{\text{opposite side}}{\text{adjacent side}}$$

i.e. $$\boldsymbol{\tan\theta = \frac{b}{a}}$$

(iv) $$\text{secant}\,\theta = \frac{\text{hypotenuse}}{\text{adjacent side}}$$

i.e. $$\boldsymbol{\sec\theta = \frac{c}{a}}$$

(v) $$\text{cosecant}\,\theta = \frac{\text{hypotenuse}}{\text{opposite side}}$$

i.e. $$\boldsymbol{\text{cosec}\,\theta = \frac{c}{b}}$$

(vi) $\text{cotangent}\,\theta = \dfrac{\text{adjacent side}}{\text{opposite side}}$

i.e. $\boldsymbol{\cot\theta = \dfrac{a}{b}}$

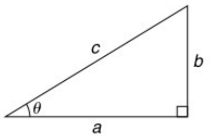

Figure 12.6

(b) From above,

(i) $$\frac{\sin\theta}{\cos\theta} = \frac{\frac{b}{c}}{\frac{a}{c}} = \frac{b}{a} = \tan\theta,$$

i.e. $$\boldsymbol{\tan\theta = \frac{\sin\theta}{\cos\theta}}$$

(ii) $$\frac{\cos\theta}{\sin\theta} = \frac{\frac{a}{c}}{\frac{b}{c}} = \frac{a}{b} = \cot\theta,$$

i.e. $$\boldsymbol{\cot\theta = \frac{\cos\theta}{\sin\theta}}$$

(iii) $$\boldsymbol{\sec\theta = \frac{1}{\cos\theta}}$$

(iv) $$\boldsymbol{\operatorname{cosec}\theta = \frac{1}{\sin\theta}}$$

(Note, the first letter of each ratio, '*s*' and '*c*' go together)

(v) $$\boldsymbol{\cot\theta = \frac{1}{\tan\theta}}$$

Secants, cosecants and cotangents are called the **reciprocal ratios**.

Problem 3. If $\cos X = \dfrac{9}{41}$ determine the value of the other five trigonometry ratios.

Fig. 12.7 shows a right-angled triangle *XYZ*.

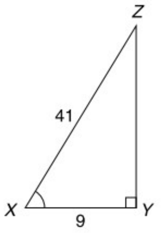

Figure 12.7

Since $\cos X = \dfrac{9}{41}$, then $XY = 9$ units and $XZ = 41$ units.

Using Pythagoras' theorem: $41^2 = 9^2 + YZ^2$ from which $YZ = \sqrt{(41^2 - 9^2)} = 40$ units.

Thus

$$\boldsymbol{\sin X = \frac{40}{41}},\ \boldsymbol{\tan X} = \frac{40}{9} \boldsymbol{= 4\frac{4}{9}},$$

$$\boldsymbol{\operatorname{cosec} X = \frac{41}{40} = 1\frac{1}{40}},$$

$$\boldsymbol{\sec X = \frac{41}{9} = 4\frac{5}{9}} \text{ and } \boldsymbol{\cot X = \frac{9}{40}}$$

Problem 4. If $\sin\theta = 0.625$ and $\cos\theta = 0.500$ determine, without using trigonometric tables or calculators, the values of $\operatorname{cosec}\theta$, $\sec\theta$, $\tan\theta$ and $\cot\theta$.

$$\operatorname{cosec}\theta = \frac{1}{\sin\theta} = \frac{1}{0.625} = \mathbf{1.60}$$

$$\sec\theta = \frac{1}{\cos\theta} = \frac{1}{0.500} = \mathbf{2.00}$$

$$\tan\theta = \frac{\sin\theta}{\cos\theta} = \frac{0.625}{0.500} = \mathbf{1.25}$$

$$\cot\theta = \frac{\cos\theta}{\sin\theta} = \frac{0.500}{0.625} = \mathbf{0.80}$$

Problem 5. Point *A* lies at co-ordinate (2, 3) and point *B* at (8, 7). Determine (a) the distance *AB*, (b) the gradient of the straight line *AB*, and (c) the angle *AB* makes with the horizontal.

(a) Points *A* and *B* are shown in Fig. 12.8(a).

In Fig. 12.8(b), the horizontal and vertical lines *AC* and *BC* are constructed.

Since *ABC* is a right-angled triangle, and $AC = (8-2) = 6$ and $BC = (7-3) = 4$, then by Pythagoras' theorem

$$AB^2 = AC^2 + BC^2 = 6^2 + 4^2$$

and $\boldsymbol{AB} = \sqrt{(6^2 + 4^2)} = \sqrt{52} = \mathbf{7.211,}$ correct to 3 decimal places.

(b) The gradient of *AB* is given by tan *A*,

i.e. $\textbf{gradient} = \tan A = \dfrac{BC}{AC} = \dfrac{4}{6} = \mathbf{\dfrac{2}{3}}$

(c) **The angle *AB* makes with the horizontal** is given by $\tan^{-1}\frac{2}{3} = \mathbf{33.69°}$

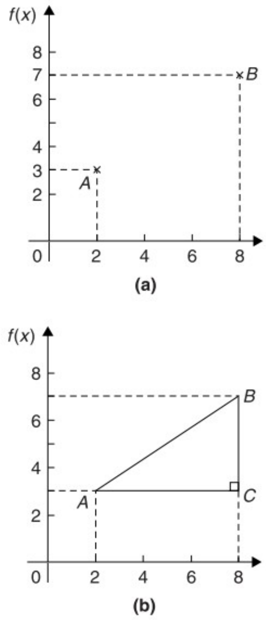

Figure 12.8

Now try the following Practice Exercise

Practice Exercise 52 Trigonometric ratios of acute angles (Answers on page 863)

1. In triangle ABC shown in Fig. 12.9, find $\sin A, \cos A, \tan A, \sin B, \cos B$ and $\tan B$.

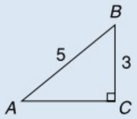

Figure 12.9

2. If $\cos A = \dfrac{15}{17}$ find $\sin A$ and $\tan A$, in fraction form.

3. For the right-angled triangle shown in Fig. 12.10, find:
   (a) $\sin\alpha$ (b) $\cos\theta$ (c) $\tan\theta$

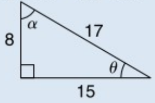

Figure 12.10

4. Point P lies at co-ordinate $(-3, 1)$ and point Q at $(5, -4)$. Determine
   (a) the distance PQ
   (b) the gradient of the straight line PQ and
   (c) the angle PQ makes with the horizontal.

12.4 Evaluating trigonometric ratios

The easiest method of evaluating trigonometric functions of any angle is by using a **calculator**.

The following values, correct to 4 decimal places, may be checked:

sine $18^\circ = 0.3090$, cosine $56^\circ = 0.5592$
sine $172^\circ = 0.1392$ cosine $115^\circ = -0.4226$,
sine $241.63^\circ = -0.8799$, cosine $331.78^\circ = 0.8811$

tangent $29^\circ = 0.5543$,
tangent $178^\circ = -0.0349$
tangent $296.42^\circ = -2.0127$

To evaluate, say, sine $42^\circ 23'$ using a calculator means finding sine $42\dfrac{23^\circ}{60}$ since there are 60 minutes in 1 degree.

$$\frac{23}{60} = 0.383\dot{3} \text{ thus } 42^\circ 23' = 42.38\dot{3}^\circ$$

Thus sine $42^\circ 23' =$ sine $42.38\dot{3}^\circ = 0.6741$, correct to 4 decimal places.

Similarly, cosine $72^\circ 38' =$ cosine $72\dfrac{38^\circ}{60} = 0.2985$, correct to 4 decimal places.

Most calculators contain only sine, cosine and tangent functions. Thus to evaluate secants, cosecants and cotangents, reciprocals need to be used. The following values, correct to 4 decimal places, may be checked:

$$\text{secant}\,32^\circ = \frac{1}{\cos 32^\circ} = 1.1792$$

$$\text{cosecant}\,75^\circ = \frac{1}{\sin 75^\circ} = 1.0353$$

$$\text{cotangent}\,41^\circ = \frac{1}{\tan 41^\circ} = 1.1504$$

$$\text{secant}\,215.12^\circ = \frac{1}{\cos 215.12^\circ} = -1.2226$$

$$\text{cosecant}\,321.62^\circ = \frac{1}{\sin 321.62^\circ} = -1.6106$$

$$\text{cotangent}\,263.59^\circ = \frac{1}{\tan 263.59^\circ} = 0.1123$$

If we know the value of a trigonometric ratio and need to find the angle we use the **inverse function** on our calculators.

For example, using shift and sin on our calculator gives $\sin^{-1}($

If, for example, we know the sine of an angle is 0.5 then the value of the angle is given by:

$$\sin^{-1} 0.5 = \mathbf{30^\circ} \quad (\text{Check that } \sin 30^\circ = 0.5)$$

(Note that $\sin^{-1} x$ does not mean $\dfrac{1}{\sin x}$; also, $\sin^{-1} x$ may also be written as $\arcsin x$)

Similarly, if $\cos\theta = 0.4371$ then

$\theta = \cos^{-1} 0.4371 = \mathbf{64.08^\circ}$

$$\text{and} \quad \text{if } \tan A = 3.5984 \text{ then } A = \tan^{-1} 3.5984 = \mathbf{74.47^\circ}$$

each correct to 2 decimal places.

Use your calculator to check the following worked examples.

Problem 6. Determine, correct to 4 decimal places, $\sin 43^\circ 39'$

$$\sin 43^\circ 39' = \sin 43\frac{39}{60}^\circ = \sin 43.65^\circ = \mathbf{0.6903}$$

This answer can be obtained using the **calculator** as follows:

1. Press sin
2. Enter 43
3. Press ° ’’’
4. Enter 39
5. Press ° ’’’
6. Press)
7. Press = Answer = **0.6902512**....

Problem 7. Determine, correct to 3 decimal places, $6\cos 62^\circ 12'$

$$6\cos 62^\circ 12' = 6\cos 62\frac{12^\circ}{60} = 6\cos 62.20^\circ = \mathbf{2.798}$$

This answer can be obtained using the **calculator** as follows:

1. Enter 6
2. Press cos
3. Enter 62
4. Press ° ’’’
5. Enter 12
6. Press ° ’’’
7. Press)
8. Press = Answer = **2.798319**....

Problem 8. Evaluate, correct to 4 decimal places: (a) $\text{sine}\,168^\circ 14'$ (b) $\text{cosine}\,271.41^\circ$ (c) $\text{tangent}\,98^\circ 4'$

(a) $\text{sine}\,168^\circ 14' = \text{sine}\,168\dfrac{14^\circ}{60} = \mathbf{0.2039}$

(b) $\text{cosine}\,271.41^\circ = \mathbf{0.0246}$

(c) $\text{tangent}\,98^\circ 4' = \tan 98\dfrac{4^\circ}{60} = \mathbf{-7.0558}$

Problem 9. Evaluate, correct to 4 decimal places: (a) $\text{secant}\,161^\circ$ (b) $\text{secant}\,302^\circ 29'$

(a) $\sec 161^\circ = \dfrac{1}{\cos 161^\circ} = \mathbf{-1.0576}$

(b) $\sec 302^\circ 29' = \dfrac{1}{\cos 302^\circ 29'} = \dfrac{1}{\cos 302\dfrac{29^\circ}{60}} = \mathbf{1.8620}$

Problem 10. Evaluate, correct to 4 significant figures: (a) $\text{cosecant}\,279.16^\circ$ (b) $\text{cosecant}\,49^\circ 7'$

(a) $\text{cosec}\,279.16^\circ = \dfrac{1}{\sin 279.16^\circ} = \mathbf{-1.013}$

(b) $\text{cosec}\,49^\circ 7' = \dfrac{1}{\sin 49^\circ 7'} = \dfrac{1}{\sin 49\dfrac{7^\circ}{60}} = \mathbf{1.323}$

Problem 11. Evaluate, correct to 4 decimal places: (a) $\text{cotangent}\,17.49^\circ$ (b) $\text{cotangent}\,163^\circ 52'$

(a) $\cot 17.49^\circ = \dfrac{1}{\tan 17.49^\circ} = \mathbf{3.1735}$

(b) $\cot 163^\circ 52' = \dfrac{1}{\tan 163^\circ 52'} = \dfrac{1}{\tan 163\dfrac{52^\circ}{60}} = \mathbf{-3.4570}$

Problem 12. Evaluate, correct to 4 significant figures: (a) $\sin 1.481$ (b) $\cos(3\pi/5)$ (c) $\tan 2.93$

(a) $\sin 1.481$ means the sine of 1.481 radians. Hence a calculator needs to be on the radian function. Hence $\sin 1.481 = \mathbf{0.9960}$

(b) $\cos(3\pi/5) = \cos 1.884955\ldots = \mathbf{-0.3090}$

(c) $\tan 2.93 = \mathbf{-0.2148}$

Problem 13. Evaluate, correct to 4 decimal places:
(a) secant 5.37 (b) cosecant $\pi/4$
(c) cotangent $\pi/24$

(a) Again, with no degrees sign, it is assumed that 5.37 means 5.37 radians.

Hence $\sec 5.37 = \dfrac{1}{\cos 5.37} = \mathbf{1.6361}$

(b) $$\operatorname{cosec}(\pi/4) = \frac{1}{\sin(\pi/4)} = \frac{1}{\sin 0.785398\ldots} = \mathbf{1.4142}$$

(c) $$\cot(5\pi/24) = \frac{1}{\tan(5\pi/24)} = \frac{1}{\tan 0.654498\ldots} = \mathbf{1.3032}$$

Problem 14. Find, in degrees, the acute angle $\sin^{-1} 0.4128$ correct to 2 decimal places.

$\sin^{-1} 0.4128$ means ‘the angle whose sine is 0.4128’

Using a calculator:

1. Press shift 2. Press sin 3. Enter 0.4128

4. Press) 5. Press = The answer 24.380848… is displayed

Hence, $\mathbf{\sin^{-1} 0.4128 = 24.38^\circ}$

Problem 15. Find the acute angle $\cos^{-1} 0.2437$ in degrees and minutes.

$\cos^{-1} 0.2437$ means ‘the angle whose cosine is 0.2437’

Using a calculator:

1. Press shift 2. Press cos 3. Enter 0.2437

4. Press) 5. Press = The answer 75.894979… is displayed

6. Press ° ’’’ and $75^\circ 53' 41.93''$ is displayed

Hence, $\mathbf{\cos^{-1} 0.2437 = 75.89^\circ = 77^\circ 54'}$ correct to the nearest minute.

Problem 16. Find the acute angle $\tan^{-1} 7.4523$ in degrees and minutes.

$\tan^{-1} 7.4523$ means ‘the angle whose tangent is 7.4523’

Using a calculator:

1. Press shift 2. Press tan 3. Enter 7.4523

4. Press) 5. Press = The answer 82.357318… is displayed

6. Press ° ’’’ and $82^\circ 21' 26.35''$ is displayed

Hence, $\mathbf{\tan^{-1} 7.4523 = 82.36^\circ = 82^\circ 21'}$ correct to the nearest minute.

Problem 17. Determine the acute angles:
(a) $\sec^{-1} 2.3164$ (b) $\operatorname{cosec}^{-1} 1.1784$
(c) $\cot^{-1} 2.1273$

(a) $$\sec^{-1} 2.3164 = \cos^{-1}\left(\frac{1}{2.3164}\right) = \cos^{-1} 0.4317\ldots = \mathbf{64.42^\circ} \text{ or } \mathbf{64^\circ 25'}$$

or **1.124 radians**

(b) $$\operatorname{cosec}^{-1} 1.1784 = \sin^{-1}\left(\frac{1}{1.1784}\right) = \sin^{-1} 0.8486\ldots = \mathbf{58.06^\circ} \text{ or } \mathbf{58^\circ 4'}$$

or **1.013 radians**

(c) $$\cot^{-1} 2.1273 = \tan^{-1}\left(\frac{1}{2.1273}\right) = \tan^{-1} 0.4700\ldots = \mathbf{25.18^\circ} \text{ or } \mathbf{25^\circ 11'}$$

or **0.439 radians**

Problem 18. Evaluate the following expression, correct to 4 significant figures:

$$\frac{4 \sec 32^\circ 10' - 2 \cot 15^\circ 19'}{3 \operatorname{cosec} 63^\circ 8' \tan 14^\circ 57'}$$

By calculator:

$$\sec 32^\circ 10' = 1.1813, \cot 15^\circ 19' = 3.6512$$

$$\operatorname{cosec} 63^\circ 8' = 1.1210, \tan 14^\circ 57' = 0.2670$$

$$\text{Hence}\quad \frac{4\sec 32^\circ 10' - 2\cot 15^\circ 19'}{3\operatorname{cosec} 63^\circ 8' \tan 14^\circ 57'}$$

$$= \frac{4(1.1813) - 2(3.6512)}{3(1.1210)(0.2670)}$$

$$= \frac{4.7252 - 7.3024}{0.8979}$$

$$= \frac{-2.5772}{0.8979} = \mathbf{-2.870}$$

correct to 4 significant figures.

Problem 19. Evaluate correct to 4 decimal places: (a) sec(–115°) (b) cosec (–95°47′)

(a) Positive angles are considered by convention to be anticlockwise and negative angles as clockwise.

Hence –115° is actually the same as 245° (i.e. 360° – 115°)

$$\text{Hence}\quad \sec(-115^\circ) = \sec 245^\circ = \frac{1}{\cos 245^\circ}$$

$$= \mathbf{-2.3662}$$

(b) $$\operatorname{cosec}(-95^\circ 47') = \frac{1}{\sin\left(-95\dfrac{47^\circ}{60}\right)} = \mathbf{-1.0051}$$

Problem 20. In triangle EFG in Fig. 12.11, calculate angle G.

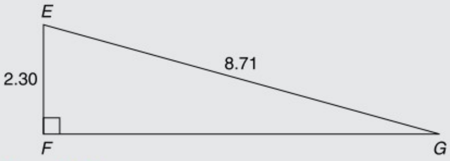

Figure 12.11

With reference to $\angle G$, the two sides of the triangle given are the opposite side EF and the hypotenuse EG; hence, sine is used,

i.e. $$\sin G = \frac{2.30}{8.71} = 0.26406429\ldots$$

from which, $$G = \sin^{-1} 0.26406429\ldots$$

i.e. $$G = 15.311360\ldots$$

Hence, $$\angle \mathbf{G} = \mathbf{15.31^\circ} \text{ or } \mathbf{15^\circ 19'}$$

Now try the following Practice Exercise

Practice Exercise 53 Evaluating trigonometric ratios (Answers on page 863)

In Problems 1 to 8, evaluate correct to 4 decimal places:

1. (a) sine 27° (b) sine 172.41° (c) sine 302°52′
2. (a) cosine 124° (b) cosine 21.46° (c) cosine 284°10′
3. (a) tangent 145° (b) tangent 310.59° (c) tangent 49°16′
4. (a) secant 73° (b) secant 286.45° (c) secant 155°41′
5. (a) cosecant 213° (b) cosecant 15.62° (c) cosecant 311°50′
6. (a) cotangent 71° (b) cotangent 151.62° (c) cotangent 321°23′
7. (a) sine $\frac{2\pi}{3}$ (b) cos 1.681 (c) tan 3.672
8. (a) sec $\frac{\pi}{8}$ (b) cosec 2.961 (c) cot 2.612

In Problems 9 to 14, determine the acute angle in degrees (correct to 2 decimal places), degrees and minutes, and in radians (correct to 3 decimal places).

9. $\sin^{-1} 0.2341$
10. $\cos^{-1} 0.8271$
11. $\tan^{-1} 0.8106$
12. $\sec^{-1} 1.6214$

13. $\text{cosec}^{-1} 2.4891$

14. $\cot^{-1} 1.9614$

15. In the triangle shown in Fig. 12.12, determine angle θ, correct to 2 decimal places.

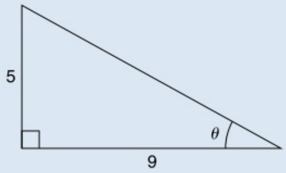

Figure 12.12

16. In the triangle shown in Fig. 12.13, determine angle θ in degrees and minutes.

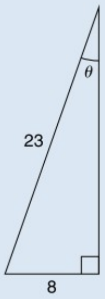

Figure 12.13

In Problems 17 to 20, evaluate correct to 4 significant figures:

17. $4\cos 56°19' - 3\sin 21°57'$

18. $\dfrac{11.5\tan 49°11' - \sin 90°}{3\cos 45°}$

19. $\dfrac{5\sin 86°3'}{3\tan 14°29' - 2\cos 31°9'}$

20. $\dfrac{6.4\,\text{cosec}\, 29°5' - \sec 81°}{2\cot 12°}$

21. Determine the acute angle, in degrees and minutes, correct to the nearest minute, given by $\sin^{-1}\left(\dfrac{4.32\sin 42°16'}{7.86}\right)$

22. If $\tan x = 1.5276$, determine $\sec x$, $\text{cosec}\, x$, and $\cot x$. (Assume x is an acute angle.)

In Problems 23 to 25 evaluate correct to 4 significant figures:

23. $\dfrac{(\sin 34°27')(\cos 69°2')}{(2\tan 53°39')}$

24. $3\cot 14°15' \sec 23°9'$

25. $\dfrac{\text{cosec}\, 27°19' + \sec 45°29'}{1 - \text{cosec}\, 27°19' \sec 45°29'}$

26. Evaluate correct to 4 decimal places:
    (a) sine $(-125°)$ (b) $\tan(-241°)$
    (c) $\cos(-49°15')$

27. Evaluate correct to 5 significant figures:
    (a) cosec $(-143°)$ (b) $\cot(-252°)$
    (c) $\sec(-67°22')$

12.5 Solution of right-angled triangles

To 'solve a right-angled triangle' means 'to find the unknown sides and angles'. This is achieved by using (i) the theorem of Pythagoras, and/or (ii) trigonometric ratios. This is demonstrated in the following problems.

Problem 21. In triangle PQR shown in Fig. 12.14, find the lengths of PQ and PR.

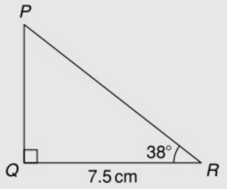

Figure 12.14

$$\tan 38° = \frac{PQ}{QR} = \frac{PQ}{7.5}$$

hence $PQ = 7.5\tan 38° = 7.5(0.7813)$

$$= \mathbf{5.860\,cm}$$

$$\cos 38° = \frac{QR}{PR} = \frac{7.5}{PR}$$

hence $PR = \dfrac{7.5}{\cos 38°} = \dfrac{7.5}{0.7880} = \mathbf{9.518\,cm}$

[Check: Using Pythagoras' theorem

$$(7.5)^2+(5.860)^2=90.59=(9.518)^2]$$

Problem 22. Solve the triangle *ABC* shown in Fig. 12.15.

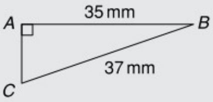

Figure 12.15

To 'solve triangle *ABC*' means 'to find the length *AC* and angles *B* and *C*'

$$\sin C=\frac{35}{37}=0.94595$$

hence $\angle \boldsymbol{C}=\sin^{-1}0.94595=71.08°=\mathbf{71°5'}$
$\angle \boldsymbol{B}=180°-90°-71°5'=\mathbf{18°55'}$ (since angles in a triangle add up to 180°)

$$\sin B=\frac{AC}{37}$$

hence $\boldsymbol{AC}=37\sin 18°55'=37(0.3242)$

$$=\mathbf{12.0\,mm}$$

or, using Pythagoras' theorem, $37^2=35^2+AC^2$, from which, $\boldsymbol{AC}=\sqrt{(37^2-35^2)}=\mathbf{12.0\,mm}$.

Problem 23. Solve triangle *XYZ* given $\angle X=90°$, $\angle Y=23°17'$ and $YZ=20.0$ mm. Determine also its area.

It is always advisable to make a reasonably accurate sketch so as to visualise the expected magnitudes of unknown sides and angles. Such a sketch is shown in Fig. 12.16.

$$\angle Z=180°-90°-23°17'=\mathbf{66°43'}$$

$$\sin 23°17'=\frac{XZ}{20.0}$$

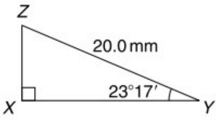

Figure 12.16

hence $\boldsymbol{XZ}=20.0\sin 23°17'$

$$=20.0(0.3953)=\mathbf{7.906\,mm}$$

$$\cos 23°17'=\frac{XY}{20.0}$$

hence $\boldsymbol{XY}=20.0\cos 23°17'$

$$=20.0(0.9186)=\mathbf{18.37\,mm}$$

[Check: Using Pythagoras' theorem

$$(18.37)^2+(7.906)^2=400.0=(20.0)^2]$$

Area of triangle *XYZ*

$$=\tfrac{1}{2}\text{ (base) (perpendicular height)}$$

$$=\tfrac{1}{2}(XY)(XZ)=\tfrac{1}{2}(18.37)(7.906)$$

$$=\mathbf{72.62\,mm^2}$$

Now try the following Practice Exercise

Practice Exercise 54 The solution of right-angled triangles (Answers on page 863)

1. Solve triangle *ABC* in Fig. 12.17(i).

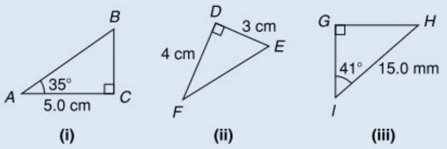

Figure 12.17

2. Solve triangle *DEF* in Fig. 12.17(ii).
3. Solve triangle *GHI* in Fig. 12.17(iii).
4. Solve the triangle *JKL* in Fig. 12.18(i) and find its area.
5. Solve the triangle *MNO* in Fig. 12.18(ii) and find its area.

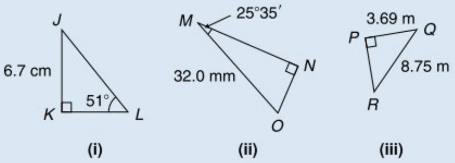

Figure 12.18

6. Solve the triangle *PQR* in Fig. 12.18(iii) and find its area.

7. A ladder rests against the top of the perpendicular wall of a building and makes an angle of 73° with the ground. If the foot of the ladder is 2 m from the wall, calculate the height of the building.

12.6 Angles of elevation and depression

(a) If, in Fig. 12.19, BC represents horizontal ground and AB a vertical flagpole, then the **angle of elevation** of the top of the flagpole, A, from the point C is the angle that the imaginary straight line AC must be raised (or elevated) from the horizontal CB, i.e. angle θ.

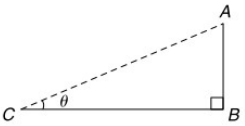

Figure 12.19

(b) If, in Fig. 12.20, PQ represents a vertical cliff and R a ship at sea, then the **angle of depression** of the ship from point P is the angle through which the imaginary straight line PR must be lowered (or depressed) from the horizontal to the ship, i.e. angle ϕ.

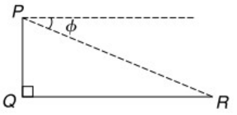

Figure 12.20

(Note, $\angle PRQ$ is also ϕ – alternate angles between parallel lines.)

Problem 24. An electricity pylon stands on horizontal ground. At a point 80 m from the base of the pylon, the angle of elevation of the top of the pylon is 23°. Calculate the height of the pylon to the nearest metre.

Figure 12.21 shows the pylon AB and the angle of elevation of A from point C is 23°

$$\tan 23° = \frac{AB}{BC} = \frac{AB}{80}$$

Hence height of pylon AB

$$= 80 \tan 23° = 80(0.4245) = 33.96\,\text{m}$$

$$= \mathbf{34\,m\ to\ the\ nearest\ metre}.$$

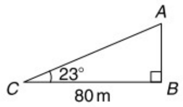

Figure 12.21

Problem 25. A surveyor measures the angle of elevation of the top of a perpendicular building as 19°. He moves 120 m nearer the building and finds the angle of elevation is now 47°. Determine the height of the building.

The building PQ and the angles of elevation are shown in Fig. 12.22.

In triangle PQS,

$$\tan 19° = \frac{h}{x+120}$$

hence $h = \tan 19°(x+120)$,

i.e. $h = 0.3443(x+120)$ (1)

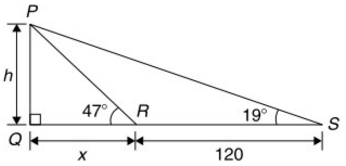

Figure 12.22

In triangle PQR, $\tan 47° = \dfrac{h}{x}$

hence $h = \tan 47°(x)$, i.e. $h = 1.0724x$ (2)

Equating equations (1) and (2) gives:

$$0.3443(x+120) = 1.0724x$$
$$0.3443x + (0.3443)(120) = 1.0724x$$
$$(0.3443)(120) = (1.0724 - 0.3443)x$$
$$41.316 = 0.7281x$$
$$x = \frac{41.316}{0.7281} = 56.74\,\text{m}$$

From equation (2), **height of building**,

$\boldsymbol{h} = 1.0724x = 1.0724(56.74) = \mathbf{60.85\,m}$

Problem 26. The angle of depression of a ship viewed at a particular instant from the top of a 75 m vertical cliff is 30°. Find the distance of the ship from the base of the cliff at this instant. The ship is sailing away from the cliff at constant speed and one minute later its angle of depression from the top of the cliff is 20°. Determine the speed of the ship in km/h.

Fig. 12.23 shows the cliff AB, the initial position of the ship at C and the final position at D. Since the angle of depression is initially 30° then $\angle ACB = 30°$ (alternate angles between parallel lines).

$$\tan 30° = \frac{AB}{BC} = \frac{75}{BC}$$

hence $$BC = \frac{75}{\tan 30°} = \frac{75}{0.5774} = \mathbf{129.9\,m}$$

$= $ **initial position of ship from base of cliff**

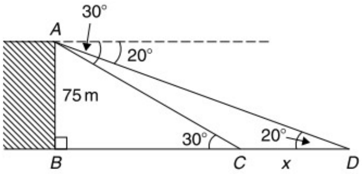

Figure 12.23

In triangle ABD,

$$\tan 20° = \frac{AB}{BD} = \frac{75}{BC+CD} = \frac{75}{129.9+x}$$

Hence $$129.9 + x = \frac{75}{\tan 20°} = \frac{75}{0.3640} = 206.0\,\text{m}$$

from which $$x = 206.0 - 129.9 = 76.1\,\text{m}$$

Thus the ship sails 76.1 m in one minute, i.e. 60 s, hence speed of ship

$$= \frac{\text{distance}}{\text{time}} = \frac{76.1}{60}\,\text{m/s}$$

$$= \frac{76.1 \times 60 \times 60}{60 \times 1000}\,\text{km/h} = \mathbf{4.57\,km/h}$$

Now try the following Practice Exercise

Practice Exercise 55 Angles of elevation and depression (Answers on page 864)

1. If the angle of elevation of the top of a vertical 30 m high aerial is 32°, how far is it to the aerial?
2. From the top of a vertical cliff 80.0 m high the angles of depression of two buoys lying due west of the cliff are 23° and 15°, respectively. How far are the buoys apart?
3. From a point on horizontal ground a surveyor measures the angle of elevation of the top of a flagpole as $18°40'$. He moves 50 m nearer to the flagpole and measures the angle of elevation as $26°22'$. Determine the height of the flagpole.
4. A flagpole stands on the edge of the top of a building. At a point 200 m from the building the angles of elevation of the top and bottom of the pole are 32° and 30° respectively. Calculate the height of the flagpole.
5. From a ship at sea, the angles of elevation of the top and bottom of a vertical lighthouse standing on the edge of a vertical cliff are 31° and 26°, respectively. If the lighthouse is 25.0 m high, calculate the height of the cliff.
6. From a window 4.2 m above horizontal ground the angle of depression of the foot of a building across the road is 24° and the angle of elevation of the top of the building is 34°. Determine, correct to the nearest centimetre, the width of the road and the height of the building.
7. The elevation of a tower from two points, one due east of the tower and the other due west of it are 20° and 24°, respectively, and the two points of observation are 300 m apart. Find the height of the tower to the nearest metre.

12.7 Sine and cosine rules

To **'solve a triangle'** means 'to find the values of unknown sides and angles'. If a triangle is **right angled**, trigonometric ratios and the theorem of Pythagoras may be used for its solution, as shown in Section 12.5.

However, for a **non-right-angled triangle**, trigonometric ratios and Pythagoras' theorem **cannot** be used. Instead, two rules, called the **sine rule** and the **cosine rule**, are used.

Sine rule

With reference to triangle *ABC* of Fig. 12.24, the **sine rule** states:

$$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C}$$

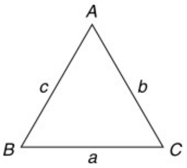

Figure 12.24

The rule may be used only when:

(i) one side and any two angles are initially given, or

(ii) two sides and an angle (not the included angle) are initially given.

Cosine rule

With reference to triangle *ABC* of Fig. 12.24, the **cosine rule** states:

$$a^2 = b^2 + c^2 - 2bc\cos A$$
$$\text{or}\quad b^2 = a^2 + c^2 - 2ac\cos B$$
$$\text{or}\quad c^2 = a^2 + b^2 - 2ab\cos C$$

The rule may be used only when:

(i) two sides and the included angle are initially given, or

(ii) three sides are initially given.

12.8 Area of any triangle

The **area of any triangle** such as *ABC* of Fig. 12.24 is given by:

(i) $\frac{1}{2}$ **× base × perpendicular height, or**

(ii) $\frac{1}{2}ab\sin C$ **or** $\frac{1}{2}ac\sin B$ **or** $\frac{1}{2}bc\sin A$**, or**

(iii) $\sqrt{[s(s-a)(s-b)(s-c)]}$**, where** $s = \frac{a+b+c}{2}$

12.9 Worked problems on the solution of triangles and finding their areas

Problem 27. In a triangle *XYZ*, $\angle X = 51°$, $\angle Y = 67°$ and $YZ = 15.2$ cm. Solve the triangle and find its area.

The triangle *XYZ* is shown in Fig. 12.25. Since the angles in a triangle add up to 180°, then $\boldsymbol{Z} = 180° - 51° - 67° = \mathbf{62°}$. Applying the sine rule:

$$\frac{15.2}{\sin 51°} = \frac{y}{\sin 67°} = \frac{z}{\sin 62°}$$

Using $\frac{15.2}{\sin 51°} = \frac{y}{\sin 67°}$ and transposing gives:

$$y = \frac{15.2\ \sin 67°}{\sin 51°} = \mathbf{18.00\,cm} = \boldsymbol{XZ}$$

Using $\frac{15.2}{\sin 51°} = \frac{z}{\sin 62°}$ and transposing gives:

$$z = \frac{15.2 \sin 62°}{\sin 51°} = \mathbf{17.27\,cm} = \boldsymbol{XY}$$

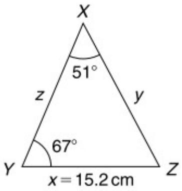

Figure 12.25

Area of triangle $\boldsymbol{XYZ} = \frac{1}{2}xy\sin Z$ $= \frac{1}{2}(15.2)(18.00)\sin 62° = \mathbf{120.8\,cm^2}$ (or area $= \frac{1}{2}xz\sin Y = \frac{1}{2}(15.2)(17.27)\sin 67° = \mathbf{120.8\,cm^2}$).

It is always worth checking with triangle problems that the longest side is opposite the largest angle, and vice-versa. In this problem, *Y* is the largest angle and *XZ* is the longest of the three sides.

Problem 28. Solve the triangle PQR and find its area given that $QR = 36.5$ mm, $PR = 29.6$ mm and $\angle Q = 36°$.

Triangle PQR is shown in Fig. 12.26.

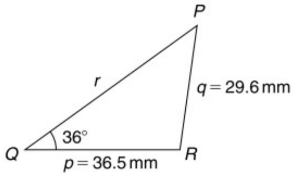

Figure 12.26

Applying the sine rule:

$$\frac{29.6}{\sin 36°} = \frac{36.5}{\sin P}$$

from which,

$$\sin P = \frac{36.5 \sin 36°}{29.6} = 0.7248$$

Hence $P = \sin^{-1} 0.7248 = 46°27'$ or $133°33'$

When $P = 46°27'$ and $Q = 36°$ then
$R = 180° - 46°27' - 36° = 97°33'$
When $P = 133°33'$ and $Q = 36°$ then
$R = 180° - 133°33' - 36° = 10°27'$

Thus, in this problem there are **two** separate sets of results and both are feasible solutions. Such a situation is called the **ambiguous case**.

Case 1. $P = 46°27'$, $Q = 36°$, $R = 97°33'$, $p = 36.5$ mm and $q = 29.6$ mm.
From the sine rule:

$$\frac{r}{\sin 97°33'} = \frac{29.6}{\sin 36°}$$

from which,

$$r = \frac{29.6 \sin 97°33'}{\sin 36°} = \mathbf{49.92\ mm}$$

$$\mathbf{Area} = \tfrac{1}{2} pq \sin R = \tfrac{1}{2}(36.5)(29.6)\sin 97°33'$$

$$= \mathbf{535.5\,mm^2}$$

Case 2. $P = 133°33'$, $Q = 36°$, $R = 10°27'$, $p = 36.5$ mm and $q = 29.6$ mm.
From the sine rule:

$$\frac{r}{\sin 10°27'} = \frac{29.6}{\sin 36°}$$

from which,

$$r = \frac{29.6 \sin 10°27'}{\sin 36°} = \mathbf{9.134\,mm}$$

$$\mathbf{Area} = \tfrac{1}{2} pq \sin R = \tfrac{1}{2}(36.5)(29.6)\sin 10°27'$$

$$= \mathbf{97.98\,mm^2}$$

Triangle PQR for case 2 is shown in Fig. 12.27.

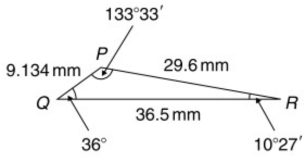

Figure 12.27

Now try the following Practice Exercise

Practice Exercise 56 Solving triangles and finding their areas (Answers on page 864)

In Problems 1 and 2, use the sine rule to solve the triangles ABC and find their areas.

1. $A = 29°$, $B = 68°$, $b = 27$ mm.
2. $B = 71°26'$, $C = 56°32'$, $b = 8.60$ cm.

In Problems 3 and 4, use the sine rule to solve the triangles DEF and find their areas.

3. $d = 17$ cm, $f = 22$ cm, $F = 26°$
4. $d = 32.6$ mm, $e = 25.4$ mm, $D = 104°22'$

In Problems 5 and 6, use the sine rule to solve the triangles JKL and find their areas.

5. $j = 3.85$ cm, $k = 3.23$ cm, $K = 36°$
6. $k = 46$ mm, $l = 36$ mm, $L = 35°$

12.10 Further worked problems on solving triangles and finding their areas

Problem 29. Solve triangle DEF and find its area given that $EF = 35.0$ mm, $DE = 25.0$ mm and $\angle E = 64°$

Triangle *DEF* is shown in Fig. 12.28.

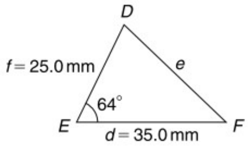

Figure 12.28

Applying the cosine rule:

$$e^2 = d^2 + f^2 - 2d\,f\cos E$$

i.e. $$e^2 = (35.0)^2 + (25.0)^2 - [2(35.0)(25.0)\cos 64°]$$

$$= 1225 + 625 - 767.1 = 1083$$

from which, $\boldsymbol{e} = \sqrt{1083} = \mathbf{32.91\,mm}$

Applying the sine rule:

$$\frac{32.91}{\sin 64°} = \frac{25.0}{\sin F}$$

from which, $$\sin F = \frac{25.0\sin 64°}{32.91} = 0.6828$$

Thus $$\angle F = \sin^{-1} 0.6828$$
$$= 43°4' \text{ or } 136°56'$$

$F = 136°56'$ is not possible in this case since $136°56' + 64°$ is greater than 180°. Thus only $\boldsymbol{F} = \mathbf{43°4'}$ is valid

$$\angle \boldsymbol{D} = 180° - 64° - 43°4' = \mathbf{72°56'}$$

Area of triangle $DEF = \frac{1}{2}\,d\,f\sin E$
$= \frac{1}{2}(35.0)(25.0)\sin 64° = \mathbf{393.2\,mm^2}$

Problem 30. A triangle *ABC* has sides $a = 9.0$ cm, $b = 7.5$ cm and $c = 6.5$ cm. Determine its three angles and its area.

Triangle *ABC* is shown in Fig. 12.29. It is usual first to calculate the largest angle to determine whether the triangle is acute or obtuse. In this case the largest angle is *A* (i.e. opposite the longest side).

Applying the cosine rule:

$$a^2 = b^2 + c^2 - 2bc\cos A$$

from which, $2bc\cos A = b^2 + c^2 - a^2$

and $$\cos A = \frac{b^2 + c^2 - a^2}{2bc} = \frac{7.5^2 + 6.5^2 - 9.0^2}{2(7.5)(6.5)}$$
$$= 0.1795$$

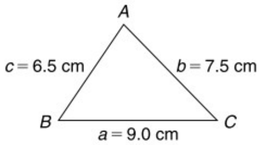

Figure 12.29

Hence $A = \cos^{-1} 0.1795 = \mathbf{79°40'}$ (or 280°20′, which is obviously impossible). The triangle is thus acute angled since cos *A* is positive. (If cos *A* had been negative, angle *A* would be obtuse, i.e. lie between 90° and 180°.)

Applying the sine rule:

$$\frac{9.0}{\sin 79°40'} = \frac{7.5}{\sin B}$$

from which,

$$\sin B = \frac{7.5\sin 79°40'}{9.0} = 0.8198$$

Hence $\boldsymbol{B} = \sin^{-1} 0.8198 = \mathbf{55°4'}$

and $\boldsymbol{C} = 180° - 79°40' - 55°4' = \mathbf{45°16'}$

$$\text{Area} = \sqrt{[s(s-a)(s-b)(s-c)]}$$

where $$s = \frac{a+b+c}{2} = \frac{9.0 + 7.5 + 6.5}{2}$$
$$= 11.5\,\text{cm}$$

Hence **area**

$$= \sqrt{[11.5(11.5 - 9.0)(11.5 - 7.5)(11.5 - 6.5)]}$$

$$= \sqrt{[11.5(2.5)(4.0)(5.0)]} = \mathbf{23.98\,cm^2}$$

Alternatively, area $= \frac{1}{2}ab\sin C$
$= \frac{1}{2}(9.0)(7.5)\sin 45°16' = \mathbf{23.98\,cm^2}$

Now try the following Practice Exercise

Practice Exercise 57 Solving triangles and finding their areas (Answers on page 864)

In Problems 1 and 2, use the cosine and sine rules to solve the triangles *PQR* and find their areas.

1. $q = 12$ cm, $r = 16$ cm, $P = 54°$
2. $q = 3.25$ m, $r = 4.42$ m, $P = 105°$

In problems 3 and 4, use the cosine and sine rules to solve the triangles *XYZ* and find their areas.

3. $x=10.0$ cm, $y=8.0$ cm, $z=7.0$ cm.
4. $x=21$ mm, $y=34$ mm, $z=42$ mm.

12.11 Practical situations involving trigonometry

There are a number of **practical situations** where the use of trigonometry is needed to find unknown sides and angles of triangles. This is demonstrated in the following problems.

Problem 31. A room 8.0 m wide has a span roof which slopes at 33° on one side and 40° on the other. Find the length of the roof slopes, correct to the nearest centimetre.

A section of the roof is shown in Fig. 12.30.

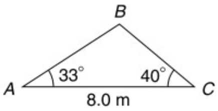

Figure 12.30

Angle at ridge, $B=180^\circ-33^\circ-40^\circ=107^\circ$
From the sine rule:

$$\frac{8.0}{\sin 107^\circ}=\frac{a}{\sin 33^\circ}$$

from which,

$$a=\frac{8.0\sin 33^\circ}{\sin 107^\circ}=4.556\,\text{m}$$

Also from the sine rule:

$$\frac{8.0}{\sin 107^\circ}=\frac{c}{\sin 40^\circ}$$

from which,

$$c=\frac{8.0\sin 40^\circ}{\sin 107^\circ}=5.377\,\text{m}$$

Hence the roof slopes are 4.56 m and 5.38 m, correct to the nearest centimetre.

Problem 32. Two voltage phasors are shown in Fig. 12.31. If $V_1=40$ V and $V_2=100$ V determine the value of their resultant (i.e. length OA) and the angle the resultant makes with V_1

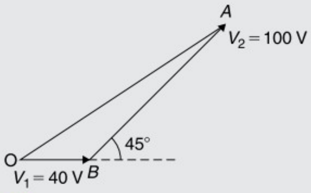

Figure 12.31

Angle $OBA=180^\circ-45^\circ=135^\circ$

Applying the cosine rule:

$$\begin{aligned}OA^2&=V_1^2+V_2^2-2V_1V_2\cos OBA\\&=40^2+100^2-\{2(40)(100)\cos 135^\circ\}\\&=1600+10\,000-\{-5657\}\\&=1600+10\,000+5657=17\,257\end{aligned}$$

The resultant

$$OA=\sqrt{(17\,257)}=131.4\,\text{V}$$

Applying the sine rule:

$$\frac{131.4}{\sin 135^\circ}=\frac{100}{\sin AOB}$$

from which, $$\sin AOB=\frac{100\sin 135^\circ}{131.4}=0.5381$$

Hence angle $AOB=\sin^{-1}0.5381=32^\circ 33'$ (or $147^\circ 27'$, which is impossible in this case).

Hence the resultant voltage is 131.4 volts at 32°33′ to V_1

Problem 33. In Fig. 12.32, PR represents the inclined jib of a crane and is 10.0 long. PQ is 4.0 m long. Determine the inclination of the jib to the vertical and the length of tie QR.

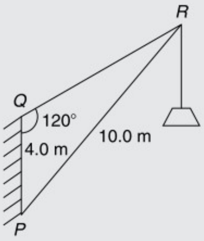

Figure 12.32

Applying the sine rule:

$$\frac{PR}{\sin 120^\circ} = \frac{PQ}{\sin R}$$

from which,

$$\sin R = \frac{PQ \sin 120^\circ}{PR} = \frac{(4.0)\sin 120^\circ}{10.0} = 0.3464$$

Hence $\angle R = \sin^{-1} 0.3464 = 20^\circ 16'$ (or $159^\circ 44'$, which is impossible in this case).

$\angle \boldsymbol{P} = 180^\circ - 120^\circ - 20^\circ 16' = \mathbf{39^\circ 44'}$, **which is the inclination of the jib to the vertical**.

Applying the sine rule:

$$\frac{10.0}{\sin 120^\circ} = \frac{QR}{\sin 39^\circ 44'}$$

from which, **length of tie**,

$$\boldsymbol{QR} = \frac{10.0 \sin 39^\circ 44'}{\sin 120^\circ} = \mathbf{7.38\,m}$$

Now try the following Practice Exercise

Practice Exercise 58 Practical situations involving trigonometry (Answers on page 864)

1. A ship P sails at a steady speed of 45 km/h in a direction of W 32° N (i.e. a bearing of 302°) from a port. At the same time another ship Q leaves the port at a steady speed of 35 km/h in a direction N 15° E (i.e. a bearing of 015°). Determine their distance apart after four hours.
2. Two sides of a triangular plot of land are 52.0 m and 34.0 m, respectively. If the area of the plot is 620 m^2 find (a) the length of fencing required to enclose the plot and (b) the angles of the triangular plot.
3. A jib crane is shown in Fig. 12.33. If the tie rod PR is 8.0 long and PQ is 4.5 m long, determine (a) the length of jib RQ and (b) the angle between the jib and the tie rod.

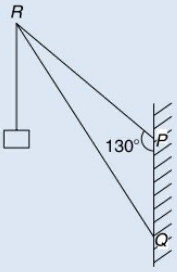

Figure 12.33

4. A building site is in the form of a quadrilateral, as shown in Fig. 12.34, and its area is 1510 m^2. Determine the length of the perimeter of the site.

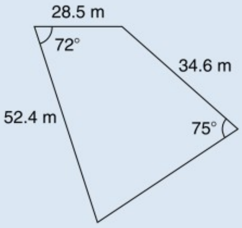

Figure 12.34

5. Determine the length of members BF and EB in the roof truss shown in Fig. 12.35.

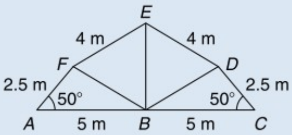

Figure 12.35

6. A laboratory 9.0 m wide has a span roof which slopes at 36° on one side and 44° on the other. Determine the lengths of the roof slopes.

12.12 Further practical situations involving trigonometry

Problem 34. A vertical aerial stands on horizontal ground. A surveyor positioned due east of the aerial measures the elevation of the top as 48°. He moves due south 30.0 m and measures the elevation as 44°. Determine the height of the aerial.

In Fig. 12.36, DC represents the aerial, A is the initial position of the surveyor and B his final position.

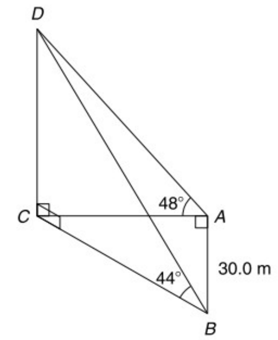

Figure 12.36

From triangle ACD, $\tan 48^\circ = \dfrac{DC}{AC}$

from which $$AC = \frac{DC}{\tan 48^\circ}$$

Similarly, from triangle BCD,

$$BC = \frac{DC}{\tan 44^\circ}$$

For triangle ABC, using Pythagoras' theorem:

$$BC^2 = AB^2 + AC^2$$

$$\left(\frac{DC}{\tan 44^\circ}\right)^2 = (30.0)^2 + \left(\frac{DC}{\tan 48^\circ}\right)^2$$

$$DC^2\left(\frac{1}{\tan^2 44^\circ} - \frac{1}{\tan^2 48^\circ}\right) = 30.0^2$$

$$DC^2(1.072323 - 0.810727) = 30.0^2$$

$$DC^2 = \frac{30.0^2}{0.261596} = 3440.4$$

Hence, height of aerial,

$$\boldsymbol{DC = \sqrt{3440.4} = 58.65\,\text{m}}$$

Problem 35. A crank mechanism of a petrol engine is shown in Fig. 12.37. Arm OA is 10.0 cm long and rotates clockwise about O. The connecting rod AB is 30.0 cm long and end B is constrained to move horizontally.

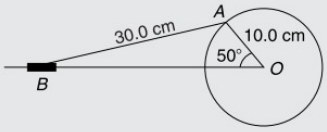

Figure 12.37

(a) For the position shown in Fig. 12.37 determine the angle between the connecting rod AB and the horizontal and the length of OB.

(b) How far does B move when angle AOB changes from 50° to 120°?

(a) Applying the sine rule:

$$\frac{AB}{\sin 50^\circ} = \frac{AO}{\sin B}$$

from which,

$$\sin B = \frac{AO \sin 50^\circ}{AB} = \frac{10.0 \sin 50^\circ}{30.0} = 0.2553$$

Hence $B = \sin^{-1} 0.2553 = 14^\circ 47'$ (or $165^\circ 13'$, which is impossible in this case).

Hence the connecting rod AB makes an angle of $14^\circ 47'$ with the horizontal.

Angle $OAB = 180^\circ - 50^\circ - 14^\circ 47' = 115^\circ 13'$.

Applying the sine rule:

$$\frac{30.0}{\sin 50^\circ} = \frac{OB}{\sin 115^\circ 13'}$$

from which,

$$\boldsymbol{OB} = \frac{30.0 \sin 115^\circ 13'}{\sin 50^\circ} = \boldsymbol{35.43\,\text{cm}}$$

(b) Fig. 12.38 shows the initial and final positions of the crank mechanism. In triangle $OA'B'$, applying the sine rule:

$$\frac{30.0}{\sin 120^\circ} = \frac{10.0}{\sin A'B'O}$$

from which,

$$\sin A'B'O = \frac{10.0 \sin 120^\circ}{30.0} = 0.2887$$

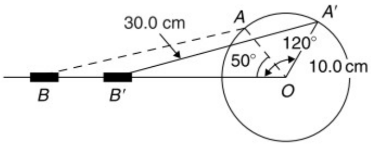

Figure 12.38

Hence $A'B'O = \sin^{-1} 0.2887 = 16^\circ 47'$ (or $163^\circ 13'$ which is impossible in this case).

Angle $OA'B' = 180^\circ - 120^\circ - 16^\circ 47' = 43^\circ 13'$

Applying the sine rule:

$$\frac{30.0}{\sin 120^\circ} = \frac{OB'}{\sin 43^\circ 13'}$$

from which,

$$OB' = \frac{30.0 \sin 43^\circ 13'}{\sin 120^\circ} = 23.72\,\text{cm}$$

Since $OB = 35.43\,\text{cm}$ and $OB' = 23.72\,\text{cm}$ then $BB' = 35.43 - 23.72 = 11.71\,\text{cm}$.

Hence *B* moves 11.71 cm when angle *AOB* changes from 50° to 120°

Problem 36. The area of a field is in the form of a quadrilateral *ABCD* as shown in Fig. 12.39. Determine its area.

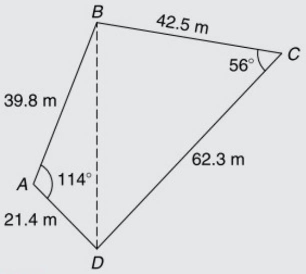

Figure 12.39

A diagonal drawn from *B* to *D* divides the quadrilateral into two triangles.

Area of quadrilateral *ABCD*

$$= \text{area of triangle } ABD + \text{area of triangle } BCD$$

$$= \tfrac{1}{2}(39.8)(21.4)\sin 114^\circ + \tfrac{1}{2}(42.5)(62.3)\sin 56^\circ$$

$$= 389.04 + 1097.5 = \mathbf{1487\,m^2}$$

Now try the following Practice Exercise

Practice Exercise 59 Practical situations involving trigonometry (Answers on page 864)

1. *PQ* and *QR* are the phasors representing the alternating currents in two branches of a circuit. Phasor *PQ* is 20.0 A and is horizontal. Phasor *QR* (which is joined to the end of *PQ* to form triangle *PQR*) is 14.0 A and is at an angle of 35° to the horizontal. Determine the resultant phasor *PR* and the angle it makes with phasor *PQ*.
2. Three forces acting on a fixed point are represented by the sides of a triangle of dimensions 7.2 cm, 9.6 cm and 11.0 cm. Determine the angles between the lines of action and the three forces.
3. Calculate, correct to 3 significant figures, the co-ordinates *x* and *y* to locate the hole centre at *P* shown in Fig. 12.40.

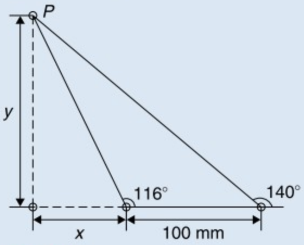

Figure 12.40

4. An idler gear, 30 mm in diameter, has to be fitted between a 70 mm diameter driving gear and a 90 mm diameter driven gear as shown in Fig. 12.41. Determine the value of angle θ between the centre lines.

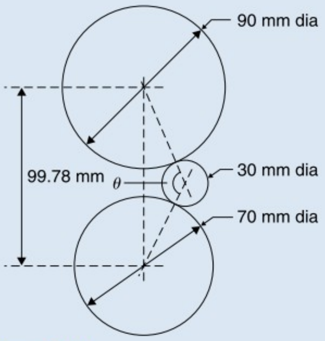

Figure 12.41

5. A reciprocating engine mechanism is shown in Fig. 12.42. The crank AB is 12.0 cm long and the connecting rod BC is 32.0 cm long. For the position shown determine the length of AC and the angle between the crank and the connecting rod.

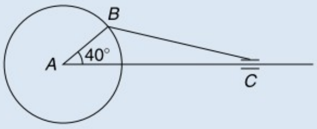

Figure 12.42

6. From Fig. 12.42, determine how far C moves, correct to the nearest millimetre, when angle CAB changes from 40° to 160°, B moving in an anticlockwise direction.

7. A surveyor, standing W 25° S of a tower, measures the angle of elevation of the top of the tower as $46°30'$. From a position E 23° S from the tower the elevation of the top is $37°15'$. Determine the height of the tower if the distance between the two observations is 75 m.

8. An aeroplane is sighted due east from a radar station at an elevation of 40° and a height of 8000 m and later at an elevation of 35° and height 5500 m in a direction E 70° S. If it is descending uniformly, find the angle of descent. Determine also the speed of the aeroplane in km/h if the time between the two observations is 45 s.

9. Sixteen holes are equally spaced on a pitch circle of 70 mm diameter. Determine the length of the chord joining the centres of two adjacent holes.

www.routledge.com/cw/bird

Chapter 13

Cartesian and polar co-ordinates

***Why it is important to understand:* Cartesian and polar co-ordinates**

Applications where polar co-ordinates would be used include terrestrial navigation with sonar-like devices, and those in engineering and science involving energy radiation patterns. Applications where Cartesian co-ordinates would be used include any navigation on a grid and anything involving raster graphics (e.g. bitmap – a dot matrix data structure representing a generally rectangular grid of pixels). The ability to change from Cartesian to polar co-ordinates is vitally important when using complex numbers and their use in a.c. electrical circuit theory and with vector geometry.

At the end of this chapter, you should be able to:

- change from Cartesian to polar co-ordinates
- change from polar to Cartesian co-ordinates
- use a scientific notation calculator to change from Cartesian to polar co-ordinates and vice-versa

---

Higher Engineering Mathematics. 978-1-138-67357-1, © 2017 John Bird. Published by Taylor & Francis. All rights reserved.

13.1 Introduction

There are two ways in which the position of a point in a plane can be represented. These are

(a) by **Cartesian co-ordinates**, (named after **Descartes***), i.e. (x, y), and

(b) by **polar co-ordinates**, i.e. (r, θ), where r is a 'radius' from a fixed point and θ is an angle from a fixed point.

13.2 Changing from Cartesian into polar co-ordinates

In Fig. 13.1, if lengths x and y are known, then the length of r can be obtained from Pythagoras' theorem (see Chapter 12) since OPQ is a right-angled triangle. Hence $r^2 = (x^2 + y^2)$

from which, $\boldsymbol{r = \sqrt{x^2 + y^2}}$

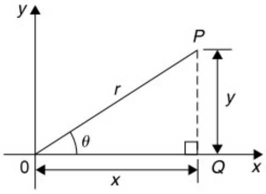

Figure 13.1

From trigonometric ratios (see Chapter 12),

$$\tan\theta = \frac{y}{x}$$

from which $\boldsymbol{\theta = \tan^{-1}\frac{y}{x}}$

$r = \sqrt{x^2 + y^2}$ and $\theta = \tan^{-1}\frac{y}{x}$ are the two formulae we need to change from Cartesian to polar co-ordinates. The angle θ, which may be expressed in degrees or radians, must **always** be measured from the positive x-axis, i.e., measured from the line OQ in Fig. 13.1. It is suggested that when changing from Cartesian to polar co-ordinates a diagram should always be sketched.

Problem 1. Change the Cartesian co-ordinates (3, 4) into polar co-ordinates.

A diagram representing the point (3, 4) is shown in Fig. 13.2.

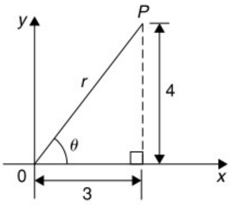

Figure 13.2

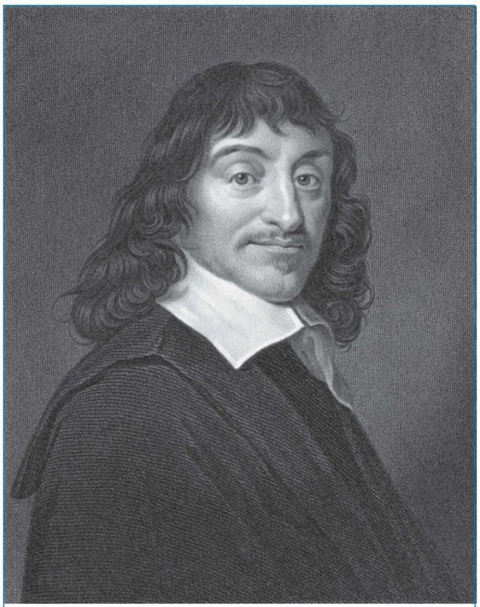
From Pythagoras' theorem, $r = \sqrt{3^2 + 4^2} = 5$ (note that -5 has no meaning in this context). By trigonometric ratios, $\theta = \tan^{-1}\frac{4}{3} = 53.13°$ or 0.927 rad.

[Note that $53.13° = 53.13 \times (\pi/180)\,\text{rad} = 0.927\,\text{rad}$.]



* **Who was Descartes?** **René Descartes** (31 March 1596–11 February 1650) was a French philosopher, mathematician, and writer. He wrote many influential texts including *Meditations on First Philosophy*. Descartes is best known for the philosophical statement '*Cogito ergo sum*' (I think, therefore I am), found in part IV of *Discourse on the Method*. To find out more go to **www.routledge.com/cw/bird**

Hence (3, 4) in Cartesian co-ordinates corresponds to (5, 53.13°) or (5, 0.927 rad) in polar co-ordinates.

Problem 2. Express in polar co-ordinates the position $(-4, 3)$

A diagram representing the point using the Cartesian co-ordinates $(-4, 3)$ is shown in Fig. 13.3.

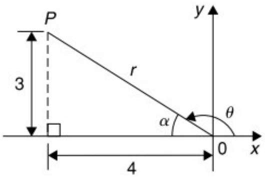


Figure 13.3

From Pythagoras' theorem, $r=\sqrt{4^2+3^2}=5$

By trigonometric ratios, $\alpha=\tan^{-1}\frac{3}{4}=36.87^\circ$ or 0.644 rad.

Hence $\theta=180^\circ-36.87^\circ=143.13^\circ$ or $\theta=\pi-0.644=2.498$ rad.

Hence the position of point *P* in polar co-ordinate form is (5, 143.13°) or (5, 2.498 rad).

Problem 3. Express $(-5, -12)$ in polar co-ordinates.

A sketch showing the position $(-5, -12)$ is shown in Fig. 13.4.

$$r=\sqrt{5^2+12^2}=13$$

and
$$\alpha=\tan^{-1}\frac{12}{5}$$
$$=67.38^\circ \text{ or } 1.176\,\text{rad}$$

Hence
$$\theta=180^\circ+67.38^\circ=247.38^\circ \text{ or}$$
$$\theta=\pi+1.176=4.318\,\text{rad}$$

Thus (−5, −12) in Cartesian co-ordinates corresponds to (13, 247.38°) or (13, 4.318 rad) in polar co-ordinates.

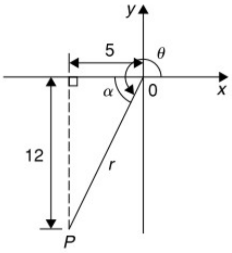

Figure 13.4

Problem 4. Express $(2, -5)$ in polar co-ordinates.

A sketch showing the position $(2, -5)$ is shown in Fig. 13.5.

$$r=\sqrt{2^2+5^2}=\sqrt{29}=5.385 \text{ correct to 3 decimal places.}$$

$$\alpha=\tan^{-1}\frac{5}{2}=68.20^\circ \text{ or } 1.190\,\text{rad}$$

Hence
$$\theta=360^\circ-68.20^\circ=291.80^\circ \text{ or}$$
$$\theta=2\pi-1.190=5.093\,\text{rad}$$

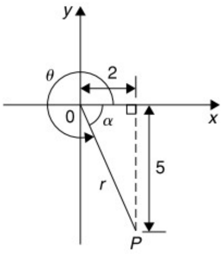

Figure 13.5

Thus (2, −5) in Cartesian co-ordinates corresponds to (5.385, 291.80°) or (5.385, 5.093 rad) in polar co-ordinates.

Now try the following Practice Exercise

Practice Exercise 60 Changing Cartesian into polar co-ordinates (Answers on page 864)

In Problems 1 to 8, express the given Cartesian co-ordinates as polar co-ordinates, correct to 2 decimal places, in both degrees and in radians.

1. (3, 5)
2. (6.18, 2.35)
3. (−2, 4)
4. (−5.4, 3.7)
5. (−7, −3)
6. (−2.4, −3.6)
7. (5, −3)
8. (9.6, −12.4)

13.3 Changing from polar into Cartesian co-ordinates

From the right-angled triangle *OPQ* in Fig. 13.6,

$$\cos\theta = \frac{x}{r} \text{ and } \sin\theta = \frac{y}{r}, \text{ from trigonometric ratios}$$

Hence $\boldsymbol{x = r\cos\theta}$ and $\boldsymbol{y = r\sin\theta}$

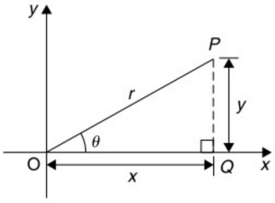

Figure 13.6

If lengths r and angle θ are known then $x = r\cos\theta$ and $y = r\sin\theta$ are the two formulae we need to change from polar to Cartesian co-ordinates.

Problem 5. Change (4, 32°) into Cartesian co-ordinates.

A sketch showing the position (4, 32°) is shown in Fig. 13.7.

Now $x = r\cos\theta = 4\cos 32^\circ = 3.39$

and $y = r\sin\theta = 4\sin 32^\circ = 2.12$

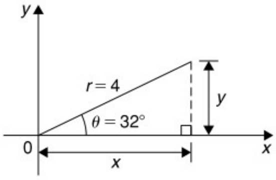

Figure 13.7

Hence (4, 32°) in polar co-ordinates corresponds to (3.39, 2.12) in Cartesian co-ordinates.

Problem 6. Express (6, 137°) in Cartesian co-ordinates.

A sketch showing the position (6, 137°) is shown in Fig. 13.8.

$$x = r\cos\theta = 6\cos 137^\circ = -4.388$$

which corresponds to length *OA* in Fig. 13.8.

$$y = r\sin\theta = 6\sin 137^\circ = 4.092$$

which corresponds to length *AB* in Fig. 13.8.

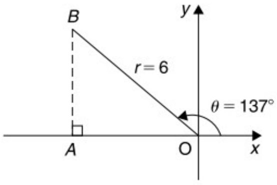

Figure 13.8

Thus (6, 137°) in polar co-ordinates corresponds to (−4.388, 4.092) in Cartesian co-ordinates.

(Note that when changing from polar to Cartesian co-ordinates it is not quite so essential to draw a sketch. Use of $x = r\cos\theta$ and $y = r\sin\theta$ automatically produces the correct signs.)

Problem 7. Express (4.5, 5.16 rad) in Cartesian co-ordinates.

A sketch showing the position (4.5, 5.16 rad) is shown in Fig. 13.9.

$$x = r\cos\theta = 4.5\cos 5.16 = 1.948$$

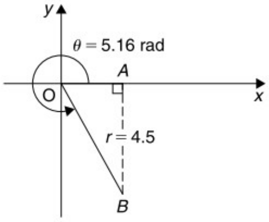

Figure 13.9

which corresponds to length OA in Fig. 13.9.

$$y = r\sin\theta = 4.5\sin 5.16 = -4.057$$

which corresponds to length AB in Fig. 13.9.

Thus (1.948, −4.057) in Cartesian co-ordinates corresponds to (4.5, 5.16 rad) in polar co-ordinates.

Now try the following Practice Exercise

Practice Exercise 61 Changing polar into Cartesian co-ordinates (Answers on page 864)

In Problems 1 to 8, express the given polar co-ordinates as Cartesian co-ordinates, correct to 3 decimal places.

1. (5, 75°)
2. (4.4, 1.12 rad)
3. (7, 140°)
4. (3.6, 2.5 rad)
5. (10.8, 210°)
6. (4, 4 rad)
7. (1.5, 300°)
8. (6, 5.5 rad)
9. Fig. 13.10 shows five equally spaced holes on an 80 mm pitch circle diameter. Calculate their co-ordinates relative to axes Ox and Oy in (a) polar form, (b) Cartesian form.
   (c) Calculate also the shortest distance between the centres of two adjacent holes.

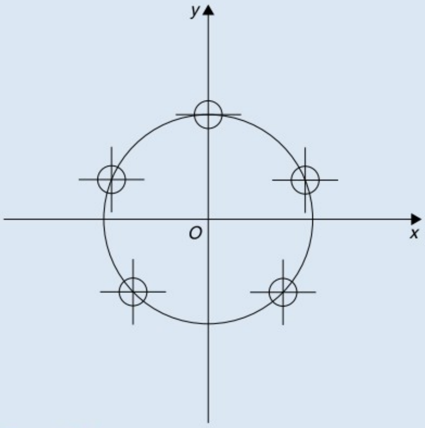

Figure 13.10

13.4 Use of Pol/Rec functions on calculators

Another name for Cartesian co-ordinates is **rectangular** co-ordinates. Many scientific notation calculators possess **Pol** and **Rec** functions. 'Rec' is an abbreviation of 'rectangular' (i.e. Cartesian) and 'Pol' is an abbreviation of 'polar'. Check the operation manual for your particular calculator to determine how to use these two functions. They make changing from Cartesian to polar co-ordinates, and vice-versa, so much quicker and easier.

For example, with the Casio fx-991ES PLUS calculator, or similar, to change the Cartesian number (3, 4) into polar form, the following procedure is adopted:

1. Press 'shift' 2. Press 'Pol' 3. Enter 3
4. Enter 'comma' (obtained by 'shift' then))
5. Enter 4 6. Press)
7. Press = The answer is: $\boldsymbol{r = 5, \theta = 53.13°}$

Hence, (3, 4) in Cartesian form is the same as $(5, 53.13°)$ in polar form.

If the angle is required in **radians**, then before repeating the above procedure press ‘shift’, ‘mode’ and then 4 to change your calculator to radian mode.

Similarly, to change the polar form number (7, 126°) into Cartesian or rectangular form, adopt the following procedure:

1. Press ‘shift’ 2. Press ‘Rec’ 3. Enter 7
4. Enter ‘comma’
5. Enter 126 (assuming your calculator is in degrees mode)
6. Press) 7. Press =

The answer is: $X = -4.11$, **and scrolling across,** $Y = 5.66$, correct to 2 decimal places.

Hence, (7, 126°) in polar form is the same as $(-4.11, 5.66)$ in rectangular or Cartesian form.

Now return to Practice Exercises 60 and 61 in this chapter and use your calculator to determine the answers, and see how much more quickly they may be obtained.

For fully worked solutions to each of the problems in Practice Exercises 60 and 61 in this chapter, go to the website:
www.routledge.com/cw/bird

Chapter 14

The circle and its properties

***Why it is important to understand:* The circle and its properties**

A circle is one of the fundamental shapes of geometry; it consists of all the points that are equidistant from a central point. Knowledge of calculations involving circles is needed with crank mechanisms, with determinations of latitude and longitude, with pendulums, and even in the design of paper clips. The floodlit area at a football ground, the area an automatic garden sprayer sprays and the angle of lap of a belt drive all rely on calculations involving the arc of a circle. The ability to handle calculations involving circles and its properties is clearly essential in several branches of engineering design.

At the end of this chapter, you should be able to:

- define a circle
- state some properties of a circle – including radius, circumference, diameter, semicircle, quadrant, tangent, sector, chord, segment and arc
- appreciate the angle in a semicircle is a right angle
- define a radian, change radians to degrees, and vice-versa
- determine arc length, area of a circle and area of a sector of a circle
- state the equation of a circle
- sketch a circle given its equation
- understand linear and angular velocity
- understand centripetal force

14.1 Introduction

A **circle** is a plain figure enclosed by a curved line, every point on which is equidistant from a point within, called the **centre**.

14.2 Properties of circles

(i) The distance from the centre to the curve is called the **radius**, r, of the circle (see OP in Fig. 14.1).

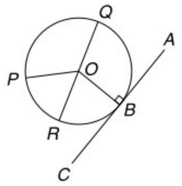

Figure 14.1

(ii) The boundary of a circle is called the **circumference**, c.

Higher Engineering Mathematics. 978-1-138-67357-1, © 2017 John Bird. Published by Taylor & Francis. All rights reserved.

(iii) Any straight line passing through the centre and touching the circumference at each end is called the **diameter**, d (see QR in Fig. 14.1). Thus $\boldsymbol{d=2r}$.

(iv) The ratio $\dfrac{\text{circumference}}{\text{diameter}}=$ a constant for any circle.

This constant is denoted by the Greek letter π (pronounced 'pie'), where $\pi=3.14159$, correct to 5 decimal places.

Hence $c/d=\pi$ or $\boldsymbol{c=\pi d}$ or $\boldsymbol{c=2\pi r}$.

(v) A **semicircle** is one half of the whole circle.

(vi) A **quadrant** is one quarter of a whole circle.

(vii) A **tangent** to a circle is a straight line which meets the circle in one point only and does not cut the circle when produced. AC in Fig. 14.1 is a tangent to the circle since it touches the curve at point B only. If radius OB is drawn, then angle ABO is a right angle.

(viii) A **sector** of a circle is the part of a circle between radii (for example, the portion OXY of Fig. 14.2 is a sector). If a sector is less than a semicircle it is called a **minor sector**, if greater than a semicircle it is called a **major sector**.

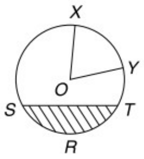

Figure 14.2

(ix) A **chord** of a circle is any straight line which divides the circle into two parts and is terminated at each end by the circumference. ST, in Fig. 14.2 is a chord.

(x) A **segment** is the name given to the parts into which a circle is divided by a chord. If the segment is less than a semicircle it is called a **minor segment** (see shaded area in Fig. 14.2). If the segment is greater than a semicircle it is called a **major segment** (see the unshaded area in Fig. 14.2).

(xi) An **arc** is a portion of the circumference of a circle. The distance SRT in Fig. 14.2 is called a **minor arc** and the distance $SXYT$ is called a **major arc**.

(xii) The angle at the centre of a circle, subtended by an arc, is double the angle at the circumference subtended by the same arc. With reference to Fig. 14.3, **Angle** $\boldsymbol{AOC=2\times}$ **angle** $\boldsymbol{ABC}$.

(xiii) The angle in a semicircle is a right angle (see angle BQP in Fig. 14.3).

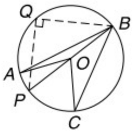

Figure 14.3

Problem 1. If the diameter of a circle is 75 mm, find its circumference.

$$\text{Circumference, } c=\pi\times\text{diameter}=\pi d$$
$$=\pi(75)=\mathbf{235.6\,mm}$$

Problem 2. In Fig. 14.4, AB is a tangent to the circle at B. If the circle radius is 40 mm and $AB=150$ mm, calculate the length AO.

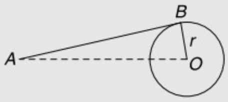

Figure 14.4

A tangent to a circle is at right angles to a radius drawn from the point of contact, i.e. $ABO=90°$. Hence, using Pythagoras' theorem:

$$AO^2=AB^2+OB^2$$
$$AO=\sqrt{(AB^2+OB^2)}=\sqrt{[(150)^2+(40)^2]}$$
$$=\mathbf{155.2\,mm}$$

Now try the following Practice Exercise

Practice Exercise 62 Properties of circles (Answers on page 864)

1. If the radius of a circle is 41.3 mm, calculate the circumference of the circle.
2. Find the diameter of a circle whose perimeter is 149.8 cm.
3. A crank mechanism is shown in Fig. 14.5, where XY is a tangent to the circle at point X. If

the circle radius OX is 10 cm and length OY is 40 cm, determine the length of the connecting rod XY.

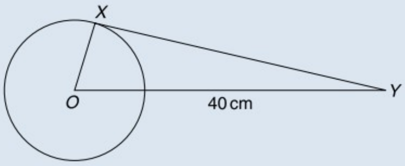

Figure 14.5

4. If the circumference of the Earth is 40 000 km at the equator, calculate its diameter.
5. Calculate the length of wire in the paper clip shown in Fig. 14.6. The dimensions are in millimetres.

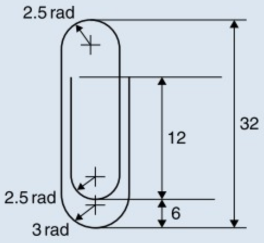

Figure 14.6

14.3 Radians and degrees

One **radian** is defined as the angle subtended at the centre of a circle by an arc equal in length to the radius.

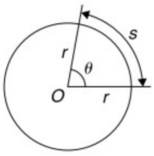

Figure 14.7

With reference to Fig. 14.7, for arc length s,

$$\theta \text{ radians} = \frac{s}{r}$$

When $s =$ whole circumference $(= 2\pi r)$ then $\theta = \frac{s}{r} = \frac{2\pi r}{r} = 2\pi$

i.e. $\mathbf{2\pi}$ **radians = 360°** or $\boldsymbol{\pi}$ **radians = 180°**

Thus, $\mathbf{1\,rad = \frac{180°}{\pi} = 57.30°}$, correct to 2 decimal places.

Since π rad $= 180°$, then $\frac{\pi}{2} = 90°, \frac{\pi}{3} = 60°, \frac{\pi}{4} = 45°$, and so on.

Problem 3. Convert to radians: (a) 125° (b) 69°47′

(a) Since $180° = \pi$ rad then $1° = \pi/180$ rad, therefore

$$125° = 125\left(\frac{\pi}{180}\right)^c = \mathbf{2.182\ rad}$$

(Note that ^{c} means 'circular measure' and indicates radian measure.)

(b) $69°47' = 69\frac{47°}{60} = 69.783°$

$$69.783° = 69.783\left(\frac{\pi}{180}\right)^c = \mathbf{1.218\,rad}$$

Problem 4. Convert to degrees and minutes: (a) 0.749 rad (b) $3\pi/4$ rad.

(a) Since π rad $= 180°$ then 1 rad $= 180°/\pi$, therefore

$$0.749 = 0.749\left(\frac{180}{\pi}\right)^{\circ} = 42.915°$$

$0.915° = (0.915 \times 60)' = 55'$, correct to the nearest minute, hence

$$\mathbf{0.749\ rad = 42°55'}$$

(b) Since 1 rad $= \left(\frac{180}{\pi}\right)^{\circ}$ then

$$\frac{3\pi}{4}\text{ rad} = \frac{3\pi}{4}\left(\frac{180}{\pi}\right)^{\circ} = \frac{3}{4}(180)^{\circ} = \mathbf{135°}$$

Problem 5. Express in radians, in terms of π, (a) 150° (b) 270° (c) 37.5°

Since $180^\circ = \pi$ rad then $1^\circ = \pi/180$, hence

(a) $150^\circ = 150\left(\frac{\pi}{180}\right)$ rad $= \mathbf{\frac{5\pi}{6}}$ **rad**

(b) $270^\circ = 270\left(\frac{\pi}{180}\right)$ rad $= \mathbf{\frac{3\pi}{2}}$ **rad**

(c) $37.5^\circ = 37.5\left(\frac{\pi}{180}\right)$ rad $= \frac{75\pi}{360}$ rad $= \mathbf{\frac{5\pi}{24}}$ **rad**

Now try the following Practice Exercise

Practice Exercise 63 Radians and degrees (Answers on page 865)

1. Convert to radians in terms of π: (a) 30° (b) 75° (c) 225°
2. Convert to radians: (a) 48° (b) $84^\circ51'$ (c) $232^\circ15'$
3. Convert to degrees: (a) $\frac{7\pi}{6}$ rad (b) $\frac{4\pi}{9}$ rad (c) $\frac{7\pi}{12}$ rad.
4. Convert to degrees and minutes: (a) 0.0125 rad (b) 2.69 rad (c) 7.241 rad.
5. A car engine speed is 1000 rev/min. Convert this speed into rad/s.

14.4 Arc length and area of circles and sectors

Arc length

From the definition of the radian in the previous section and Fig. 14.7,

arc length, $\boldsymbol{s = r\theta}$ where θ is in radians

Area of circle

For any circle, area $= \pi \times (\text{radius})^2$

i.e. $\mathbf{area} = \boldsymbol{\pi r^2}$

Since $r = \frac{d}{2}$, then $\mathbf{area} = \boldsymbol{\pi r^2}$ or $\boldsymbol{\frac{\pi d^2}{4}}$

Area of sector

Area of a sector $= \boldsymbol{\frac{\theta}{360}(\pi r^2)}$ when θ is in degrees

$$= \frac{\theta}{2\pi}(\pi r^2) = \boldsymbol{\frac{1}{2}r^2\theta}$$

when θ is in radians

Problem 6. A hockey pitch has a semicircle of radius 14.63 m around each goal net. Find the area enclosed by the semicircle, correct to the nearest square metre.

Area of a semicircle $= \frac{1}{2}\pi r^2$

When $r = 14.63$ m, area $= \frac{1}{2}\pi(14.63)^2$

i.e. **area of semicircle = 336 m^2**

Problem 7. Find the area of a circular metal plate, correct to the nearest square millimetre, having a diameter of 35.0 mm.

Area of a circle $= \pi r^2 = \frac{\pi d^2}{4}$

When $d = 35.0$ mm, area $= \frac{\pi(35.0)^2}{4}$

i.e. **area of circular plate = 962 mm^2**

Problem 8. Find the area of a circle having a circumference of 60.0 mm.

Circumference, $c = 2\pi r$

from which radius $r = \frac{c}{2\pi} = \frac{60.0}{2\pi} = \frac{30.0}{\pi}$

Area of a circle $= \pi r^2$

i.e. **area** $= \pi\left(\frac{30.0}{\pi}\right)^2 = \mathbf{286.5\,mm^2}$

Problem 9. Find the length of arc of a circle of radius 5.5 cm when the angle subtended at the centre is 1.20 rad.

Length of arc, $s = r\theta$, where θ is in radians, hence

$s = (5.5)(1.20) = \mathbf{6.60\,cm}$

Problem 10. Determine the diameter and circumference of a circle if an arc of length 4.75 cm subtends an angle of 0.91 rad.

Since $s = r\theta$ then $r = \dfrac{s}{\theta} = \dfrac{4.75}{0.91} = 5.22\,\text{cm}$

Diameter $= 2 \times$ radius $= 2 \times 5.22 = \mathbf{10.44\,cm}$

Circumference, $c = \pi d = \pi(10.44) = \mathbf{32.80\,cm}$

Problem 11. If an angle of 125° is subtended by an arc of a circle of radius 8.4 cm, find the length of (a) the minor arc, and (b) the major arc, correct to 3 significant figures.

(a) Since $180° = \pi$ rad then $1° = \left(\dfrac{\pi}{180}\right)$ rad and $125° = 125\left(\dfrac{\pi}{180}\right)$ rad.

Length of minor arc,

$$s = r\theta = (8.4)(125)\left(\frac{\pi}{180}\right) = \mathbf{18.3\,cm},$$

correct to 3 significant figures.

(b) Length of major arc

$= $ (circumference − minor arc)

$= 2\pi(8.4) - 18.3 = 34.5\,\text{cm}$,

correct to 3 significant figures.

(Alternatively, major arc $= r\theta$
$= 8.4(360 - 125)(\pi/180) = \mathbf{34.5\,cm}$.)

Problem 12. Determine the angle, in degrees and minutes, subtended at the centre of a circle of diameter 42 mm by an arc of length 36 mm. Calculate also the area of the minor sector formed.

Since length of arc, $s = r\theta$ then $\theta = s/r$

$$\text{Radius, } r = \frac{\text{diameter}}{2} = \frac{42}{2} = 21\,\text{mm}$$

$$\text{hence } \theta = \frac{s}{r} = \frac{36}{21} = 1.7143\,\text{rad}$$

$1.7143\,\text{rad} = 1.7143 \times (180/\pi)° = 98.22° = \mathbf{98°13'} =$ angle subtended at centre of circle.

Area of sector

$$= \tfrac{1}{2}r^2\theta = \tfrac{1}{2}(21)^2(1.7143) = \mathbf{378\,mm^2}$$

Problem 13. A football stadium floodlight can spread its illumination over an angle of 45° to a distance of 55 m. Determine the maximum area that is floodlit.

Floodlit area $=$ area of sector

$$= \frac{1}{2}r^2\theta = \frac{1}{2}(55)^2\left(45 \times \frac{\pi}{180}\right)$$

$$= \mathbf{1188\,m^2}$$

Problem 14. An automatic garden spray produces a spray to a distance of 1.8 m and revolves through an angle α which may be varied. If the desired spray catchment area is to be 2.5 m^2, to what should angle α be set, correct to the nearest degree.

Area of sector $= \tfrac{1}{2}r^2\theta$, hence $2.5 = \tfrac{1}{2}(1.8)^2\alpha$

from which, $\alpha = \dfrac{2.5 \times 2}{1.8^2} = 1.5432\,\text{rad}$

$1.5432\,\text{rad} = \left(1.5432 \times \dfrac{180°}{\pi}\right) = 88.42°$

Hence **angle $\alpha = 88°$**, correct to the nearest degree.

Problem 15. The angle of a tapered groove is checked using a 20 mm diameter roller as shown in Fig. 14.8. If the roller lies 2.12 mm below the top of the groove, determine the value of angle θ.

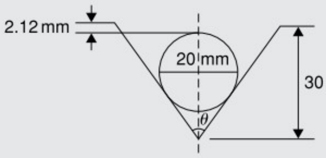

Figure 14.8

In Fig. 14.9, triangle ABC is right-angled at C (see Section 14.2 (vii)).

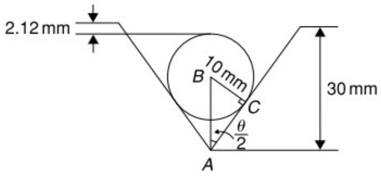

Figure 14.9

Length $BC = 10\,\text{mm}$ (i.e. the radius of the circle), and $AB = 30 - 10 - 2.12 = 17.88\,\text{mm}$ from Fig. 14.9.

Hence, $\sin\dfrac{\theta}{2} = \dfrac{10}{17.88}$ and $\dfrac{\theta}{2} = \sin^{-1}\left(\dfrac{10}{17.88}\right) = 34°$ and **angle $\theta = 68°$**

Now try the following Practice Exercise

Practice Exercise 64 Arc length and area of circles and sectors (Answers on page 865)

1. Calculate the area of a circle of radius 6.0 cm, correct to the nearest square centimetre.
2. The diameter of a circle is 55.0 mm. Determine its area, correct to the nearest square millimetre.
3. The perimeter of a circle is 150 mm. Find its area, correct to the nearest square millimetre.
4. Find the area of the sector, correct to the nearest square millimetre, of a circle having a radius of 35 mm, with angle subtended at centre of 75°
5. An annulus has an outside diameter of 49.0 mm and an inside diameter of 15.0 mm. Find its area correct to 4 significant figures.
6. Find the area, correct to the nearest square metre, of a 2 m wide path surrounding a circular plot of land 200 m in diameter.
7. A rectangular park measures 50 m by 40 m. A 3 m flower bed is made round the two longer sides and one short side. A circular fish pond of diameter 8.0 m is constructed in the centre of the park. It is planned to grass the remaining area. Find, correct to the nearest square metre, the area of grass.
8. Find the length of an arc of a circle of radius 8.32 cm when the angle subtended at the centre is 2.14 rad. Calculate also the area of the minor sector formed.
9. If the angle subtended at the centre of a circle of diameter 82 mm is 1.46 rad, find the lengths of the (a) minor arc (b) major arc.
10. A pendulum of length 1.5 m swings through an angle of 10° in a single swing. Find, in centimetres, the length of the arc traced by the pendulum bob.
11. Determine the length of the radius and circumference of a circle if an arc length of 32.6 cm subtends an angle of 3.76 rad.
12. Determine the angle of lap, in degrees and minutes, if 180 mm of a belt drive are in contact with a pulley of diameter 250 mm.
13. Determine the number of complete revolutions a motorcycle wheel will make in travelling 2 km, if the wheel's diameter is 85.1 cm.
14. The floodlight at a sports ground spreads its illumination over an angle of 40° to a distance of 48 m. Determine (a) the angle in radians, and (b) the maximum area that is floodlit.
15. Determine (a) the shaded area in Fig. 14.10 (b) the percentage of the whole sector that the area of the shaded portion represents.

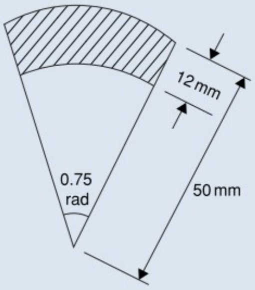

Figure 14.10

16. Determine the length of steel strip required to make the clip shown in Fig. 14.11.

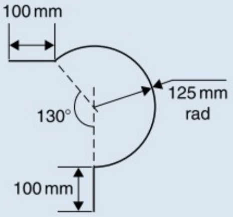

Figure 14.11

17. A 50° tapered hole is checked with a 40 mm diameter ball as shown in Fig. 14.12. Determine the length shown as x.

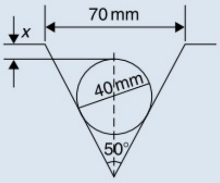

Figure 14.12

14.5 The equation of a circle

The simplest equation of a circle, centre at the origin, radius r, is given by:

$$x^2 + y^2 = r^2$$

For example, Fig. 14.13 shows a circle $x^2 + y^2 = 9$. More generally, the equation of a circle, centre (a, b), radius r, is given by:

$$(x - a)^2 + (y - b)^2 = r^2 \qquad (1)$$

Figure 14.14 shows a circle $(x - 2)^2 + (y - 3)^2 = 4$. The general equation of a circle is:

$$x^2 + y^2 + 2ex + 2fy + c = 0 \qquad (2)$$

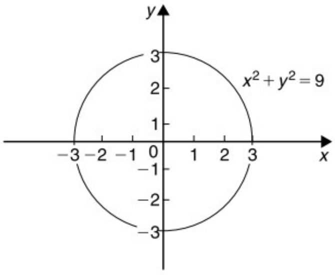

Figure 14.13

Multiplying out the bracketed terms in equation (1) gives:

$$x^2 - 2ax + a^2 + y^2 - 2by + b^2 = r^2$$

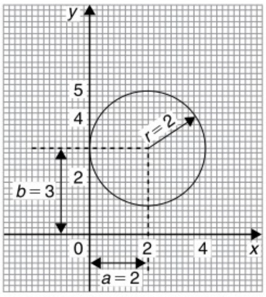

Figure 14.14

Comparing this with equation (2) gives:

$$2e = -2a, \text{ i.e. } \boldsymbol{a = -\frac{2e}{2}}$$

and $2f = -2b$, i.e. $\boldsymbol{b = -\frac{2f}{2}}$

and $c = a^2 + b^2 - r^2$,

i.e., $\boldsymbol{r = \sqrt{(a^2 + b^2 - c)}}$

Thus, for example, the equation

$$x^2 + y^2 - 4x - 6y + 9 = 0$$

represents a circle with centre $a = -\left(\frac{-4}{2}\right)$, $b = -\left(\frac{-6}{2}\right)$, i.e. at (2, 3) and radius $r = \sqrt{(2^2 + 3^2 - 9)} = 2$

Hence $x^2 + y^2 - 4x - 6y + 9 = 0$ is the circle shown in Fig. 14.14 (which may be checked by multiplying out the brackets in the equation

$$(x - 2)^2 + (y - 3)^2 = 4)$$

Problem 16. Determine (a) the radius and (b) the co-ordinates of the centre of the circle given by the equation: $x^2 + y^2 + 8x - 2y + 8 = 0$

$x^2 + y^2 + 8x - 2y + 8 = 0$ is of the form shown in equation (2),

where $a = -\left(\frac{8}{2}\right) = -4, b = -\left(\frac{-2}{2}\right) = 1$

and $r = \sqrt{[(-4)^2 + (1)^2 - 8]} = \sqrt{9} = 3$

Hence $x^2 + y^2 + 8x - 2y + 8 = 0$ represents a circle **centre (−4, 1)** and **radius 3**, as shown in Fig. 14.15.

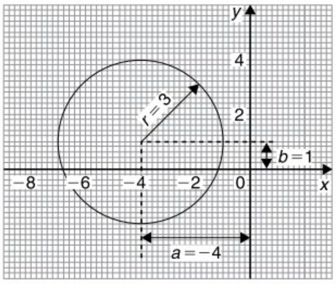

Figure 14.15

Alternatively, $x^2+y^2+8x-2y+8=0$ may be rearranged as:

$$(x+4)^2+(y-1)^2-9=0$$

i.e. $$(x+4)^2+(y-1)^2=3^2$$

which represents a circle, **centre (−4, 1)** and **radius 3**, as stated above.

Problem 17. Sketch the circle given by the equation: $x^2+y^2-4x+6y-3=0$

The equation of a circle, centre (a, b), radius r is given by:

$$(x-a)^2+(y-b)^2=r^2$$

The general equation of a circle is

$$x^2+y^2+2ex+2fy+c=0$$

From above, $a=-\frac{2e}{2}$, $b=-\frac{2f}{2}$ and

$$r=\sqrt{(a^2+b^2-c)}$$

Hence if $x^2+y^2-4x+6y-3=0$

then $a=-\left(\frac{-4}{2}\right)=2,\quad b=-\left(\frac{6}{2}\right)=-3$

and $$r=\sqrt{[(2)^2+(-3)^2-(-3)]}$$
$$=\sqrt{16}=4$$

Thus **the circle has centre (2, −3) and radius 4**, as shown in Fig. 14.16.

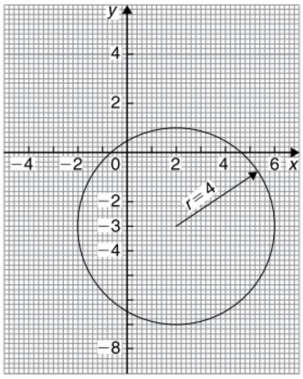

Figure 14.16

Alternatively, $x^2+y^2-4x+6y-3=0$ may be rearranged as:

$$(x-2)^2+(y+3)^2-3-13=0$$

i.e. $$(x-2)^2+(y+3)^2=4^2$$

which represents a circle, **centre (2, −3)** and **radius 4**, as stated above.

Now try the following Practice Exercise

Practice Exercise 65 The equation of a circle (Answers on page 865)

1. Determine (a) the radius, and (b) the co-ordinates of the centre of the circle given by the equation $x^2+y^2+6x-2y-26=0$
2. Sketch the circle given by the equation $x^2+y^2-6x+4y-3=0$
3. Sketch the curve $x^2+(y-1)^2-25=0$
4. Sketch the curve $x=6\sqrt{[1-(y/6)^2]}$

14.6 Linear and angular velocity

Linear velocity

Linear velocity v is defined as the rate of change of linear displacement s with respect to time t. For motion in a straight line:

$$\text{linear velocity}=\frac{\text{change of displacement}}{\text{change of time}}$$

i.e. $$v=\frac{s}{t} \qquad (1)$$

The unit of linear velocity is metres per second (m/s).

Angular velocity

The speed of revolution of a wheel or a shaft is usually measured in revolutions per minute or revolutions per second but these units do not form part of a coherent system of units. The basis in SI units is the angle turned through in one second.

Angular velocity is defined as the rate of change of angular displacement θ, with respect to time t. For an object rotating about a fixed axis at a constant speed:

$$\text{angular velocity}=\frac{\text{angle turned through}}{\text{time taken}}$$

i.e. $$\boldsymbol{\omega = \frac{\theta}{t}} \qquad (2)$$

The unit of angular velocity is radians per second (rad/s). An object rotating at a constant speed of n revolutions per second subtends an angle of $2\pi n$ radians in one second, i.e. its angular velocity ω is given by:

$$\boldsymbol{\omega = 2\pi n\,\text{rad/s}} \qquad (3)$$

From page 152, $s = r\theta$ and from equation (2) above, $\theta = \omega t$

hence $$s = r(\omega t)$$

from which $$\frac{s}{t} = \omega r$$

However, from equation (1) $v = \frac{s}{t}$

hence $$\boldsymbol{v = \omega r} \qquad (4)$$

Equation (4) gives the relationship between linear velocity v and angular velocity ω.

Problem 18. A wheel of diameter 540 mm is rotating at $\frac{1500}{\pi}$ rev/min. Calculate the angular velocity of the wheel and the linear velocity of a point on the rim of the wheel.

From equation (3), angular velocity $\omega = 2\pi n$ where n is the speed of revolution in rev/s. Since in this case $n = \frac{1500}{\pi}\,\text{rev/min} = \frac{1500}{60\pi} = \text{rev/s}$, then

$$\textbf{angular velocity}\,\omega = 2\pi\left(\frac{1500}{60\pi}\right) = \mathbf{50\,rad/s}$$

The linear velocity of a point on the rim, $v = \omega r$, where r is the radius of the wheel, i.e.

$$\frac{540}{2}\,\text{mm} = \frac{0.54}{2}\,\text{m} = 0.27\,\text{m}$$

Thus **linear velocity** $v = \omega r = (50)(0.27)$

$$= \mathbf{13.5\,m/s}$$

Problem 19. A car is travelling at 64.8 km/h and has wheels of diameter 600 mm.

(a) Find the angular velocity of the wheels in both rad/s and rev/min.

(b) If the speed remains constant for 1.44 km, determine the number of revolutions made by the wheel, assuming no slipping occurs.

(a) Linear velocity $v = 64.8\,\text{km/h}$

$$= 64.8\frac{\text{km}}{\text{h}} \times 1000\frac{\text{m}}{\text{km}} \times \frac{1}{3600}\frac{\text{h}}{\text{s}} = 18\,\text{m/s}$$

The radius of a wheel $= \frac{600}{2} = 300\,\text{mm}$

$= 0.3\,\text{m}$

From equation (5), $v = \omega r$, from which,

$$\textbf{angular velocity}\,\omega = \frac{v}{r} = \frac{18}{0.3} = \mathbf{60\,rad/s}$$

From equation (4), angular velocity, $\omega = 2\pi n$, where n is in rev/s.

Hence angular speed $n = \frac{\omega}{2\pi} = \frac{60}{2\pi}\,\text{rev/s}$

$$= 60 \times \frac{60}{2\pi}\,\text{rev/min}$$

$$= \mathbf{573\,rev/min}$$

(b) From equation (1), since $v = s/t$ then the time taken to travel 1.44 km, i.e. 1440 m at a constant speed of 18 m/s is given by:

$$\text{time } t = \frac{s}{v} = \frac{1440\,\text{m}}{18\,\text{m/s}} = 80\,\text{s}$$

Since a wheel is rotating at 573 rev/min, then in 80/60 minutes it makes

$$573\,\text{rev/min} \times \frac{80}{60}\,\text{min} = \mathbf{764\,revolutions}$$

Now try the following Practice Exercise

Practice Exercise 66 Linear and angular velocity (Answers on page 865)

1. A pulley driving a belt has a diameter of 300 mm and is turning at $2700/\pi$ revolutions per minute. Find the angular velocity of the pulley and the linear velocity of the belt assuming that no slip occurs.
2. A bicycle is travelling at 36 km/h and the diameter of the wheels of the bicycle is 500 mm. Determine the linear velocity of a point on the rim of one of the wheels of the bicycle, and the angular velocity of the wheels.

3. A train is travelling at 108 km/h and has wheels of diameter 800 mm.
   (a) Determine the angular velocity of the wheels in both rad/s and rev/min.
   (b) If the speed remains constant for 2.70 km, determine the number of revolutions made by a wheel, assuming no slipping occurs.

14.7 Centripetal force

When an object moves in a circular path at constant speed, its direction of motion is continually changing and hence its velocity (which depends on both magnitude and direction) is also continually changing. Since acceleration is the (change in velocity)/(time taken), the object has an acceleration. Let the object be moving with a constant angular velocity of ω and a tangential velocity of magnitude v and let the change of velocity for a small change of angle of θ $(=\omega t)$ be V in Fig. 14.17. Then $v_2 - v_1 = V$. The vector diagram is shown in Fig. 14.17(b) and since the magnitudes of v_1 and v_2 are the same, i.e. v, the vector diagram is an isosceles triangle.

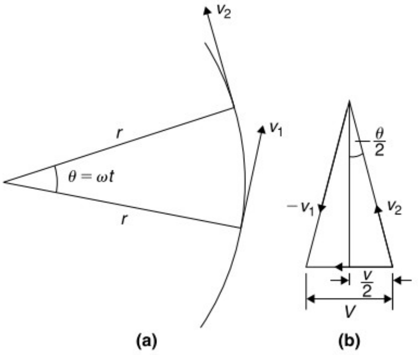

Figure 14.17

Bisecting the angle between v_2 and v_1 gives:

$$\sin\frac{\theta}{2} = \frac{V/2}{v_2} = \frac{V}{2v}$$

i.e. $$V = 2v\sin\frac{\theta}{2} \qquad (1)$$

Since $\theta = \omega t$ then

$$t = \frac{\theta}{\omega} \qquad (2)$$

Dividing equation (1) by equation (2) gives:

$$\frac{V}{t} = \frac{2v\sin(\theta/2)}{(\theta/\omega)} = \frac{v\omega\sin(\theta/2)}{(\theta/2)}$$

For small angles $\frac{\sin(\theta/2)}{(\theta/2)} \approx 1$,

hence $$\frac{V}{t} = \frac{\text{change of velocity}}{\text{change of time}}$$

$$= \text{acceleration } a = v\omega$$

However, $\omega = \frac{v}{r}$ (from Section 14.6)

thus $$v\omega = v\cdot\frac{v}{r} = \frac{v^2}{r}$$

i.e. the acceleration a is $\frac{v^2}{r}$ and is towards the centre of the circle of motion (along V). It is called the **centripetal acceleration**. If the mass of the rotating object is m, then by Newton's second law, the **centripetal force is** $\boldsymbol{\frac{mv^2}{r}}$ and its direction is towards the centre of the circle of motion.

Problem 20. A vehicle of mass 750 kg travels around a bend of radius 150 m, at 50.4 km/h. Determine the centripetal force acting on the vehicle.

The centripetal force is given by $\frac{mv^2}{r}$ and its direction is towards the centre of the circle.

$$\text{Mass } m = 750\,\text{kg},\ v = 50.4\,\text{km/h}$$
$$= \frac{50.4 \times 1000}{60 \times 60}\,\text{m/s}$$
$$= 14\,\text{m/s}$$

and radius $r = 150\,\text{m}$,

thus **centripetal force** $= \frac{750(14)^2}{150} = \mathbf{980\,N}$

Problem 21. An object is suspended by a thread 250 mm long and both object and thread move in a horizontal circle with a constant angular velocity of 2.0 rad/s. If the tension in the thread is 12.5 N, determine the mass of the object.

Centripetal force (i.e. tension in thread),

$$F = \frac{mv^2}{r} = 12.5\,\text{N}$$

Angular velocity $\omega = 2.0$ rad/s and
radius $r = 250$ mm $= 0.25$ m.

Since linear velocity $v = \omega r$, $v = (2.0)(0.25)$
$= 0.5$ m/s.

Since $F = \dfrac{mv^2}{r}$, then mass $m = \dfrac{Fr}{v^2}$,

i.e. **mass of object,** $\boldsymbol{m} = \dfrac{(12.5)(0.25)}{0.5^2} = \mathbf{12.5\ kg}$

Problem 22. An aircraft is turning at constant altitude, the turn following the arc of a circle of radius 1.5 km. If the maximum allowable acceleration of the aircraft is $2.5g$, determine the maximum speed of the turn in km/h. Take g as $9.8\,\text{m/s}^2$.

The acceleration of an object turning in a circle is $\dfrac{v^2}{r}$. Thus, to determine the maximum speed of turn, $\dfrac{v^2}{r} = 2.5g$, from which,

$$\textbf{velocity, } \boldsymbol{v} = \sqrt{(2.5gr)} = \sqrt{(2.5)(9.8)(1500)}$$
$$= \sqrt{36\,750} = 191.7\,\text{m/s}$$

and $191.7\,\text{m/s} = 191.7 \times \dfrac{60 \times 60}{1000}\,\text{km/h} = \mathbf{690\,km/h}$

Now try the following Practice Exercise

Practice Exercise 67 Centripetal force (Answers on page 865)

1. Calculate the tension in a string when it is used to whirl a stone of mass 200 g round in a horizontal circle of radius 90 cm with a constant speed of 3 m/s.
2. Calculate the centripetal force acting on a vehicle of mass 1 tonne when travelling around a bend of radius 125 m at 40 km/h. If this force should not exceed 750 N, determine the reduction in speed of the vehicle to meet this requirement.
3. A speed-boat negotiates an S-bend consisting of two circular arcs of radii 100 m and 150 m. If the speed of the boat is constant at 34 km/h, determine the change in acceleration when leaving one arc and entering the other.

For fully worked solutions to each of the problems in Practice Exercises 62 to 67 in this chapter, go to the website:
www.routledge.com/cw/bird

Revision Test 4 Trigonometry, Cartesian and polar co-ordinates and properties of circles

This Revision Test covers the material contained in Chapters 12 to 14. *The marks for each question are shown in brackets at the end of each question.*

1. A 2.0 m long ladder is placed against a perpendicular pylon with its foot 52 cm from the pylon. (a) Find how far up the pylon (correct to the nearest mm) the ladder reaches. (b) If the foot of the ladder is moved 10 cm towards the pylon, how far does the top of the ladder rise? (7)

2. Evaluate correct to 4 significant figures:

   (a) $\cos 124°13'$ (b) $\cot 72.68°$ (4)

3. From a point on horizontal ground a surveyor measures the angle of elevation of a church spire as 15°. He moves 30 m nearer to the church and measures the angle of elevation as 20°. Calculate the height of the spire. (9)

4. If secant $\theta = 2.4613$, determine the acute angle θ (4)

5. Evaluate, correct to 3 significant figures:

$$\frac{3.5 \operatorname{cosec} 31°17' - \cot(-12°)}{3 \sec 79°41'} \qquad (5)$$

6. A man leaves a point walking at 6.5 km/h in a direction E 20° N (i.e. a bearing of 70°). A cyclist leaves the same point at the same time in a direction E 40° S (i.e. a bearing of 130°) travelling at a constant speed. Find the average speed of the cyclist if the walker and cyclist are 80 km apart after five hours. (8)

7. A crank mechanism shown in Fig. RT4.1 comprises arm *OP*, of length 0.90 m, which rotates anticlockwise about the fixed point *O*, and connecting rod *PQ* of length 4.20 m. End *Q* moves horizontally in a straight line *OR*.

   (a) If $\angle POR$ is initially zero, how far does end *Q* travel in $\frac{1}{4}$ revolution.

   (b) If $\angle POR$ is initially 40° find the angle between the connecting rod and the horizontal and the length *OQ*.

   (c) Find the distance *Q* moves (correct to the nearest cm) when $\angle POR$ changes from 40° to 140°. (16)

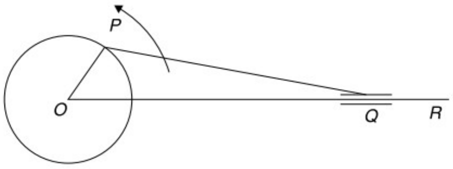

Figure RT4.1

8. Change the following Cartesian co-ordinates into polar co-ordinates, correct to 2 decimal places, in both degrees and in radians:

   (a) (−2.3, 5.4) (b) (7.6, −9.2) (10)

9. Change the following polar co-ordinates into Cartesian co-ordinates, correct to 3 decimal places: (a) (6.5, 132°) (b) (3, 3 rad) (6)

10. (a) Convert 2.154 radians into degrees and minutes.

    (b) Change 71°17′ into radians. (4)

11. 140 mm of a belt drive is in contact with a pulley of diameter 180 mm which is turning at 300 revolutions per minute. Determine (a) the angle of lap, (b) the angular velocity of the pulley, and (c) the linear velocity of the belt, assuming that no slipping occurs. (9)

12. Figure RT4.2 shows a cross-section through a circular water container where the shaded area represents the water in the container. Determine: (a) the depth, *h*, (b) the area of the shaded portion, and (c) the area of the unshaded area. (11)

3.1.2 Right-Handed Convention

Because three constant coordinate surfaces are involved in determining the coordinates of any point, the question that arises is in which order the three coordinates are to be mentioned while specifying a point. In this context, the choice of the first coordinate (u_1) or surface (f_1) is arbitrary. Once f_1 is chosen, then the order in which the other two constant coordinate surfaces f_2 and f_3 is to be taken is determined by the right-handed system as governed by the definition of vector cross product. In other words, the cross product of the first and second unit vectors must be equal to the third unit vector.

This right-handed property of the coordinate system is an arbitrary convention. But once that choice is made for one coordinate system, it has to be followed for all other coordinate systems to ensure that the expressions for the laws of electric field have the same form in all the coordinate systems.

3.1.3 Differential Distance and Metric Coefficient

The constant coordinate surfaces could be of many different types. The simplest of them is constant distance surfaces for which the differential change du_i in the coordinate u_i is the same as the differential distance dl_i between the surfaces $f_i = u_i$ and $f_i = u_i + du_i$. However, there are other types of surfaces such as constant angle surfaces, in which case the differential distance is related to differential coordinate (angle) change as

$$dl_i = h_i du_i = h_i d\theta_i \tag{3.2}$$

where:
The scale factor h_i is the corresponding radius

The scale factors for each of the coordinate system are called the *metric coefficients* of the respective coordinate system. The three metric functions of any coordinate system (h_1,h_2,h_3) constitute a unique set and hence are often known as the *signature of a coordinate system*. Metric coefficients are also very important in writing the vector operators in the general orthogonal curvilinear coordinate system, as will be explained in Section 3.5.

3.1.4 Choice of Origin

A basic element of any coordinate system is the choice of origin. If any object or any arrangement is given, then any point within the object or within the whole arrangement could be chosen as origin.

From the earlier discussions, it is clear that the same point will have very different coordinates when defined in different coordinate systems. Therefore, the question that needs to be answered is that whether there is any property of the position of the point that remains the same in different coordinate systems. The answer to this question is that the distance of the point from the origin remains the same in all the coordinate systems if the origin is kept the same in all the cases. As a logical extension, it may be stated that the distance between any two points remains the same no matter how their coordinates are defined in any coordinate system.

3.2 Cartesian Coordinate System

The invention of Cartesian coordinates in the seventeenth century by the French mathematician René Descartes revolutionized mathematics by providing the first systematic link between Euclidean geometry and algebra. In this coordinate system, the three constant coordinate surfaces are defined by Equation 3.3

$$f_1 = x, f_2 = y, f_3 = z \tag{3.3}$$

Figure 3.2 shows such constant coordinate surfaces, which are three planes. Cartesian coordinate system has the unique feature that all the three constant coordinate surfaces are constant distance surfaces.

Each point P in space is then assigned a triplet of values (x,y,z), the so-called Cartesian coordinates of that point. The ranges of the values of three coordinates are $-\infty < x < \infty$, $-\infty < y < \infty$ and $-\infty < z < \infty$. Coordinates can be

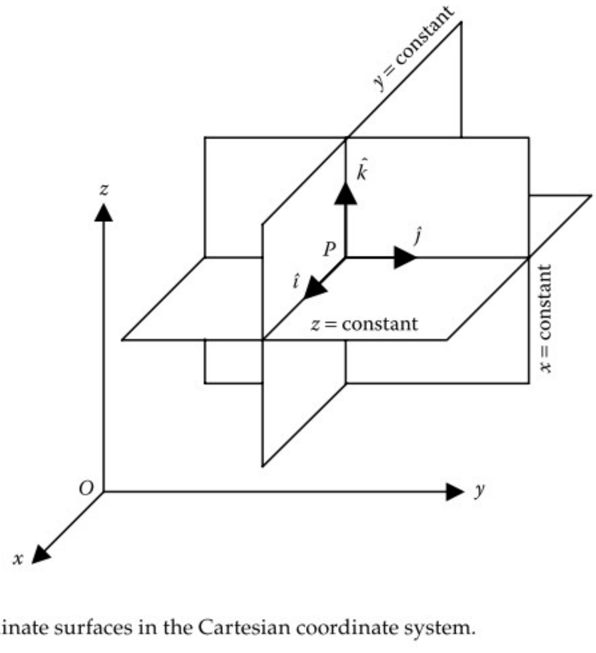

FIGURE 3.2
Constant coordinate surfaces in the Cartesian coordinate system.

defined as the positions of the normal projections of the point onto three mutually perpendicular constant coordinate surfaces passing through the origin, expressed as signed distances from the origin.

In the Cartesian coordinate system, three mutually perpendicular axes are commonly defined as follows. The intersection of two mutually perpendicular planes y = constant and z = constant passing through the origin gives a coordinate curve, which is a straight line. This line is then defined as the x-axis. Similarly, the intersections of other two pairs of mutually perpendicular constant coordinate planes passing through origin define the y- and z-axes.

The unit vector $\hat{i}$ is perpendicular to all the surfaces described by x = constant and points in the direction of increasing value of x-coordinate. In the same manner, unit vectors $\hat{j}$ and $\hat{k}$ are defined in y- and z-directions, respectively. Another unique feature of the Cartesian coordinate system is that the directions of the three unit vectors remain the same irrespective of the location of the point in space. The orthogonality of the Cartesian coordinate system is defined by Equation 3.4

$$\hat{i}\cdot\hat{j}=0,\ \hat{j}\cdot\hat{k}=0,\ \hat{k}\cdot\hat{i}=0 \tag{3.4}$$

and the right handedness is defined by Equation 3.5

$$\hat{i}\times\hat{j}=\hat{k},\ \hat{j}\times\hat{k}=\hat{i},\ \hat{k}\times\hat{i}=\hat{j} \tag{3.5}$$

As shown in Figure 3.3, the differential line element in the Cartesian coordinate system is given by Equation 3.6

$$d\vec{l}=dl_1\hat{i}+dl_2\hat{j}+dl_3\hat{k}=dx\hat{i}+dy\hat{j}+dz\bar{k} \tag{3.6}$$

As shown in Figure 3.4, the differential area element corresponding to the surface of a differential cubical volume is given by Equation 3.7

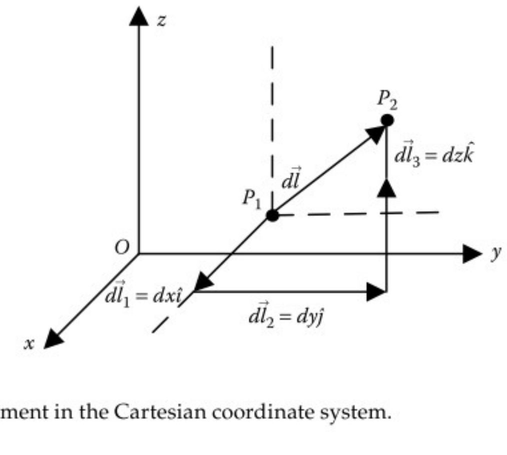

FIGURE 3.3
Differential line element in the Cartesian coordinate system.

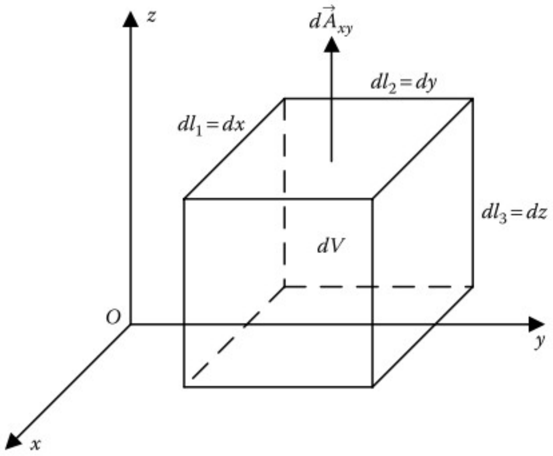

FIGURE 3.4
Differential area and volume elements in the Cartesian coordinate system.

$$d\vec{A}_{xy} = dl_1 dl_2 \hat{k} = dxdy\hat{k} \tag{3.7}$$

As shown in Figure 3.4, the differential volume element is given by Equation 3.8

$$dV = dl_1 dl_2 dl_3 = dxdydz \tag{3.8}$$

As depicted in Equation 3.6 the differential distance in x-direction is $dl_1 = dx = h_1 dx$, that is, $h_1 = 1$. Similarly, in y- and z-directions, $h_2 = h_3 = 1$. The metric coefficients of the Cartesian coordinate system are, therefore, $h_1 = 1$, $h_2 = 1$ and $h_3 = 1$.

3.3 Cylindrical Coordinate System

Cylindrical coordinates are an alternate way of describing points in a three-dimensional space. In this coordinate system, one of the rectangular coordinate planes, namely, the x–y plane, as described by the Cartesian coordinate system, is replaced by a polar plane. In the cylindrical coordinate system, everything is measured with respect to a fixed point called the *pole* and an axis called the *polar axis*. The pole is the equivalent to the origin in the Cartesian coordinate system and the polar axis corresponds to the positive direction of the x-axis. The cylindrical coordinates of a point are then the ordered triplet (r,θ,z), as defined in Figure 3.5.

As shown in Figure 3.5, r is the distance from the pole to the projection of the point P on the polar plane, that is, the x–y plane passing through the pole, θ is the azimuthal angle, that is, the angle from the polar axis spinning around the z-axis in counter-clockwise direction, and z is the vertical height from the polar plane. The ranges of the values of the three coordinates are $0 \le r < \infty$, $0 \le \theta \le 2\pi$ and $-\infty < z < \infty$.

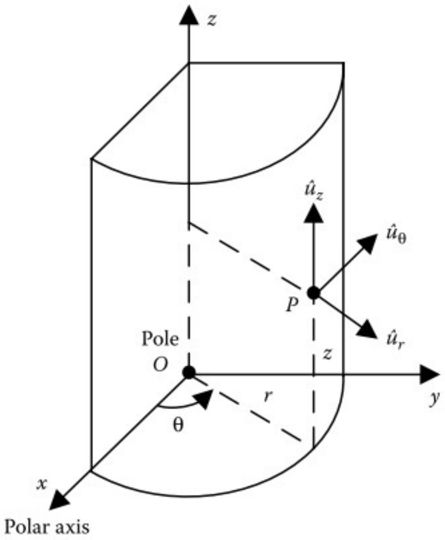

FIGURE 3.5
Depiction of cylindrical coordinates of a point.

In the cylindrical coordinate system, the three constant coordinate surfaces are defined by Equation 3.9

$$f_1 = r, f_2 = \theta, f_3 = z \tag{3.9}$$

Figure 3.6 shows the three constant coordinate surfaces in the cylindrical coordinate system. Out of these three surfaces, the first and the third surfaces, namely, $f_1 = r$ and $f_3 = z$, are constant distance surfaces, whereas the second one, that is, $f_2 = \theta$, is a constant angle surface. As shown in Figure 3.6, the surfaces θ = constant and z = constant are planes, whereas the surface r = constant is a cylindrical surface.

In this coordinate system, two unit vectors are defined on the x–y plane. The unit vector $\hat{u}_r$ points in the direction of increasing r, that is, radially outwards from the z-axis and the unit vector $\hat{u}_\theta$ points in the direction of increasing θ, that is, it points in the direction of the tangent to the circle of radius r in the counter-clockwise sense. The third unit vector $\hat{u}_z$ points in the direction of increasing z, that is, vertically upwards from the x–y plane. The unit vectors are shown in Figure 3.5. The orthogonality of cylindrical coordinate system is defined by Equation 3.10

$$\hat{u}_r \cdot \hat{u}_\theta = 0, \hat{u}_\theta \cdot \hat{u}_z = 0, \hat{u}_z \cdot \hat{u}_r = 0 \tag{3.10}$$

and the right handedness is defined by Equation 3.11

$$\hat{u}_r \times \hat{u}_\theta = \hat{u}_z, \hat{u}_\theta \times \hat{u}_z = \hat{u}_r, \hat{u}_z \times \hat{u}_r = \hat{u}_\theta \tag{3.11}$$

FIGURE 3.7
Unit vectors at different points in the cylindrical coordinate system.

Unlike the Cartesian system, in the cylindrical coordinate system, the directions of all the three unit vectors do not remain the same as one moves around the space. As shown in Figure 3.7, the directions of the unit vectors $\hat{u}_r$ and $\hat{u}_\theta$ get changed at different points in space keeping $\hat{u}_z$ unchanged.

As shown in Figure 3.8, the differential line element in the cylindrical coordinate system is given by Equation 3.12

$$d\vec{l} = dl_1\hat{u}_r + dl_2\hat{u}_\theta + dl_3\hat{u}_z = dr\hat{u}_r + rd_\theta\hat{u}_\theta + dz\hat{u}_z \tag{3.12}$$

As shown in Figure 3.9, in the cylindrical coordinate system, the differential area element on the surface of a cylinder of radius r is given by Equation 3.13

$$d\vec{A}_{\theta z} = dl_2 dl_3 \hat{u}_r = rd\theta dz\hat{u}_r \tag{3.13}$$

and the differential area element on the surface of a disc in the x–y plane, as shown in Figure 3.10, is given by Equation 3.14

$$d\vec{A}_{r\theta} = dl_1 dl_2 \hat{u}_z = drrd\theta\hat{u}_z \tag{3.14}$$

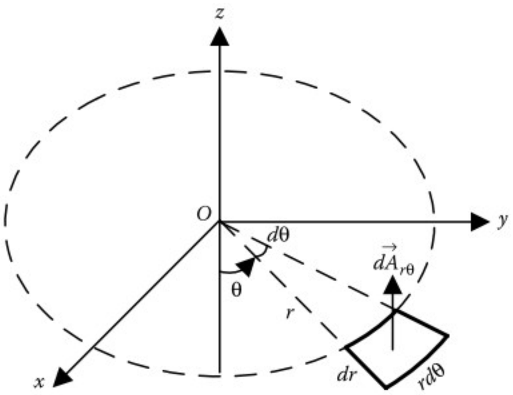

FIGURE 3.10

As shown in Figure 3.11, the differential volume element is given by Equation 3.15

$$dV = dl_1 dl_2 dl_3 = dr r d\theta dz \tag{3.15}$$

As depicted in Equation 3.12, the differential distance in r-direction is $dl_1 = dr = h_1 dr$, that is, $h_1 = 1$, in θ-direction, it is $dl_2 = r d\theta = h_2 d\theta$, that is, $h_2 = r$ and in z-direction, it is $dl_3 = dz = h_3 dz$, that is, $h_3 = 1$. The metric coefficients of cylindrical coordinate system are, therefore, $h_1 = 1$, $h_2 = r$ and $h_3 = 1$.

3.4 Spherical Coordinate System

Spherical coordinates are particularly useful for analyzing fields having spherical symmetry. In the spherical coordinate system, the coordinates of any point in space are the ordered triplet (r,θ,ϕ), as shown in Figure 3.12. The coordinate r measures the radial distance from the origin to the point P. The coordinate θ is the angle that the r vector makes with the positive direction of the z-axis, whereas the coordinate ϕ is the azimuthal angle with respect to the positive direction of the x-axis spinning around the z-axis in counterclockwise sense. The angle ϕ is defined on the x–y plane. The ranges of the values of the three coordinates are $0 \le r < \infty$, $0 \le \theta \le \pi$ and $0 \le \phi \le 2\pi$.

In the spherical coordinate system, the three constant coordinate surfaces are defined by Equation 3.16

$$f_1 = r,\ f_2 = \theta,\ f_3 = \phi \tag{3.16}$$

Figure 3.13 shows the three constant coordinate surfaces in the spherical coordinate system. Out of these three surfaces, the first surface, namely, $f_1 = r$, is a constant distance surface, whereas the other two surfaces, that is, $f_2 = \theta$ and $f_3 = \phi$, are constant angle surfaces. As shown in Figure 3.13, r = constant is a spherical surface, θ = constant is a conical surface and ϕ = constant is a plane.

In this coordinate system, the unit vector $\hat{u}_r$ points in the direction of increasing r, that is, radially outwards from the origin. The unit vector $\hat{u}_\theta$ points in the direction of increasing θ along the tangent to a circle of radius r in the plane containing the z-axis and the r vector. The unit vector $\hat{u}_\phi$ points

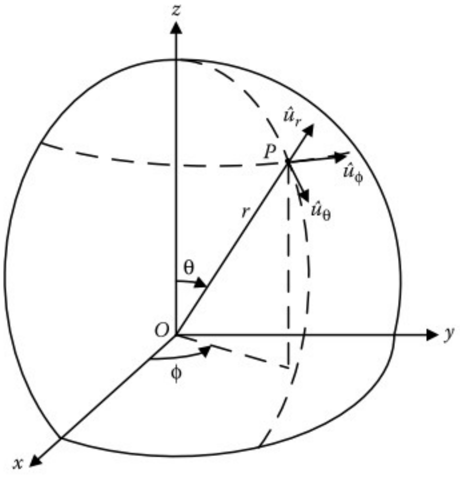

FIGURE 3.12
Depiction of spherical coordinates of a point.

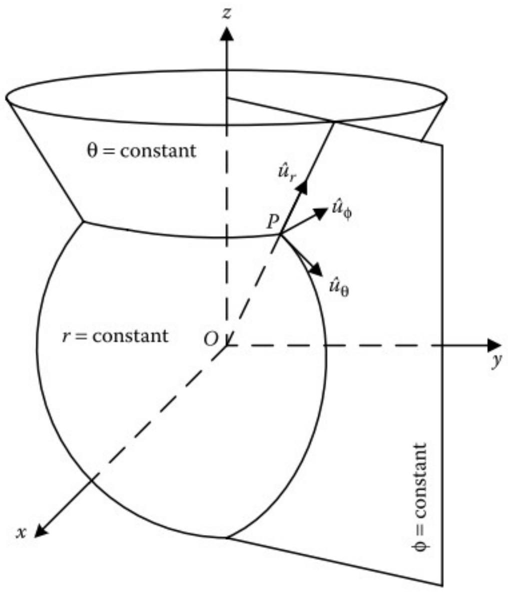

FIGURE 3.13
Constant coordinate surfaces in the spherical coordinate system.

in the direction of increasing ϕ along the tangent to a circle in the x–y plane, which is centred on the z-axis. The unit vectors are shown in Figure 3.12. The orthogonality of the spherical coordinate system is defined by Equation 3.17

$$\hat{u}_r \cdot \hat{u}_\theta = 0,\ \hat{u}_\theta \cdot \hat{u}_\phi = 0,\ \hat{u}_\phi \cdot \hat{u}_r = 0 \tag{3.17}$$

and the right handedness is defined by Equation 3.18

$$\hat{u}_r \times \hat{u}_\theta = \hat{u}_\phi,\ \hat{u}_\theta \times \hat{u}_\phi = \hat{u}_r,\ \hat{u}_\phi \times \hat{u}_r = \hat{u}_\theta \tag{3.18}$$

Similar to the cylindrical coordinate system, in the spherical coordinate system, the directions of all the three unit vectors do not remain the same as one move around the space. As shown in Figure 3.14, the directions of all the three unit vectors $\hat{u}_r$, $\hat{u}_\theta$ and $\hat{u}_\phi$ get changed at different points in space.

As shown in Figure 3.15, the differential line element in the spherical coordinate system is given by Equation 3.19

$$d\vec{l} = dl_1\hat{u}_r + dl_2\hat{u}_\theta + dl_3\hat{u}_\phi = dr\hat{u}_r + rd\theta\hat{u}_\theta + r\sin\theta d\phi\hat{u}_\phi \tag{3.19}$$

As shown in Figure 3.16, in the spherical coordinate system, the differential area element on the surface of a sphere of radius r is given by Equation 3.20

$$d\vec{A}_{\theta\phi} = dl_2dl_3\hat{u}_r = (rd\theta)(r\sin\theta d\phi)\hat{u}_r = r^2\sin\theta d\theta d\phi\hat{u}_r \tag{3.20}$$

As shown in Figure 3.17, the differential volume element is given by Equation 3.21

$$dV = dl_1 dl_2 dl_3 = (dr)(rd\theta)(r\sin\theta d\phi) = r^2 \sin\theta drd\theta d\phi \tag{3.21}$$

As depicted in Equation 3.19, the differential distance in r-direction is $dl_1 = dr = h_1 dr$, that is, $h_1 = 1$, in θ-direction, it is $dl_2 = rd\theta = h_2 d\theta$, that is, $h_2 = r$ and in ϕ-direction, it is $dl_3 = r\sin\theta d\phi = h_3 d\phi$, that is, $h_3 = r\sin\theta$. Therefore, the metric coefficients of spherical coordinate system are $h_1 = 1$, $h_2 = r$ and $h_3 = r\sin\theta$.

3.5 Generalized Orthogonal Curvilinear Coordinate System

From the discussions of the previous sections, it may be seen that a major hindrance in treating the three commonly used orthogonal coordinate systems, namely, Cartesian, cylindrical and spherical coordinate systems, on an equal footing is that the unit vectors are not the best way to visualize these three coordinate systems. In this context, a generalized orthogonal curvilinear coordinate system provides insight for useful linkage between such orthogonal coordinate systems. Generalized orthogonal curvilinear coordinate system emphasizes on the similarities between different orthogonal coordinate systems rather than highlighting their differences. Thus, the definition and utilization of generalized

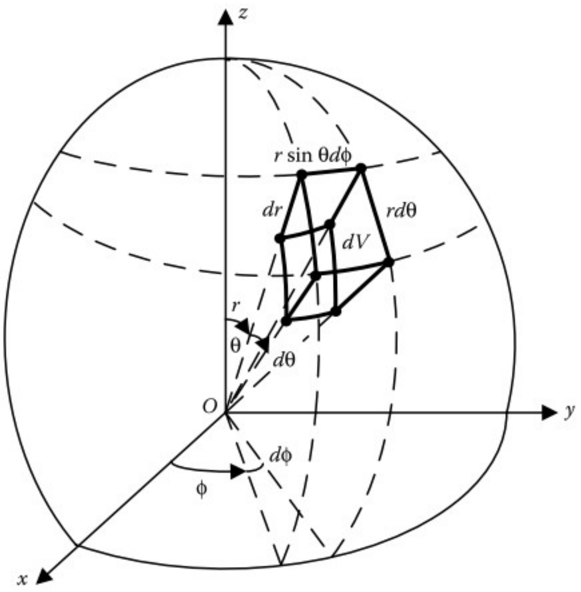

FIGURE 3.17
Differential volume element of a sphere in the spherical coordinate system.

orthogonal curvilinear coordinate system is very important for the proper understanding of the formulation and solution of electric field problems.

Consider that $f(x,y,z) = u$ is a function of three independent space variables x,y,z in the Cartesian coordinate system that specify a surface characterized by the constant parameter u. Setting such function equal to three different constant parameters u_1, u_2 and u_3 defines three different surfaces as follows:

$$f_1(x,y,z) = u_1,\ f_2(x,y,z) = u_2 \text{ and } f_3(x,y,z) = u_3 \tag{3.22}$$

Considering that these three surfaces are orthogonal, they intersect in space only at one point. In other words, any point in space could be uniquely defined by a set of values of the three parameters (u_1,u_2,u_3), which are then called the *orthogonal curvilinear coordinates* of the point being defined. The constant coordinate surfaces for a generalized orthogonal curvilinear coordinate system are shown in Figure 3.18.

As shown in Figure 3.18, the unit vectors $\hat{a}_1$, $\hat{a}_2$ and $\hat{a}_3$ are normal to the surfaces u_1 = constant, u_2 = constant and u_3 = constant, respectively, and point towards the increasing values of the coordinates u_1, u_2 and u_3, respectively. The orthogonality of the generalized curvilinear coordinate system is defined by Equation 3.23

$$\hat{a}_1 \cdot \hat{a}_2 = 0,\ \hat{a}_2 \cdot \hat{a}_3 = 0,\ \hat{a}_3 \cdot \hat{a}_1 = 0 \tag{3.23}$$

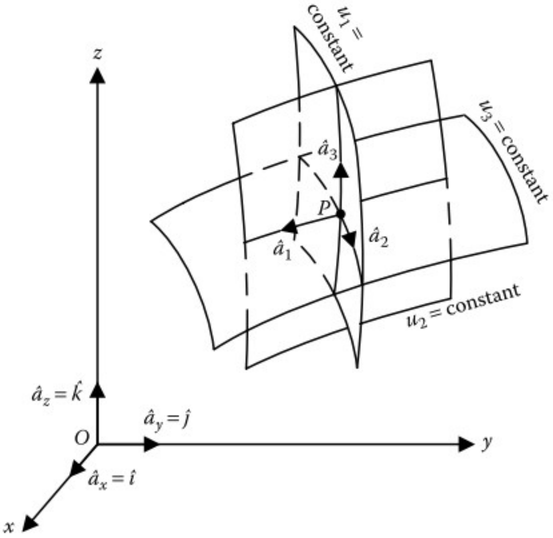

FIGURE 3.18
Constant coordinate surfaces in the generalized orthogonal curvilinear coordinate system.

and the right handedness is defined by Equation 3.24

$$\hat{a}_1 \times \hat{a}_2 = \hat{a}_3,\ \hat{a}_2 \times \hat{a}_3 = \hat{a}_1,\ \hat{a}_3 \times \hat{a}_1 = \hat{a}_2 \tag{3.24}$$

As shown in Figure 3.19, the surfaces $u = u_1$ and $u = u_1 + du_1$ are separated by a differential length element dl_1, which is normal to the surface $u = u_1$, where $dl_1 = h_1(u_1,u_2,u_3)du_1$. The scale factor or the metric coefficient h_1 is a function of the three curvilinear coordinates (u_1,u_2,u_3). The other two metric coefficients, that is, $h_2(u_1,u_2,u_3)$ and $h_3(u_1,u_2,u_3)$, are also similarly defined.

As shown in Figure 3.19, the differential line element in the generalized orthogonal curvilinear coordinate system is given by Equation 3.25

$$d\vec{l} = dl_1\hat{a}_1 + dl_2\hat{a}_2 + dl_3\hat{a}_3 = h_1du_1\hat{a}_1 + h_2du_2\hat{a}_2 + h_3du_3\hat{a}_3 \tag{3.25}$$

As shown in Figure 3.19, the differential area elements in the generalized orthogonal curvilinear coordinate system are given by Equation 3.26

$$\begin{aligned} d\vec{A}_{12} &= (h_1du_1)(h_2du_2)\hat{a}_3 = h_1h_2du_1du_2\hat{a}_3 \\ d\vec{A}_{23} &= (h_2du_2)(h_3du_3)\hat{a}_1 = h_2h_3du_2du_3\hat{a}_1 \\ d\vec{A}_{31} &= (h_3du_3)(h_1du_1)\hat{a}_2 = h_3h_1du_3du_1\hat{a}_2 \end{aligned} \tag{3.26}$$

and the differential volume element in generalized orthogonal curvilinear coordinate system is given by Equation 3.27

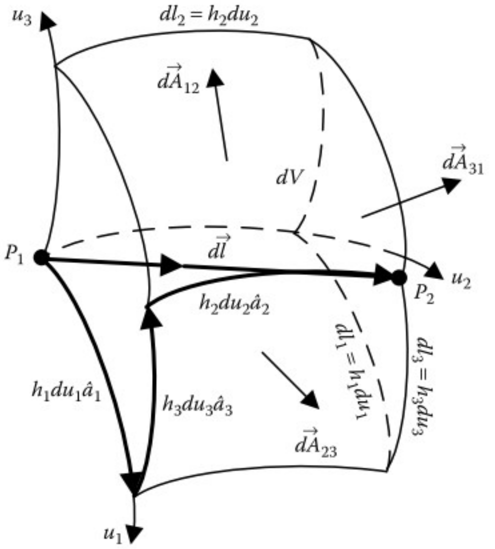

FIGURE 3.19
Differential line, area and volume elements in the generalized orthogonal curvilinear coordinate system.

$$dV = (h_1du_1)(h_2du_2)(h_3du_3) = h_1h_2h_3du_1du_2du_3 \tag{3.27}$$

In the light of the generalized orthogonal curvilinear coordinate system, the three commonly used orthogonal coordinate systems could be summarized as in Table 3.1.

Recall that the metric coefficients were earlier stated to be functions of the coordinates (u_1,u_2,u_3). Table 3.1 clearly shows such dependence of the metric coefficients on the respective coordinates in cylindrical and spherical coordinate systems. Cartesian coordinate system is unique in the sense that its metric coefficients are constant.

TABLE 3.1

Characterization of Orthogonal Coordinate Systems

Orthogonal Coordinate System	Coordinates	Unit Vectors	Metric Coefficients

Gauss's Law and Related Topics

ABSTRACT Gauss's law constitutes one of the fundamental laws of electromagnetism. Gauss's law provides an easy means of finding electric field intensity or electric flux density for symmetrical charge distributions such as a point charge, an infinite line charge, an infinite cylindrical surface charge and so forth. The procedure for applying Gauss's law to calculate the electric field involves the introduction of Gaussian surfaces, which are closed surfaces on which electric field is either constant or zero. In most of the cases, electric field is either normal or tangential to the Gaussian surfaces. There are two different ways of stating Gauss's law, namely, integral form and differential form, which are employed to solve field problems depending on suitability. These two forms of Gauss's law in combination lead to *divergence theorem*. The divergence relationship between electric flux density and volume charge density as obtained from Gauss's law and the gradient relationship between electric field intensity and electric potential could be combined in the form of an elliptic partial differential equation known as Poisson's equation. In charge-free field region, Poisson's equation reduces to Laplace's equation. Both Poisson's and Laplace's equations could be solved for field quantities imposing suitable boundary conditions.

2.1 Introduction

German mathematician and physicist Karl Friedrich Gauss published his famous flux theorem in 1867, which is now well known in physics as Gauss's law. It is one of the basic laws of classical field theory. Gauss's law is a general law that can be applied to any closed surface. With the help of Gauss's law, the amount of enclosed charge could be assessed by mapping the field on a surface outside the charge distribution. By the application of Gauss's law, the electric field in many practical arrangements could be evaluated by forming a symmetric surface, commonly known as *Gaussian surface*, surrounding a charge distribution and then determining the electric flux through that surface.

In electric field theory, distinction is made between free charge and bound charge. Free charge implies a charge that is free to move over distances large as compared to atomic scale lengths. Free charge typically comes from electrons, for example, in the case of metals, or ions, or in the case of aqueous solutions. Bound charge implies charges of equal magnitude but opposite signs that are held close to each other and are free to move only through atomic scale lengths. Bound charges arise in the context of polarizable dielectric materials. Typical example of bound charge is the positive charge of an atomic nucleus and the negative charge of its associated electron cloud. The microscopic charge displacements in dielectric materials are not as dramatic as the rearrangement of charge in a conductor, but their cumulative effects account for the characteristic behaviour of dielectric materials. Typically, the detailed effect of bound charge is represented through electrical permittivity of dielectric materials, which will be discussed in Chapter 5. The Gauss's law, as discussed in this chapter, is in terms of electric flux and the free charge only.

2.2 Useful Definitions and Integrals

2.2.1 Electric Flux through a Surface

Consider that the total electric flux through the surface *S* of an area *A* needs to be evaluated, as shown in Figure 2.1. The first important point to be noted here is that the electric flux density at different locations on *S* may not be the same. Therefore, the total flux through *S* has to be computed by subdividing the entire surface into a large number of smaller surfaces, such that over each small surface area, the electric flux density vector is uniform. As shown in Figure 2.1, for any small surface area *dA*, the area vector $d\vec{A}$ and the electric flux density vector $\vec{D}$ could be along different directions. Then the electric flux through *dA* is given by $\vec{D}\cdot d\vec{A}$

Then the total flux through *S* is given by the summation $\vec{D}_1 \cdot d\vec{A}_1 + \vec{D}_2 \cdot d\vec{A}_2 + \cdots$

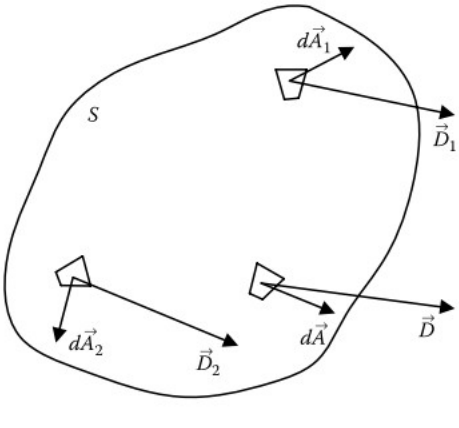

FIGURE 2.1
Evaluation of the total electric flux through a surface.

When the sizes of the individual areas become infinitesimally small, then the total flux through *S* is given by the integral

$$\int_S \vec{D}\cdot d\vec{A} = \iint \vec{D}\cdot d\vec{A} \tag{2.1}$$

2.2.2 Charge within a Closed Volume

Consider that the total charge within the volume *V* enclosed by the surface *S* needs to be evaluated, as shown in Figure 2.2. Here also, it is to be kept in mind that the distributed charge distribution may not be uniform throughout *V*. Then the entire volume needs to be subdivided into a large number of small volumes such that within each small volume, charge density is constant. Then the total charge within *V* is given by the summation $\rho_{v1}dV_1 + \rho_{v2}dV_2 + \rho_{v3}dV_3 + \cdots$

When the sizes of the individual volumes become infinitesimally small, then the total charge within *V* is given by the integral $\int_V \rho_v dV = \iiint \rho_v\, dV$.

2.2.3 Solid Angle

The concept of solid angle is a natural extension of two-dimensional plane angle to three dimensions. The solid angle subtended by an area *A* at the point *O* is measured by the area Ω on the surface of the unit sphere centred at *O*, as shown in Figure 2.3. This is the area that would be cut out on the unit sphere surface by lines drawn from *O* to every point on the periphery of *A*. It is measured in terms of the unit called *steradian*, abbreviated as sr.

Consider an elementary area *dA*, as shown in Figure 2.4. If all the points on the periphery of *dA* are joined to the point *O*, then these lines cut out an area *d*Ω on the surface of the unit sphere. In other words, *dA* subtends a solid angle *d*Ω at *O*. Because the area is infinitesimally small, all points on *dA*

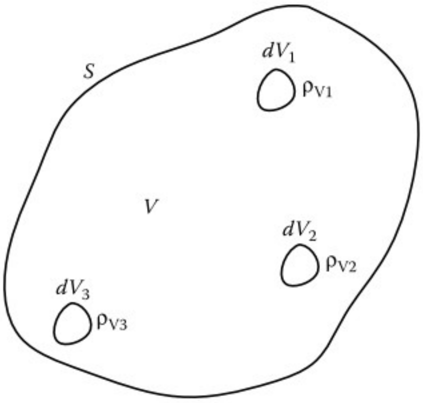

FIGURE 2.2
Evaluation of the total charge within a volume.

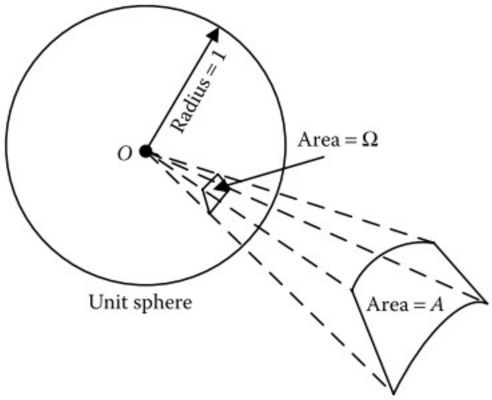

FIGURE 2.3
Solid angle subtended by an area at a point.

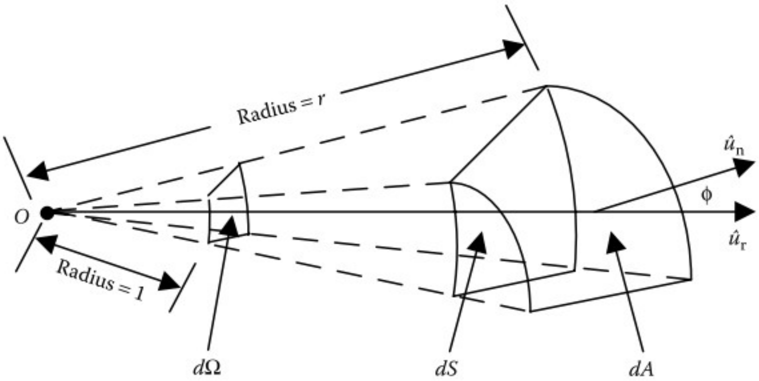

FIGURE 2.4
Evaluation of the solid angle subtended by an elementary area.

could be considered to be equidistant from O. Let the distance of dA from O be r. The unit vector in the direction of the distance vector $\vec{r}$ is $\hat{u}_r$. Because dA is infinitesimally small, it may be taken as flat for practical purposes and hence $\hat{u}_n$ is defined as the unit vector in the direction normal to dA, as shown in Figure 2.4. The angle between $\hat{u}_r$ and $\hat{u}_n$ is ϕ. Then the projection of dA on the sphere of radius r will be $dS = dA\cos\phi$.

The areas dS and $d\Omega$ have the same general shape and are related to the respective radii of the spheres having the following proportionality:

$$\frac{d\Omega}{dS} = \frac{1^2}{r^2}, \text{ or, } d\Omega = \frac{dA\cos\phi}{r^2} = \frac{\hat{u}_r \cdot d\vec{A}}{r^2} \tag{2.2}$$

When an area completely encloses O, then Ω due to that area on the unit sphere will be 4π. Hence, the solid angle subtended at a point by an area that completely encloses the point is 4π sr, which happens to be maximum possible value of the solid angle.

2.3 Integral Form of Gauss's Law

Gauss's law states that the net electric flux through any closed surface enclosing a homogeneous volume of material is equal to the net electric charge enclosed by that closed surface. In other words, the surface integral of electric flux density vector over a closed surface is equal to the volume integral of charge densities within the volume enclosed by that surface.

In integral form,

$$\int_A \vec{D} \cdot d\vec{A} = \int_V \rho_v dV \tag{2.3}$$

Gauss's law is valid for any discrete set of point charges. Nevertheless, this law is also valid when an electric field is produced by charged objects with continuously distributed charges, because any continuously distributed charge may be viewed as a combination of discrete point charges.

Figure 2.5 shows a certain volume V of homogeneous material enclosed by a surface A. This volume is continuously charged by distributed charges. Consider these distributed charges to be represented by N number of discrete point charges, as shown in Figure 2.5.

Take a point charge q_1 located within V. Then consider an elementary area dA on A, as shown in Figure 2.5. The distance of dA from q_1 is, say, r.

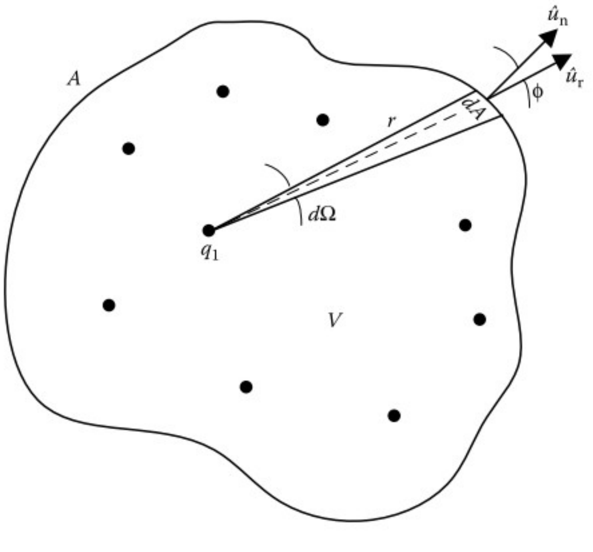

FIGURE 2.5
Pertaining to the integral form of Gauss's law.

Then at a distance r from q_1,

$$\vec{E}_1 = \frac{q_1}{4\pi\varepsilon_0 r^2}\hat{u}_\text{r} \text{ and } \vec{D}_1 = \frac{q_1}{4\pi r^2}\hat{u}_\text{r} \tag{2.4}$$

Then, the total flux through A due to q_1 could be obtained as follows:

$$\int_A \vec{D}_1 \cdot d\vec{A} = \int_A \frac{q_1}{4\pi}\frac{\hat{u}_\text{r} \cdot d\vec{A}}{r^2} = \frac{q_1}{4\pi}\int_A d\Omega, \text{ as } \frac{\hat{u}_\text{r} \cdot d\vec{A}}{r^2} = d\Omega \tag{2.5}$$

Because A completely encloses q_1, the solid angle subtended by A at the location of q_1 is 4π. Thus,

$$\int_A \vec{D}_1 \cdot d\vec{A} = \frac{q_1}{4\pi} \times 4\pi = q_1 \tag{2.6}$$

Considering, N number of point charges within V, total electric flux density at the location of dA, as shown in Figure 2.5, will be as follows:

$$\vec{D} = \vec{D}_1 + \vec{D}_2 + \vec{D}_3 + \cdots + \vec{D}_N \tag{2.7}$$

Therefore, the total flux through A will be as follows:

$$\begin{aligned} \int_A \vec{D} \cdot d\vec{A} &= \int_A \left(\vec{D}_1 + \vec{D}_2 + \vec{D}_3 + \cdots + \vec{D}_N\right) \cdot d\vec{A} \\ &= \int_A \vec{D}_1 \cdot d\vec{A} + \int_A \vec{D}_2 \cdot d\vec{A} + \int_A \vec{D}_3 \cdot d\vec{A} + \cdots + \int_A \vec{D}_N \cdot d\vec{A} \\ &= q_1 + q_2 + q_3 + \cdots + q_N \end{aligned} \tag{2.8}$$

The right-hand side (RHS) of Equation 2.8 is equal to the total electric charge enclosed within V. Considering continuously distributed charge within V,

The total charge within is

$$V = \int_V \rho_\text{v}\, dV$$

where:

ρ_v is the volume charge density within V

Hence, Equation 2.8 can be rewritten as

$$\int_A \vec{D} \cdot d\vec{A} = \int_V \rho_\text{v} dV$$

From a physical viewpoint, the above expression indicates that the sum of all sources (positive electric charges) and all sinks (negative electric charges) within a volume gives the net flux through the surface enclosing the same volume.

Gauss's law in integral form is only useful for exact solutions when the electric field has symmetry, for example, spherical, cylindrical or planar symmetry. The symmetry of the electric field follows from the symmetry of the charge distribution that is given. Therefore, the electric field of a symmetrically charged sphere will also have the spherical symmetry.

2.3.1 Gaussian Surface

A closed surface in a three-dimensional space through which the flux of a vector field is calculated is known as *Gaussian surface*. It is an arbitrary closed surface over which surface integral is performed to evaluate the total amount of enclosed source quantity, for example, electric charge. A Gaussian surface could also be used for calculating the electric field due to a given charge distribution.

Gaussian surfaces are normally carefully chosen in order to exploit symmetries to simplify the evaluation of the surface integral. If the symmetry is such that a surface can be found on which the electric field is constant, then the evaluation of electric flux can be done by multiplying the value of the field with the area of the Gaussian surface.

Two commonly used Gaussian surfaces are as follows:

1. The spherical Gaussian surface, which is chosen to be concentric with the charge distribution. It can be used to determine the electric field or electric flux due to a point charge or a spherical shell of uniform charge density or any other charge distribution with spherical symmetry, as shown in Figure 2.6.
2. The cylindrical Gaussian surface, which is chosen to be co-axial with the charge distribution. It can be used to determine the electric

field or electric flux due to an infinitely long line of uniform charge density or an infinitely long cylinder of uniform charge density, as shown in Figure 2.7.

2.4 Differential Form of Gauss's Law

If the electric field is known everywhere, then with the help of integral form of Gauss's law, the charge in any given field region can be deduced by integrating the electric field. However, in most of the practical cases, the electric field needs to be computed when the electric charge distribution is known. This is much more difficult because even if the total flux through a given surface is known, the information about the electric field may be unknown, as electric flux could go in and out of the surface in complex patterns. In this context, the differential form of Gauss's law becomes useful.

Consider that Gauss's law is to be applied for the infinitesimal parallelepiped, as shown in Figure 2.8. The volume of the infinitesimal parallelepiped is

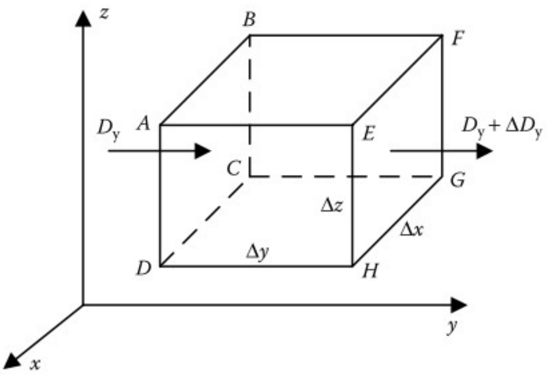

FIGURE 2.8
Application of Gauss's law to a differential volume.

$\Delta V = \Delta x \Delta y \Delta z$. Let the component of electric flux density going normally into the surface ABCD be D_y and that coming out of the surface EFGH be $D_y + \Delta D_y$. Surfaces ABCD and EFGH are lying along the x–z plane. Then the net electric flux coming out in the y-direction, which is normal, to x–z plane is given by

$$(D_y + \Delta D_y)\Delta x \Delta z - D_y \Delta x \Delta z = \Delta D_y \Delta x \Delta z = \frac{\Delta D_y}{\Delta y}\Delta x \Delta y \Delta z \approx \frac{\partial D_y}{\partial y}\Delta V \qquad (2.9)$$

Similarly, the net electric fluxes coming out in x- and z-directions are given by $(\partial D_x/\partial x)\Delta V$ and $(\partial D_z/\partial z)\Delta V$, respectively. Hence, net electric flux coming of the volume ΔV

$$= \frac{\partial D_x}{\partial x}\Delta V + \frac{\partial D_y}{\partial y}\Delta V + \frac{\partial D_z}{\partial z}\Delta V = \left(\frac{\partial D_x}{\partial x} + \frac{\partial D_y}{\partial y} + \frac{\partial D_z}{\partial z}\right)\Delta V$$

Let ρ_v be the volume charge density of the small volume ΔV. Then according to Gauss's law, the above expression for the net flux coming out of ΔV is equal to the total charge within the volume, that is, $\rho_v \Delta V$. Therefore,

$$\begin{aligned} &\left(\frac{\partial D_x}{\partial x} + \frac{\partial D_y}{\partial y} + \frac{\partial D_z}{\partial z}\right)\Delta V = \rho_v \Delta V \\ &\text{or, } \frac{\partial D_x}{\partial x} + \frac{\partial D_y}{\partial y} + \frac{\partial D_z}{\partial z} = \rho_v \end{aligned} \qquad (2.10)$$

Equation 2.10 is known as the differential form of Gauss's law. It can be expanded as follows:

$$\left(\frac{\partial}{\partial x}\hat{i}+\frac{\partial}{\partial y}\hat{j}+\frac{\partial}{\partial z}\hat{k}\right)\left(D_x\hat{i}+D_y\hat{j}+D_z\hat{k}\right)=\rho_v,\ \text{or},\ \vec{\nabla}\cdot\vec{D}=\rho_v \tag{2.11}$$

In Section 1.7.4, it has been mentioned that when the $\vec{\nabla}$ operator acts on a scalar quantity, it is denoted as gradient. As depicted in Equation 2.11, when the $\vec{\nabla}$ operator acts on a vector quantity with a dot product, then it is denoted as divergence.

The physical meaning of divergence of a vector field can be explained from the left-hand side (LHS) of Equation 2.10. From the above discussion, it may be seen that the LHS of Equation 2.10 is the net flux coming out per unit volume at a given location. Consequently, the divergence of a vector field at any location is the net flux of that vector field coming out per unit volume at that given location. If the divergence of a vector field is positive at any location, then the flux coming out of unit volume is higher than the flux going into the unit volume at that location. On the other hand, if the divergence of a vector field is negative, then the flux going into the unit volume is higher than the flux coming out of the unit volume.

2.5 Divergence Theorem

Integral form of Gauss's law is, $\int_A \vec{D}\cdot d\vec{A}=\int_V \rho_v dV$ and differential form of Gauss's law is, $\vec{\nabla}\cdot\vec{D}=\rho_v$.

By substituting ρ_v on the RHS of the integral form by the LHS of the differential form, the above two equations could be combined as follows:

$$\int_A \vec{D}\cdot d\vec{A}=\int_V (\vec{\nabla}\cdot\vec{D})dV \tag{2.12}$$

where:

The volume V is enclosed by the surface A

Equation 2.12 shows that the divergence theorem could be used to convert a volume integral over V to a surface integral over A enclosing V.

2.6 Poisson's and Laplace's Equations

A useful approach to the calculation of electric potentials is to relate electric potential to electric charge density, which causes electric potential. Because electric potential is a scalar quantity, this approach has advantages over

3

Orthogonal Coordinate Systems

ABSTRACT The purpose of this chapter is to present coordinate systems in such a way that it improves the ability of readers to use them to describe the electric field in a better way. The goal is to put forward the coordinate system as a useful language for describing, visualizing and understanding the concepts that are central to electric field analysis. Many mathematical operators related to electric field analysis have simple forms in Cartesian coordinates and are easy to remember and evaluate. In fact, all the problems could be solved using the Cartesian coordinate system. However, the resulting expressions might be unnecessarily complex. While dealing with problems that have high degree of symmetry, it is helpful to use a coordinate system that exploits the symmetry. As a result, it is useful to have a general method for expressing mathematical operators in non-Cartesian forms. Orthogonal curvilinear coordinate system is a useful approach by which the matching of the symmetry of a given physical configuration could be done and simplified mathematical models could be built to clarify the field concepts clearly.

3.1 Basic Concepts

The concept that unifies the different coordinate systems is surfaces of constant coordinates. It means that an equation of the form (coordinate = value) defines a surface. In order to specify a point uniquely in a three-dimensional space, three different types of surfaces are needed. The values associated with the three constant coordinate surfaces that intersect at a specific point are the three coordinates, which uniquely define that point.

Consider that three surfaces are defined by three functions f_1, f_2 and f_3, respectively, in a three-dimensional space. The coordinate, that is, the value, that describes a surface could be defined by the equation $f_i = u_i$. Here, u is introduced to represent a generalized coordinate. In the stated equation, u_i refers to one of the coordinates in a particular system. Thus, the three values (u_1,u_2,u_3) define a point, where the three surfaces defined by Equation 3.1 intersect. These three values (u_1,u_2,u_3) are then called the *coordinates* of that particular point.

$$f_1 = u_1,\ f_2 = u_2 \text{ and } f_3 = u_3 \tag{3.1}$$

The three functions, however, could not be chosen arbitrarily. The three functions are to be chosen in such a way that for any choice of the three coordinates (u_1,u_2,u_3), the three surfaces generated by Equation 3.1 will intersect only at one point. It will ensure that a given set of three coordinate values (u_1,u_2,u_3) always specifies only one point in space. Moreover, the constant coordinate surfaces are always perpendicular to each other, that is, orthogonal, at the point where they intersect. The intersection of any two constant coordinate surfaces defines a coordinate curve.

3.1.1 Unit Vector

An important concept associated with coordinate system is unit vector. It will be easy to understand the concept if it is explained with the help of a specific example involving the Cartesian coordinate system, as shown in Figure 3.1. Each value of z, for example, z_1, z_2 or z_3, defines a plane normal to the z-axis. The unit vector $\hat{k}$ is defined in such a way that it is normal to all such z = constant planes and points in the direction of the planes with increasing values of z, as shown in Figure 3.1. The magnitude of the vector $\hat{k}$ is taken as unity. The other two unit vectors in the Cartesian coordinate system could be visualized in the same manner.

In a generalized manner, the properties of the unit vector associated with a constant coordinate surface defined by the function f_i are as follows: (1) it is perpendicular to the surface $f_i = u_i$ at any point (u_1,u_2,u_3); (2) it points in the direction of the surfaces with increasing value of u_i and (3) it is one unit in magnitude. Orthogonality of the constant coordinate surfaces, as discussed earlier, demands that the dot product of any two different unit vectors will always be zero. Conversely, the dot product of two same unit vectors, for example, $\hat{k}\cdot\hat{k}$, will always be 1.

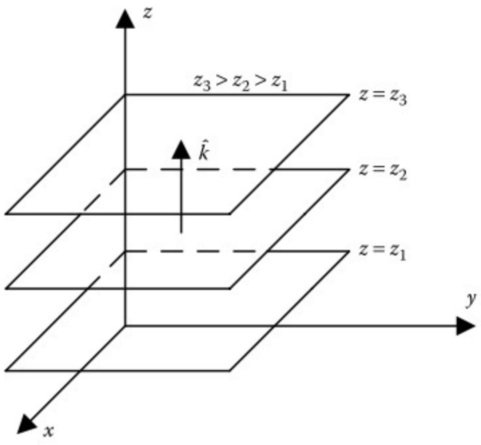

FIGURE 3.1
The unit vector $\hat{k}$.

3.1.2 Right-Handed Convention

Because three constant coordinate surfaces are involved in determining the coordinates of any point, the question that arises is in which order the three coordinates are to be mentioned while specifying a point. In this context, the choice of the first coordinate (u_1) or surface (f_1) is arbitrary. Once f_1 is chosen, then the order in which the other two constant coordinate surfaces f_2 and f_3 is to be taken is determined by the right-handed system as governed by the definition of vector cross product. In other words, the cross product of the first and second unit vectors must be equal to the third unit vector.

This right-handed property of the coordinate system is an arbitrary convention. But once that choice is made for one coordinate system, it has to be followed for all other coordinate systems to ensure that the expressions for the laws of electric field have the same form in all the coordinate systems.

3.1.3 Differential Distance and Metric Coefficient

The constant coordinate surfaces could be of many different types. The simplest of them is constant distance surfaces for which the differential change du_i in the coordinate u_i is the same as the differential distance dl_i between the surfaces $f_i = u_i$ and $f_i = u_i + du_i$. However, there are other types of surfaces such as constant angle surfaces, in which case the differential distance is related to differential coordinate (angle) change as

$$dl_i = h_i du_i = h_i d\theta_i \tag{3.2}$$

where:

The scale factor h_i is the corresponding radius

The scale factors for each of the coordinate system are called the *metric coefficients* of the respective coordinate system. The three metric functions of any coordinate system (h_1,h_2,h_3) constitute a unique set and hence are often known as the *signature of a coordinate system*. Metric coefficients are also very important in writing the vector operators in the general orthogonal curvilinear coordinate system, as will be explained in Section 3.5.

3.1.4 Choice of Origin

A basic element of any coordinate system is the choice of origin. If any object or any arrangement is given, then any point within the object or within the whole arrangement could be chosen as origin.

From the earlier discussions, it is clear that the same point will have very different coordinates when defined in different coordinate systems. Therefore, the question that needs to be answered is that whether there is any property of the position of the point that remains the same in different coordinate systems. The answer to this question is that the distance of the point from the origin remains the same in all the coordinate systems if the origin is kept the same in all the cases. As a logical extension, it may be stated that the distance between any two points remains the same no matter how their coordinates are defined in any coordinate system.

3.2 Cartesian Coordinate System

The invention of Cartesian coordinates in the seventeenth century by the French mathematician René Descartes revolutionized mathematics by providing the first systematic link between Euclidean geometry and algebra. In this coordinate system, the three constant coordinate surfaces are defined by Equation 3.3

$$f_1 = x\,,\, f_2 = y\,,\, f_3 = z \tag{3.3}$$

Figure 3.2 shows such constant coordinate surfaces, which are three planes. Cartesian coordinate system has the unique feature that all the three constant coordinate surfaces are constant distance surfaces.

Each point P in space is then assigned a triplet of values (x,y,z), the so-called Cartesian coordinates of that point. The ranges of the values of three coordinates are $-\infty < x < \infty$, $-\infty < y < \infty$ and $-\infty < z < \infty$. Coordinates can be

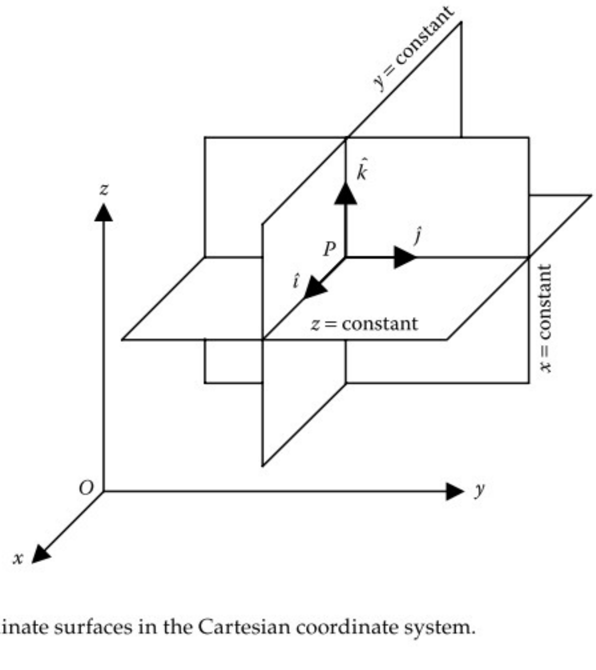

FIGURE 3.2
Constant coordinate surfaces in the Cartesian coordinate system.

defined as the positions of the normal projections of the point onto three mutually perpendicular constant coordinate surfaces passing through the origin, expressed as signed distances from the origin.

In the Cartesian coordinate system, three mutually perpendicular axes are commonly defined as follows. The intersection of two mutually perpendicular planes y = constant and z = constant passing through the origin gives a coordinate curve, which is a straight line. This line is then defined as the x-axis. Similarly, the intersections of other two pairs of mutually perpendicular constant coordinate planes passing through origin define the y- and z-axes.

The unit vector $\hat{i}$ is perpendicular to all the surfaces described by x = constant and points in the direction of increasing value of x-coordinate. In the same manner, unit vectors $\hat{j}$ and $\hat{k}$ are defined in y- and z-directions, respectively. Another unique feature of the Cartesian coordinate system is that the directions of the three unit vectors remain the same irrespective of the location of the point in space. The orthogonality of the Cartesian coordinate system is defined by Equation 3.4

$$\hat{i}\cdot\hat{j} = 0,\ \hat{j}\cdot\hat{k} = 0,\ \hat{k}\cdot\hat{i} = 0 \tag{3.4}$$

and the right handedness is defined by Equation 3.5

$$\hat{i}\times\hat{j} = \hat{k},\ \hat{j}\times\hat{k} = \hat{i},\ \hat{k}\times\hat{i} = \hat{j} \tag{3.5}$$

As shown in Figure 3.3, the differential line element in the Cartesian coordinate system is given by Equation 3.6

$$d\vec{l} = dl_1\hat{i} + dl_2\hat{j} + dl_3\hat{k} = dx\hat{i} + dy\hat{j} + dz\overleftarrow{k} \tag{3.6}$$

As shown in Figure 3.4, the differential area element corresponding to the surface of a differential cubical volume is given by Equation 3.7

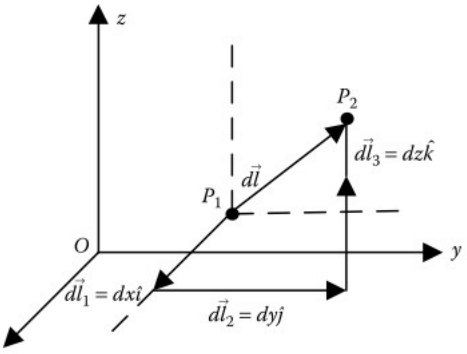

FIGURE 3.3
Differential line element in the Cartesian coordinate system.

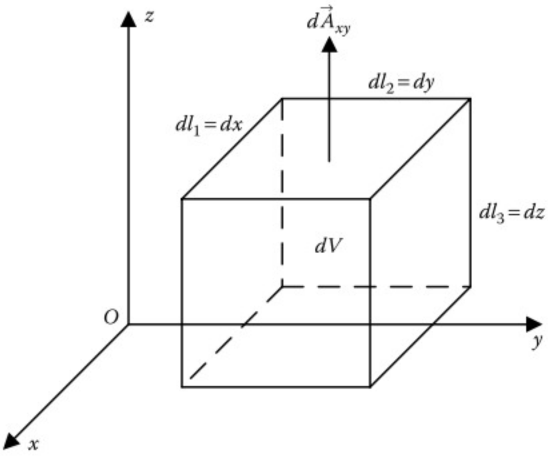

FIGURE 3.4
Differential area and volume elements in the Cartesian coordinate system.

$$d\vec{A}_{xy} = dl_1 dl_2 \hat{k} = dxdy\hat{k} \tag{3.7}$$

As shown in Figure 3.4, the differential volume element is given by Equation 3.8

$$dV = dl_1 dl_2 dl_3 = dxdydz \tag{3.8}$$

As depicted in Equation 3.6 the differential distance in x-direction is $dl_1 = dx = h_1 dx$, that is, $h_1 = 1$. Similarly, in y- and z-directions, $h_2 = h_3 = 1$. The metric coefficients of the Cartesian coordinate system are, therefore, $h_1 = 1$, $h_2 = 1$ and $h_3 = 1$.

3.3 Cylindrical Coordinate System

Cylindrical coordinates are an alternate way of describing points in a three-dimensional space. In this coordinate system, one of the rectangular coordinate planes, namely, the x–y plane, as described by the Cartesian coordinate system, is replaced by a polar plane. In the cylindrical coordinate system, everything is measured with respect to a fixed point called the *pole* and an axis called the *polar axis*. The pole is the equivalent to the origin in the Cartesian coordinate system and the polar axis corresponds to the positive direction of the x-axis. The cylindrical coordinates of a point are then the ordered triplet (r,θ,z), as defined in Figure 3.5.

As shown in Figure 3.5, r is the distance from the pole to the projection of the point P on the polar plane, that is, the x–y plane passing through the pole, θ is the azimuthal angle, that is, the angle from the polar axis spinning around the z-axis in counter-clockwise direction, and z is the vertical height from the polar plane. The ranges of the values of the three coordinates are $0 \le r < \infty$, $0 \le \theta \le 2\pi$ and $-\infty < z < \infty$.

10

Sphere or Cylinder in Uniform External Field

ABSTRACT If a conducting or dielectric object is present within the electric field caused by external sources, then the induced charges on such an object adds to the existing external field. If the size of the conducting or dielectric object is small compared to the external field region, then the electric field is modified only in the vicinity of such an object. In order to get the complete solution of the electric field in such configuration, the boundary conditions imposed by the conducting or dielectric object must also be satisfied. If the object is of well-defined geometric shape such as cylinder or sphere, and if the external field is considered to be uniform in space, then the complete solution for the electric field could be obtained analytically with the help of method of separation of variables. These analytical solutions are often used to validate numerical methodology and could also be used to estimate field modification due to small conducting or dielectric pieces present in large high-voltage insulation arrangement.

10.1 Introduction

Conducting and dielectric components are integral parts of any electrical equipment. If the size of the conducting or dielectric object is very small compared to dimensions of the field region where the object is located, then the object contributes to the field only in the domain near the object. In many cases, such objects are present as stray bodies in high-voltage insulation arrangement. As practical examples, one may cite a small piece of conductor or dielectric floating in liquid insulation of large volume in transformers, metallic dust particles floating in gaseous insulation within gas-insulated system (GIS) and so on. It is important to understand how the presence of a conducting or dielectric object modifies the external field in the vicinity of the object, because any enhancement of the electric field intensity due to the conducting or dielectric object may lead to unwanted discharge or in the worst case failure of the insulation system.

If it is assumed that the source charges (in practical arrangement, the electrodes or conductors with specific potentials) that produce the external field is located far away from the object under consideration, then they are unaffected by the presence of the object. Consequently, the field due to the source charges may be considered to be uniform at the location of the object. If the object is such that its shape is defined by well-known mathematical functions, for example, cylinders or spheres, then the complete solution for the electric field due to the source charges located at far away positions and the induced charges on the surface of the object could be obtained by solving Laplace's equation considering the field region to be free from any volume charge. However, in order to get the complete solution appropriate boundary conditions on the surface of the object, whether it is conducting or dielectric, need to be satisfied. One of the common methods of getting the analytical solution for a cylinder or sphere in a uniform external field is the method of separation of variables as described in this chapter.

10.2 Sphere in Uniform External Field

Consider a spherical object of radius a within uniform external field, as shown in Figure 10.1. Because the boundary is a sphere of r = constant, hence the system is best described in spherical coordinates, as shown in Figure 10.1. The uniform external field is given by $\vec{E}_0 = -E_0\hat{u}_z$ and the potential at any point due to the external field is given by $E_0 r\cos\theta = E_0 z$ with respect to the centre of the sphere. In order to get the complete solution for the electric field in this system, Laplace's equation in spherical coordinates, as given in Equation 10.1, needs to be solved.

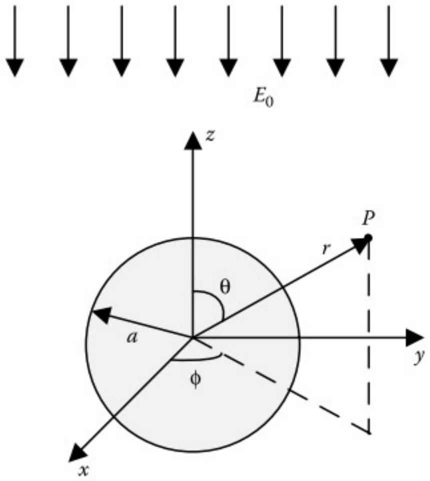

FIGURE 10.1
Sphere in uniform external field.

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial V}{\partial r}\right)+\frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right)+\frac{1}{r^2\sin^2\theta}\frac{\partial^2 V}{\partial\phi^2}=0 \tag{10.1}$$

The field system has azimuthal symmetry with respect to the z-axis, that is, the field system does not change with the rotation around the z-axis. Therefore, z-axis is made the polar axis in the spherical coordinate system. Then the field is independent of coordinate φ and Laplace's equation reduces to

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial V}{\partial r}\right)+\frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right)=0 \tag{10.2}$$

In order to separate the terms of the left-hand side (LHS) of Equation 10.2 into functions of only one variable, Equation 10.2 may be rewritten by multiplying r^2 as

$$\frac{\partial}{\partial r}\left(r^2\frac{\partial V}{\partial r}\right)+\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right)=0 \tag{10.3}$$

Then LHS of Equation 10.3 is the sum of two terms, which are functions of only one variable each, that is, the first term is function of r only, whereas the second term is function of θ only. The solution to Equation 10.3 can be obtained as the product of two functions of which one is dependent only on r and the other is dependent only on θ.

Let the assumed solution be

$$V(r,\theta)=M(r)N(\theta) \tag{10.4}$$

The assumed solution is convenient as the boundary lies at r = constant.

Combining Equations 10.3 and 10.4

$$\frac{\partial}{\partial r}\left[r^2\frac{\partial M(r)N(\theta)}{\partial r}\right]+\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left[\sin\theta\frac{\partial M(r)N(\theta)}{\partial\theta}\right]=0$$

$$\text{or, } N(\theta)\frac{\partial}{\partial r}\left[r^2\frac{\partial M(r)}{\partial r}\right]+M(r)\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left[\sin\theta\frac{\partial N(\theta)}{\partial\theta}\right]=0$$

Dividing by $M(r)N(\theta)$,

$$\frac{1}{M(r)}\frac{d}{dr}\left[r^2\frac{dM(r)}{dr}\right]+\frac{1}{N(\theta)}\frac{1}{\sin\theta}\frac{d}{d\theta}\left[\sin\theta\frac{dN(\theta)}{d\theta}\right]=0 \tag{10.5}$$

The partial derivatives become total derivatives in Equation 10.5, as each term is dependent on only one coordinate.

The sum of two terms of the LHS of Equation 10.5 could be zero only when the two terms are separately equal to opposite and equal constant terms as given in Equation 10.6.

Equal and opposite separation constant solution:

$$\frac{1}{M(r)}\frac{d}{dr}\left[r^2\frac{dM(r)}{dr}\right]=+p \text{ and } \frac{1}{N(\theta)}\frac{1}{\sin\theta}\frac{d}{d\theta}\left[\sin\theta\frac{dN(\theta)}{d\theta}\right]=-p \qquad (10.6)$$

where:
p is a positive constant

Another solution is obtained when the separation constant is zero.
Hence, the zero separation constant solution

$$\frac{1}{M(r)}\frac{d}{dr}\left[r^2\frac{dM(r)}{dr}\right]=0 \text{ and } \frac{1}{N(\theta)}\frac{1}{\sin\theta}\frac{d}{d\theta}\left[\sin\theta\frac{dN(\theta)}{d\theta}\right]=0 \qquad (10.7)$$

Each of the above-mentioned two solutions is to be obtained separately.

Determination of the zero separation constant solution:
The first term of Equation 10.7 is

$$\frac{1}{M(r)}\frac{d}{dr}\left[r^2\frac{dM(r)}{dr}\right]=0$$

where:
$M(r)$ is non-zero

Therefore,

$$\frac{d}{dr}\left[r^2\frac{dM(r)}{dr}\right]=0,\text{ or, } r^2\frac{dM(r)}{dr}=C_0,\text{ or, }\frac{dM(r)}{dr}=\frac{C_0}{r^2}$$

Integrating and incorporating constants of integration

$$M(r)=\frac{C_{10}}{r}+C_{20} \qquad (10.8)$$

Next the second term of Equation 10.7 is

$$\frac{1}{N(\theta)}\frac{1}{\sin\theta}\frac{d}{d\theta}\left[\sin\theta\frac{dN(\theta)}{d\theta}\right]=0$$

where:
$N(\theta)$ is non-zero

Therefore,

$$\frac{1}{\sin\theta}\frac{d}{d\theta}\left[\sin\theta\frac{dN(\theta)}{d\theta}\right]=0,\text{ or, }\frac{d}{d\theta}\left[\sin\theta\frac{dN(\theta)}{d\theta}\right]=0$$

$$\text{or, }\sin\theta\frac{dN(\theta)}{d\theta}=A_0$$

Integrating and incorporating constant of integration

$$N(\theta) = A_{10}\ln\left(\tan\frac{\theta}{2}\right) + A_{20} \tag{10.9}$$

Equation 10.9 becomes undefined for $\theta = \pi$. But this is not feasible in the given system as potential must be a continuous function. Therefore, A_{10} should be zero in Equation 10.9. Therefore,

$$N(\theta) = A_{20} \tag{10.10}$$

Then from Equations 10.4, 10.8 and 10.10, the zero separation constant solution can be obtained as

$$V(r,\theta) = \frac{C_1}{r} + C_2 \tag{10.11}$$

where:
$C_1 = A_{20}C_{10}$ and $C_2 = A_{20}C_{20}$

Determination of the equal and opposite separation constant solution:
The first term of Equation 10.6 is

$$\frac{1}{M(r)}\frac{d}{dr}\left[r^2\frac{dM(r)}{dr}\right] = +p$$

$$\text{or, } \frac{d}{dr}\left[r^2\frac{dM(r)}{dr}\right] = +pM(r) \tag{10.12}$$

Putting $M(r) = Cr^n$ in Equation 10.12, we get

$$\frac{d}{dr}\left(r^2Cnr^{n-1}\right) = +pCr^n, \text{ or, } Cn(n+1)r^n = pCr^n, \text{ or, } n^2 + n - p = 0$$

Hence,

$$n = \frac{1}{2}\left(-1 \pm \sqrt{1+4p}\right) \tag{10.13}$$

The second term of Equation 10.6 is

$$\frac{1}{N(\theta)}\frac{1}{\sin\theta}\frac{d}{d\theta}\left[\sin\theta\frac{dN(\theta)}{d\theta}\right] = -p$$

$$\text{or, } \frac{1}{\sin\theta}\frac{d}{d\theta}\left[\sin\theta\frac{dN(\theta)}{d\theta}\right] = -pN(\theta) \tag{10.14}$$

Putting $N(\theta) = B\cos\theta$ in Equation 10.14,

$$\frac{d}{d\theta}\left(-B\sin^2\theta\right) = -pB\cos\theta\sin\theta, \text{ or, } p = 2.$$

Hence, from Equation 10.13 $n = +1, -2$.

$$\text{Therefore, } M(r) = C'r + \frac{C''}{r^{-2}} \text{ and } N(\theta) = B\cos\theta \tag{10.15}$$

From Equations 10.4 and 10.15,

$$V(r,\theta) = \left(C_3 r + \frac{C_4}{r^2}\right)\cos\theta \tag{10.16}$$

where:

$C_3 = C'B$ and $C_4 = C''B$

The complete solution for potential function is uniquely given as a linear combination of the two solutions given by Equations 10.11 and 10.16.

$$V(r,\theta) = \frac{C_1}{r} + C_2 + \left(C_3 r + \frac{C_4}{r^2}\right)\cos\theta \tag{10.17}$$

where:

The constants are determined by satisfying the boundary conditions

It is evident from Equation 10.17 that the first term corresponds to a net charge on the sphere and the second term to a finite potential.

10.2.1 Conducting Sphere in Uniform Field

Consider that the sphere is a conducting one and is isolated and uncharged. Further, consider that the potential at the location of the centre of the sphere due to the external field is V_0.

Because the perturbing action of the sphere is negligible at a large distance from the sphere, the potential at a large distance from the sphere ($r >> a$) is given by

$$V(r,\theta) = V_0 + E_0 r\cos\theta \tag{10.18}$$

If the sphere is charged with a finite amount of charge Q, then

$$V(r,\theta) = \frac{Q}{4\pi\varepsilon_0 r} + V_0 + E_0 r\cos\theta \tag{10.19}$$

In practical systems, floating metallic particles are usually not charged and hence Equation 10.18 is taken here for further discussion.

Comparing Equations 10.17 and 10.18 for $r \to \infty$, $C_2 = V_0$ and $C_3 = E_0$. C_1 will be zero for uncharged sphere.

Therefore, Equation 10.17 can be rewritten as

$$V(r,\theta) = V_0 + \left(E_0 r + \frac{C_4}{r^2} \right) \cos\theta \tag{10.20}$$

On the conductor surface, that is, for $r = a$,

$$V(a,\theta) = V_0 + \left(E_0 a + \frac{C_4}{a^2} \right) \cos\theta \tag{10.21}$$

But the conducting sphere surface is an equipotential and hence electric potential is independent of θ on the conductor surface.

Therefore, from Equation 10.21,

$$C_4 = -E_0 a^3$$

Hence, the complete solution for an electric potential in the domain $r > a$ is given by

$$V(r,\theta) = V_0 + E_0 \left(r - \frac{a^3}{r^2} \right) \cos\theta \tag{10.22}$$

The r and θ components of the electric field intensity could be obtained as follows:

$$E_{\mathrm{r}} = -\frac{\partial V}{\partial r} = -E_0 \left(1 + \frac{2a^3}{r^3} \right) \cos\theta \tag{10.23}$$

$$E_\theta = -\frac{1}{r}\frac{\partial V}{\partial \theta} = E_0 \left(1 - \frac{a^3}{r^3} \right) \sin\theta \tag{10.24}$$

On the conducting sphere surface, tangential component of the electric field intensity must be zero as it is an equipotential surface. Equation 10.24 shows that for $r = a$, E_θ is zero, which in turn validates the solution obtained.

Again, on the conducting sphere surface, E_{r} is the normal component of the electric field intensity, which is given by $E_{\mathrm{r}}\big|_{r=a} = -3E_0 \cos\theta$. Thus, the maximum value of the electric field intensity on the surface of the conducting sphere is $3E_0$, that is, three times the strength of the uniform external field.

This is the reason why metallic dust particles should be avoided at all costs for GISs. Because the presence of metallic dust particles will increase the local electric field intensity three times, which will result into partial discharge within the GIS, that is very detrimental for the GIS operation.

Induced surface charge density on the surface of the conducting sphere may be obtained as follows:

$$\frac{\sigma_s}{\varepsilon_0} = E_r\bigg|_{r=a} = -3E_0\cos\theta, \text{ or, } \sigma_s = -3\varepsilon_0 E_0\cos\theta \tag{10.25}$$

As stated earlier, the sphere may be charged with an additional charge Q, which is distributed uniformly on the sphere surface and its effect on the field could be found by superposition.

10.2.2 Dielectric Sphere in Uniform Field

In the case of dielectric sphere present in uniform external field, there will be two solutions to potential function, V_i valid for the region within the sphere having dielectric of permittivity ε_i and V_e valid for the region outside the sphere having dielectric of permittivity ε_e. Therefore, from Equation 10.17

$$V_i(r,\theta) = \frac{C_{1i}}{r} + C_{2i} + \left(C_{3i}r + \frac{C_{4i}}{r^2}\right)\cos\theta \tag{10.26}$$

and

$$V_e(r,\theta) = \frac{C_{1e}}{r} + C_{2e} + \left(C_{3e}r + \frac{C_{4e}}{r^2}\right)\cos\theta \tag{10.27}$$

The potential at large distance r ($r >> a$) from the sphere

$$V(r,\theta) = V_0 + E_0 r\cos\theta \tag{10.28}$$

where:

V_0 is the potential at the location of the centre of the sphere due to the external field

Comparing Equations 10.27 and 10.28 for $r \to \infty$, $C_{2e} = V_0$ and $C_{3e} = E_0$. C_{1e} will be zero as a dielectric sphere is not considered to have any free charge.

Hence, Equation 10.27 can be rewritten as

$$V_e(r,\theta) = V_0 + \left(E_0 r + \frac{C_{4e}}{r^2}\right)\cos\theta \tag{10.29}$$

Inside the dielectric sphere electric potential must be finite at all the points. Hence, from Equation 10.26 $C_{1i} = C_{4i} = 0$, $C_{2i} = V_0$. Hence, Equation 10.26 can be rewritten as

$$V_i(r,\theta) = V_0 + C_{3i}\, r\cos\theta \tag{10.30}$$

At $r = a$, both Equations 10.29 and 10.30 should yield the same electric potential. Therefore,

5.2. La trigonometria.

Pur essendo maturata entro i confini dell'astronomia, nella scienza araba la trigonometria ha rappresentato il crocevia di diverse attività matematiche. L'astronomia aveva conosciuto un importante sviluppo a partire fondamentalmente dal patrimonio indiano e greco. In principio tale sviluppo era stato favorito dalle necessità della pratica religiosa e da alcune commissioni statali, come il finanziamento delle traduzioni voluto dai califfi al-Mansūr, al-Mahdī e Hārūn ar-Rashīd e l'avvio di un esteso programma di osservazioni e misurazioni da parte di al-Ma'mūn.

Tra le varie espressioni dell'astronomia, a stimolare lo sviluppo degli strumenti della trigonometria sono stati in particolare lo studio del movimento dei pianeti, il calcolo del tempo, la concezione di strumento e soprattutto la realizzazione di centinaia di tabelle per usi di ogni tipo. Queste tavole (chiamate *zījs*) contenevano, in particolare, i calendari adattati ai bisogni di questa o quella comunità in funzione delle sue credenze, attività e modi di vivere. In base a determinati calcoli, le *zījs* stabilivano gli orari delle preghiere, le latitudini e longitudini delle città, la direzione della Mecca a partire da qualunque città dell'impero, previsioni sull'apparizione dei quarti di luna, ecc. A fianco di questa quantità di informazioni direttamente utilizzabili vi era una parte matematica, che comprendeva le tavole trigonometriche e i metodi di calcolo che permettevano di determinare il movimento degli astri e di prevedere fenomeni di vario genere, come per esempio le eclissi [Kennedy 1966; King 1973; Juškevič 1976, pp. 141-50].

Prendendo le mosse dai primi problemi trigonometrici posti dall'*Almagesto* di Tolomeo, che poggiavano sul teorema di Menelao, alcuni astronomi arabi preferivano però utilizzare per i loro calcoli espliciti la piccola tavola di seni contenuta nei *Siddhānta* indiani, che si rivelava, ai fini dei calcoli, piú economica della tavola delle corde dell'angolo doppio elaborata dalla tradizione greca. In un secondo momento gli stessi astronomi hanno considerevolmente accresciuto il volume della tavola del seno (raffinando le approssimazioni) e creato tavole del seno verso e del coseno. Poi hanno introdotto nuove linee trigonometriche come la tangente, la cotangente, la secante e la cosecante, alcune delle quali sono state utilizzate per la prima volta da Ḥabash al-Ḥāsib nella seconda metà del IX secolo. Nel medesimo periodo è stata realizzata anche la loro tabulazione, come si può vedere nell'*Iṣlāḥ al-Mājisṭī* (La revisione dell'Almagesto) di al-Battānī (m. 929) [Debarnot 1997; Nallino 1899-1907; Djebbar 2004].

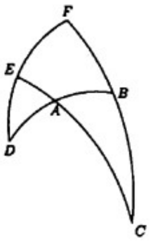
Teorema di Menelao. Se CE, CF, DF, DB sono archi di cerchi massimi su una sfera, si avrà:

(i)
$$\frac{\mathrm{crd}\,(2CB)}{\mathrm{crd}\,(2BF)} = \frac{\mathrm{crd}\,(2CA)}{\mathrm{crd}\,(2AE)} \times \frac{\mathrm{crd}\,(2ED)}{\mathrm{crd}\,(2DF)}$$

(formulazione basata sulle corde dell'angolo doppio);

(ii)
$$\frac{\mathrm{sen}\,(CB)}{\mathrm{sen}\,(BF)} = \frac{\mathrm{sen}\,(CA)}{\mathrm{sen}\,(AE)} \times \frac{\mathrm{sen}\,(ED)}{\mathrm{sen}\,(DF)}$$

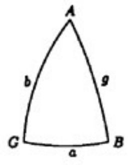
(formulazione basata sui seni).



Una terza tappa è stata raggiunta nella prima metà del x secolo con la definizione delle relazioni fondamentali esistenti tra queste sei funzioni trigonometriche. Successivamente, in uno sforzo di ottimizzazione dei calcoli, sono state intraprese alcune ricerche per trovare nuove relazioni trigonometriche. Tali ricerche sono sfociate nella definizione di nuovi teoremi e di nuove formule piú facili da utilizzare. La piú celebre è quella a cui verrà dato il nome di «formula che rende superfluo». Di fatto si tratta della versione sferica del teorema del seno, ed è stata denominata in questo modo perché, facendo intervenire soltanto quattro grandezze (mentre quella di Menelao ne utilizza sei), riduceva considerevolmente i tempi di calcolo per la creazione delle tavole [Debarnot 1985].

Teorema del seno. Se a, b, g sono archi di cerchi massimi e A, B, G sono i rispettivi angoli opposti, si avrà:

$$\frac{\mathrm{sen}\,(a)}{\mathrm{sen}\,(A)} = \frac{\mathrm{sen}\,(b)}{\mathrm{sen}\,(B)} = \frac{\mathrm{sen}\,(g)}{\mathrm{sen}\,(G)}$$



Tra i ricercatori che hanno contribuito a questo progresso, o che hanno rapidamente compreso l'importanza del teorema integrandolo nelle loro opere, figurano Abū 'l-Wafā', Ibn 'Irāq (XI secolo) e al-Bīrūnī in Oriente, Ibn Mu'ādh (XI secolo) e Jābir ibn Aflaḥ (m. 1145) in Andalusia [Villuendas 1979; Lorch 1975]. Questa ripartizione geografica rivela in particolare l'uniformazione del livello scientifico che aveva avuto luogo nei paesi dell'Islam quale risultato di una grande circolazione delle idee attraverso i libri, gli scambi epistolari e gli spostamenti degli stessi uomini di scienza, come Ibn Mu'ādh, trasferitosi al Cairo.

Il superamento della quarta e ultima tappa nella storia della trigonometria araba ha avuto inizio con la comparsa nei trattati di astronomia di capitoli specificamente dedicati agli oggetti e agli strumenti della nuova disciplina. È questo il caso, per esempio, del *Risāla fī qusiyy al-kura* (Epistola sugli archi della sfera) di Ibn 'Irāq o del *Kitāb al-Mājisṭī* (Libro dell'Almagesto) di Abū 'l-Wafā'. Il processo si è compiuto con la pubblicazione di opere interamente consacrate a questa materia, come il *Kitāb majhūlāt quisiyy al-kura* (Libro degli archi non noti della sfera) di Ibn Mu'ādh e, soprattutto, il *Kitāb ash-ṣakl al-qaṭṭā'* (Libro della figura secante) di Naṣīr ad-Dīn aṭ-Ṭūsī [Caratheodory 1891; Villuendas 1979].

5.3. L'analisi combinatoria.

È in un'opera maghrebina del XII secolo, il *Fiqh al-ḥisāb* (La scienza del calcolo) di Ibn Mun'im (m. 1228), che a quanto ci risulta compare per la prima volta nella storia della matematica un capitolo dedicato in modo specifico a un argomento puramente combinatorio [Djebbar 1985]. Ma questo evento è stato preceduto dall'esistenza di diverse pratiche di enumerazione e computazione nell'ambito di svariati campi, a volte molto lontani gli uni dagli altri, come l'astronomia, l'algebra e la linguistica.

In astronomia, processi combinatori elementari che utilizzano il computo ottenuto per mezzo di semplice enumerazione intervengono in un opuscolo di Thābit ibn Qurra e in un trattato di al-Bīrūnī [Djebbar 1980, pp. 56-60]. In algebra, procedimenti analoghi si trovano in Abū Kāmil e as-Samaw'al per il computo delle equazioni o delle soluzioni di un problema dato. Nel *Kitāb aṭ-ṭarā'if fī 'l-ḥisāb* (Libro delle rarità nel calcolo), il primo di questi studiosi effetti, la trasformazione che si andava attuando del sistema di mecenatismo individuale in un sistema di ricerca collettiva, ben presto finanziato dagli Stati, esercitò una forte pressione sugli orientamenti della ricerca e sulla scelta dei problemi da studiare. Mordechai Feingold [1984, p. 216] ha mostrato che in Inghilterra, fra il 1560 e il 1640, l'attività scientifica tradizionalmente distribuita in vari settori «venne progressivamente indirizzata in ricerche influenzate in larga parte dalle esigenze e dalle richieste dei mecenati. Il risultato immediato di questo reindirizzamento fu la proliferazione di progetti di carattere pratico che da una parte assicurarono all'Inghilterra un posto fra le nazioni piú potenti e accrebbero in maniera considerevole le fortune dei loro committenti, dall'altra portarono alla creazione di meccanismi e artifici destinati a dilettare le classi superiori». Presteremo dunque una particolare attenzione alle possibili influenze – legate ai meccanismi propri del mecenatismo – esercitate sugli interessi matematici dei protagonisti.

Sullo sfondo della nostra analisi terremo presente anche l'ipotesi formulata da Mario Biagioli nell'epilogo del suo *Galileo, Courtier*, intitolato *From Patronage to Academies. A Hypothesis* [Biagioli 1993, pp. 353-62]. Biagioli sostiene che «la comprensione del processo di legittimazione sociale e cognitiva offerto dalla Corte offre importanti elementi per definire la genealogia del sistema sociale che venne successivamente a crearsi, del suo ethos e dello stile della filosofia naturale» [p. 354]. La questione delle nuove pratiche scientifiche generate dal passaggio dal mecenatismo alle istituzioni scientifiche sarà uno dei cardini della nostra riflessione, tenendo presente che tali pratiche includevano: i protocolli di legittimazione e dunque di reclutamento; i codici di comportamento, soprattutto nel caso di controversie; le ragioni soggiacenti alla scelta dei temi di ricerca; gli approcci adottati nell'affrontare i problemi e altre analoghe questioni.

2. *Leibniz, consigliere dei principi.*

2.1. Per la gloria e il diletto di un principe.

Quando Leibniz, giurista di formazione e futuro diplomatico di professione, alla fine dei suoi studi universitari, si trovò di fronte alla necessità di guadagnarsi da vivere, scelse di mettersi al servizio di un potente, sebbene gli fosse stata offerta una cattedra all'Università di Altdorf nel 1667. Ricordiamo che Leibniz (nato a Lipsia il 1° luglio 1646, due anni prima che la pace di Westfalia mettesse fine alle guerre di religione che avevano devastato la Germania da cima a fondo) aveva studiato filosofia e diritto a Lipsia e a Jena. Perché dunque rifiutare una tranquilla carriera universitaria come quella di suo padre, Friedrich Leibnütz? Certamente il giovane Leibniz nutriva l'ambizione di influenzare la politica del suo paese e pensava di realizzarla diventando consigliere di uno dei suoi principi. In effetti è questo il concetto che esprime nel dicembre 1675 in una lettera indirizzata a Johann Carl Kahm, valletto di camera del duca Giovanni Federico di Brunswick-Lüneburg:

> Per natura io non sono avido di denaro, ma, una volta che possa contare su un reddito soddisfacente, cerco soltanto di accrescere il mio prestigio, lavorando e svolgendo dei servizi per il bene comune [...]: è soprattutto per questo motivo che desideravo trovare un'alta personalità [...] la cui protezione, l'autorità, l'aiuto e i favori potessero dare corpo a idee utili; in cambio io non avrei altra preoccupazione che lavorare per la sua gloria e per il suo diletto [Heinekamp et al. 1994, pp. 43-44].

Leibniz trovò questo patrono nella persona di Johann Christian von Boineburg, ministro del principe elettore di Magonza, Giovanni Filippo di Schönborn. Il giovane Leibniz cominciò dunque la sua carriera di giurista e diplomatico a Magonza – dove sarà poi segretario, bibliotecario e consigliere di Corte d'appello – redigendo rapporti e *memoranda* per Boineburg. Nel marzo 1672, accompagnò il nipote del principe elettore in missione diplomatica a Parigi, ma la morte di Boineburg e successivamente quella di Schönborn misero fine alla sua promettente carriera. Leibniz cercò allora di stabilirsi a Parigi per potersi introdurre nei circoli eruditi della capitale e ottenere uno stipendio dall'Académie des Sciences, senza successo: «Parigi è un posto dove è difficile emergere: si trovano, in tutti i campi scientifici, gli uomini piú brillanti dell'epoca e serve molto tempo per costruirsi una solida reputazione» [*ibid.*, p. 46]. In ottobre, lasciò Parigi per mettersi al servizio di Giovanni Federico di Brunswick-Lüneburg, con il titolo di consigliere della Corte ducale.

2.2. Leibniz a Parigi: un periodo di libertà creativa.

Il soggiorno parigino fu, per il matematico Leibniz, uno dei periodi piú fruttuosi. Fu l'occasione per incontrare studiosi della statura di Christiaan Huygens, membro dell'Académie des Sciences, conoscenza che gli fece capire quanto fosse vasta la sua ignoranza in matematica; Edme Mariotte; l'ormai anziano Roberval o il giovane Ehrenfried Walter Tschirnaus. Grazie alla loro frequentazione, poté assimilare la matematica del suo tempo e fare ampie letture nelle ricche biblioteche parigine. In questo periodo di piena maturità intellettuale, Leibniz riuscí a impadronirsi da autodidatta – in soli quattro anni e con rara intensità – di quelle tecniche matematiche che seppe poi rapidamente impiegare in maniera del tutto originale. Fece la conoscenza di Étienne Périer, nipote di Pascal, che gli permise di consultare i manoscritti dello zio, da cui Leibniz trasse il famoso *Traité des coniques*.

Nell'ottobre del 1675, inventò il calcolo differenziale mentre era impegnato nella risoluzione di un problema inverso di tangenti (cioè un problema di quadratura) e stava cercando di presentare nella maniera piú semplice e chiara il suo risultato. In seguito, nel corso di queste ricerche, Leibniz introdusse i suoi famosi simboli, una «S» stilizzata per la somma (o l'integrale) e una «d» per la differenza. Come commenta Josef E. Hofmann [1974, p. 194]: «dal momento in cui furono compiuti questi primi passi cruciali verso l'algebrizzazione dei problemi infinitesimali, si aprí una nuova prospettiva, per quest'uomo abituato a identificare gli elementi generali e caratterizzanti in mezzo a un'accozzaglia di cose simili». Leibniz pubblicò il suo nuovo calcolo solo nel 1684 negli *Acta Eruditorum* di Lipsia. La storia di questa invenzione e dei suoi sviluppi è ben nota e rinviamo chi desiderasse approfondirla alla vasta letteratura esistente.

2.3. Leibniz al servizio degli Hannover.

Leibniz si stabilí a Hannover, dove rimase per il resto dei suoi giorni (morí il 14 novembre 1716, all'età di 70 anni), nonostante si lamentasse spesso del provincialismo della cittadina, della mancanza di «eruditi» con cui discutere e della totale assenza di circoli intellettuali in cui si sviluppasse una qualche ricerca. Del resto, scrive a Thomas Burnett in una famosa lettera del 17 marzo 1696, «la vita di Corte e le conversazioni dotte si escludono vicendevolmente» [Heinekamp et al. 1994, p. 51]. Leibniz lavorò successivamente per tre esponenti della casa di Hannover: dal 1676 al 1679 serví Giovanni Federico, duca di Brunswick-Lüneburg; dal 1679 al 1698 Ernesto Augusto (fratello di Giovanni Federico) e suo figlio Giorgio Ludovico, il futuro Giorgio I d'Inghilterra. Le relazioni che Leibniz stabilí con ognuno dei suoi tre protettori furono diverse: confidenziali con il primo, che apprezzava le conversazioni filosofiche e le opinioni del suo protetto; piú formali con Ernst August che, affidando a Leibniz l'incarico di redigere la storia dei Guelfi, lo coinvolse nel suo progetto di glorificazione della casa di Hannover, progetto poi trascurato da Giorgio Ludovico, il quale comunque rimproverò Leibniz di non aver portato a termine i suoi *Annali* e lo mortificò continuamente (rifiutandogli, per l'esempio, l'autorizzazione a viaggiare).

I suoi protettori non si accontentarono di trarre vantaggio dai consigli giuridici dispensati da Leibniz, dalle sue ricerche storiche o dalla sua attività di collezionista di libri e bibliotecario, ma gli chiesero anche, secondo la piú classica tradizione del mecenatismo rinascimentale, di intervenire nella risoluzione di problemi tecnologici e nella pianificazione del territorio. Johann Friedrich affidò infatti a Leibniz il compito di migliorare le difficili tecniche di estrazione dell'argento dalle miniere dello Harz. Fedele al proprio motto «Theoria cum praxi», Leibniz propose di utilizzare l'energia eolica per drenare l'acqua dai pozzi e dalle gallerie delle miniere. Il progetto venne portato avanti per diversi anni, nel corso dei quali egli sperimentò sul campo diverse tecniche, sviluppò i calcoli necessari e cercò di prendere accordi con gli amministratori delle miniere che erano ostili alle innovazioni tecnologiche, finché l'esperienza venne bruscamente interrotta da Ernesto Augusto, che nel frattempo era succeduto al fratello, nel 1685. Poiché il nuovo duca aveva deciso di stabilire la propria residenza estiva a Herrenhausen, dove voleva creare un giardino alla francese con fontane e giochi d'acqua, si rivolse a Leibniz, il quale nel 1696 preparò un progetto di cui vennero messi in opera solo alcuni importanti elementi – il progetto infatti non venne mai realizzato nel suo complesso – che si possono ammirare ancora oggi.

Gli studi leibniziani nel campo delle matematiche erano destinati a rimanere di dominio privato. I 7300 manoscritti matematici, per la maggior parte inediti, conservati a Hannover e i carteggi fra Leibniz e numerosi matematici dell'epoca, testimoniano l'ampiezza e la varietà di queste ricerche. Alcuni carteggi, come quello con Johann Bernoulli, documentano l'attività di un vero e proprio laboratorio di matematiche, nel quale si discute, oltre che di problemi scientifici, anche dell'organizzazione sociale e dell'istituzionalizzazione della disciplina: posti, strategie di conquista di cattedre, controversie e risposte da opporre, ecc. La matematica offriva solo raramente materia di discussioni dotte alla Corte degli Hannover, anche se in un'occasione Leibniz riuscí a destare l'interesse di Rodolfo Augusto, duca di Brunswick-Wolfenbüttel, per una delle sue invenzioni matematiche.

2.4. Il sistema binario presentato al duca di Brunswick-Wolfenbüttel.

Mentre era bibliotecario della Bibliotheca Augusta di Wolfenbüttel (a partire dal 1691), Leibniz inviò il 2 gennaio 1697 i suoi auguri per l'anno nuovo a Rodolfo Augusto, in ossequio all'uso comune, come afferma egli stesso, ma anche per l'affetto che nutriva verso il duca. In quella lettera[1] spiega al duca il calcolo binario inventato alcuni anni addietro e pubblicato nei «Mémoires de l'Académie Royale des Sciences» (1703) per giustificare la sua elezione come membro straniero[2]. In occasione di un incontro precedente all'invio della lettera, Leibniz aveva già avuto modo di illustrare la sua invenzione al duca, che aveva suggerito un'analogia fra il sistema binario e la Creazione [Aiton 1985]. Leibniz fece sua questa analogia e offrí al duca il bozzetto di una medaglia in cui essa veniva rappresentata in forma emblematica. Uno dei principali misteri della fede cristiana, diceva Leibniz, è la creazione *ex nihilo* di tutte le cose da parte dell'onnipotenza divina:

---

[1] Nella pagina web www.fh-augsburg.de/ harsch/germanica/Chronologie/17Jh/Leibniz/lei bina.html si trova la riproduzione e la trascrizione della lettera originale che abbiamo parafrasato nel testo. Si veda anche G. W. Leibniz, *Sämtliche Schriften und Briefe*, 8 Reihen, Akademie-Ausgabe, Berlin, I, 13 [d'ora in poi: *Akademie-Ausgabe*].

[2] Il diplomatico Christophe Brosseau, residente di Hannover a Parigi, aveva dovuto ricordare a Leibniz i suoi doveri di cittadino della *République des lettres*. Gli scriveva infatti il 16 agosto 1700 da Parigi: «Mi figuravo, Signore, e l'avevo anche fatto sperare al Signor Abate Bignon, che con la prima delle Vostre lettere avrei ricevuto le risposte che dovete non solo a lui ma anche a Monsieur de Fontenelle, che Vi hanno scritto con l'occasione di inviarVi il vostro appannaggio di accademico onorario. Purtroppo io queste risposte non le ho trovate affatto con la Vostra che mi è arrivata il giorno 3 di questo mese. Permettetemi di essere alquanto sorpreso, poiché sembrerebbe che Voi non stiate nemmeno pensando di scrivere loro. Tuttavia, Signore, l'onestà e la buona creanza Vi obbligano ad adempiere ai Vostri doveri, pertanto Vi supplico di non serbarmi rancore se Vi esorto e se oso dirVi che si tratta di un dovere dal quale non potete dispensarVi» [*Akademie-Ausgabe*, I, 18,

> Dunque, nulla rappresenta meglio la Creazione, anzi nulla la dimostra meglio dell'origine dei numeri cosí come viene spiegata qui: tutti i numeri vengono generati in base alla loro sola espressione formata da successioni di Uno e Zero, cioè niente. Sarà difficile poter trovare in natura o in filosofia un simbolo migliore per questo mistero ed è per questo motivo che ho iscritto sulla medaglia le parole: IMAGO CREATIONIS.

L'emblema avrebbe dovuto rendere manifesto che tutto quello che è stato creato, è stato perfettamente creato. Nella usuale rappresentazione dei numeri, non c'è nessun ordine che si palesi nella successione dei caratteri, contrariamente a ciò che avviene nel sistema binario, fondato su una regola che permette di scrivere i numeri senza alcun calcolo e tanto grandi quanto si vuole: per ottenere la rappresentazione binaria dei numeri interi disposti in una colonna verticale[3], basta scrivere nella colonna di destra alternativamente: 0, 1, 0, 1, 0, 1, ecc.; nella colonna successiva, partendo da destra, si scriverà: 0, 0, 1, 1, 0, 0, 1, 1, ecc.; nella terza colonna: 0, 0, 0, 0, 1, 1, 1, 1, 0, 0, 0, 0, 1, 1, 1, 1, ecc.; nella quarta 0, 0, 0, 0, 0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, 0, 0, 0, 0, 0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, ecc. Lo spazio centrale della medaglia è occupato da una piccola tabella che presenta la scrittura binaria dei numeri interi da 1 a 17 e mette in evidenza questo bell'ordine univoco. Leibniz ne deduceva che

> il disordine che si immagina nelle opere di Dio è solo apparente; non appena si osservano le cose da un giusto punto di vista, come nella prospettiva, si coglie la loro simmetria. Questo ci spingerà sempre piú a lodare e ad amare la saggezza, la bontà e la bellezza del Bene Supremo, da cui deriva tutta la bontà e tutta la bellezza.

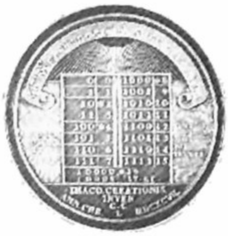
Nel prosieguo della lettera, Leibniz menzionava Claudio Filippo Grimaldi, missionario gesuita in Cina, che aveva conosciuto a Roma e che gli aveva scritto da Goa in occasione del suo viaggio di ritorno in Cina; Leibniz aveva ritenuto opportuno illustrargli la rappresentazione binaria dei numeri nella speranza che l'emblema raffigurante il mistero della Creazione potesse servire a rendere manifesta la superiorità della fede cristiana, dal momento

---

pp. 804-5]. Leibniz fece pervenire a Fontenelle il 26 febbraio 1701 il trattato dal titolo *Essay d'une nouvelle science des nombres* che non volle però veder pubblicato; al suo posto, inserí la memoria (G. W. Leibniz, *Mathematische Schriften*, a cura di C. I. Gerhardt, 7 voll., Halle, Berlin 1849-63, nuova edizione Olms, Hildesheim 1960-61, vol. VII, pp. 223-27 [d'ora in poi: *Math. Schriften*]).

[3] Ricordiamo che nel sistema binario un numero intero si scrive come somma di potenze di 2 moltiplicate per i coefficienti 0 o 1. Cosí, per esempio, $3 = 1 \times 2^1 + 1 \times 2^0$ si scrive 11; $8 = 1 \times 2^3 + 0 \times 2^2 + 0 \times 2^1 + 0 \times 2^0$ si scrive 1000

che Grimaldi gli aveva raccontato che l'imperatore cinese era un grande estimatore dell'arte di calcolare, anche al modo europeo, che aveva appreso da padre Ferdinand Verbiest, predecessore di Grimaldi.



Leibniz continuava poi descrivendo gli altri elementi della medaglia e spiegando l'addizione e la moltiplicazione dei numeri binari, sebbene ritenesse che non fosse il caso di usare questi numeri nella vita quotidiana. Per fare in modo che la medaglia avesse un aspetto gradevole e la sua superficie non fosse completamente riempita di numeri, Leibniz pensava di rappresentarvi la luce e le tenebre, dal momento che le tenebre ricoprivano l'abisso e lo Spirito di Dio aleggiava sulla superficie delle acque. Allora Dio disse: «Sia la luce, e la luce fu». L'abisso e le tenebre sono assimilabili allo Zero e al nulla, lo spirito di Dio con la sua luce all'Uno onnipotente. Come motto dell'impresa Leibniz propone i versi seguenti, che mostrano bene per quale motivo l'emblema è IMAGO CREATIONIS:

2, 3, 4, 5 etc. 0
Omnibus ex nihilo ducendis, SUFFICIT UNUM

Ovvero: per dedurre il tutto dal nulla, basta l'Uno.

Al termine della lettera, Leibniz osservava che il sistema binario racchiude in sé una tale quantità di osservazioni meravigliose e utili al progresso delle scienze che la Società matematica di Amburgo avrebbe dovuto esercitare la sua intelligenza per sviluppare quello che lui, Leibniz, assicurava di poter trovare e che avrebbe contribuito alla loro gloria e a quella della nazione tedesca. Non è questa l'unica occasione in cui Leibniz si rivolge a un'istituzione per invitarla a impegnarsi in determinate ricerche. In effetti, aveva suggerito a Christophe Sturm, membro della Deutsche Akademie der Naturforscher, di effettuare in diversi luoghi dei rilievi della declinazione magnetica e di ripetere le misurazioni a intervalli di tempo regolari. A questo invito non ne erano seguiti altri fino al tentativo di coinvolgimento della Società matematica di Amburgo [Heinekamp et al. 1994, p. 85].

La straordinaria lettera che abbiamo appena parafrasato riassume da sola diverse ossessioni di Leibniz. Egli offre al suo protettore un'invenzione matematica celebrata da una medaglia che, allo stesso tempo, avrebbe glorificato il duca. Questa invenzione racchiude potenzialmente molti risultati nuovi che sarebbe opportuno mettere a disposizione di una comunità scientifica, in questo caso una delle piú antiche società matematiche d'Europa. Peraltro, raffigurando l'analogia, suggerita dal duca e ripresa da Leibniz, fra numerazione binaria e Creazione, la medaglia avrebbe potuto inoltre servire all'attività di proselitismo portata avanti dai Gesuiti in Cina, dal momento che incoraggiava i Cinesi ad accogliere la matematica europea assieme alla fede cristiana.

Forte di questa convinzione, il 15 febbraio 1701, Leibniz descrisse la sua invenzione – principî di aritmetica binaria e analogia con la Genesi – al missionario gesuita Joachim Bouvet, che riconobbe un legame (puramente formale) fra i numeri binari e i cosiddetti «esagrammi di Fohy», ovvero i diagrammi contenuti nel *Libro dei mutamenti* (*I Ching*). Si puo supporre che Leibniz abbia incluso questa citazione nella memoria che stava redigendo per l'Accademia parigina *Explication de l'arithmétique binaire [...]* per effetto dell'entusiasmo che la lettera di Bouvet gli aveva provocato [*Math. Schriften*, VII, pp. 223-27]. Non era piú questione di medaglia, né di analogia con la Creazione del mondo a partire dal nulla, ma di «perfezione della scienza dei Numeri» in termini spesso assimilabili a quelli impiegati nella lettera al duca Rodolfo Augusto. Anzi, nel titolo completo del trattato, *Explication de l'arithmétique binaire, qui se sert des seuls caractères 0 et 1 avec des remarques sur son utilité et sur ce qu'elle donne le sens des anciennes figures chinoises de Fohy*, si mettono generosamente in evidenza le «figure cinesi di Fohy» (*Fu Xi*), le quali secondo Leibniz (che in questo segue Bouvet) «sono forse il piú antico monumento scientifico che esista al mondo» [*ibid.*, pp. 226-27] e sarebbero identiche alla tavola binaria di Leibniz[4]. Conclude la sua breve memoria avanzando però il sospetto che ci fosse «nella scrittura cinese un vantaggio simile a quello che esiste necessariamente in una Caratteristica che sto progettando. Ogni ragionamento che si può dedurre dalle nozioni potrebbe essere dedotto dai loro Caratteri attraverso una specie di calcolo e questo sarebbe uno dei piú importanti mezzi per aiutare lo spirito umano» [*ibid.*, p. 227].

2.5. La storia dei Guelfi, un pretesto per viaggi scientifici.

Nel 1685 Leibniz aveva ricevuto l'incarico di redigere la storia della casa dei Guelfi e per questo gli era stato concesso un vitalizio. Nelle intenzioni di Ernesto Augusto, questa *Historia domus* era concepita come una genealogia del suo casato, finalizzata a far valere i propri diritti per l'Elettorato, ottenuto poi nel 1692. Per Leibniz, invece, si trattava di scrivere la storia del Casato del Brunswick-Lüneburg basandosi su fonti storiche attendibili e per fare questo mise insieme un impressionante *corpus* di documenti (pubblicati poi nel XVIII secolo) ma non portò mai a termine la sua storia dei Guelfi, subendo cosí vivaci rimproveri da parte del duca Giorgio Ludovico. La strategia che mise in atto per reperire le fonti storiche necessarie si articolò in due fasi: dapprima provvide ad ampliare la sua rete epistolare e successivamente si mise a viaggiare per visitare archivi e biblioteche. Dal novembre 1687 al giugno 1690 intraprese dunque un viaggio che gli avrebbe dato l'occasione per stabilire nuovi contatti con vari studiosi. André Robinet [1988] ha ampiamente documentato queste nuove relazioni, e ha descritto il soggiorno romano di Leibniz – dalla metà dell'aprile fino al 21 novembre 1689 – come un «felice momento creativo». In effetti, Leibniz venne ammesso all'Accademia fisico-matematica, i cui membri si riunivano tutte le sere nel palazzo di Giovanni Ciampini situato dietro la chiesa di Sant'Agnese. Secondo Robinet, è proprio a Roma che Leibniz avrebbe iniziato a redigere la sua *Dynamica*, i cui appunti preparatori si erano mescolati a quelli di un altro testo, il *Phoranomus*, rimasto inedito fino alla pubblicazione curata da Robinet nel 1991. Quest'ultimo documento sarebbe, secondo l'interpretazione originale e affascinante di Robinet, il rendiconto, o meglio la messa in scena, di una seduta dell'Accademia romana, nel corso della quale Leibniz avrebbe presentato per la prima volta in pubblico la sua dinamica (sotto forma di *Phoranomus*) legando «non soltanto il ricordo di Parigi al presente di Roma, ma anche al futuro dell'Accademia di Pechino» [Robinet 1988, p. 95].

---

[4] Questa interpretazione si fonda tuttavia su un malinteso. Sulla questione si veda Aiton [1985, p. 248].

In effetti, Leibniz comincia l'opera come se fosse una lettera indirizzata a Melchisédech Thévenot, membro dell'Académie des Sciences di Parigi, e si riferisce a un libello che Pierre-Daniel Huet, vescovo di Soissons, aveva appena pubblicato contro la filosofia di Descartes. In seguito, dopo aver divagato (§ 2) sulle antichità romane, Leibniz fa intervenire nella *pièce* lo stesso padre Grimaldi, di cui parlerà al duca di Wolfenbüttel nel 1697. Il gesuita era appena arrivato a Roma di ritorno dalla Cina ed era stato interpellato a proposito della possibilità di succedere a padre Verbiest come presidente del Tribunale dei matematici di Pechino. Per questo motivo tutti gli occhi si volgono verso il nuovo venuto e alcuni gli fanno domande sulla Cina. Leibniz, in particolare, gli chiede informazioni sui caratteri cinesi, sui fuochi d'artificio, sull'astronomia, su una pianta capace di dare sollievo ai dolori della gotta e sulle officine tessili che si sarebbero sviluppate in Cina. Si passa poi a parlare delle macchine che i cinesi desidererebbero importare dall'Europa.

Leibniz ne approfitta per fare l'elogio della sua macchina aritmetica, che permette «anche a un bambino di fare molto rapidamente delle moltiplicazioni e delle divisioni molto complesse, senza nessuno sforzo e quasi distrattamente, come in un gioco»’ [Robinet 1991, § 4, p. 451]. Interrogato da Grimaldi sulla differenza fra la sua macchina e quella di Pascal, Leibniz cita la testimonianza di Périer, nipote di Pascal, che, in occasione della presentazione dell'invenzione all'Académie di Parigi ne aveva riconosciuto l'originalità. Successivamente egli spiega, con un esempio, le operazioni e i movimenti necessari per ottenere il risultato. Nel seguito, la discussione si sposta sulle matematiche pratiche e si aggiunge un nuovo arrivato, Domenico Quartaroni, professore alla Sapienza e animatore di un'Accademia matematica. Grimaldi indirizza la conversazione sui principî meno certi sui quali si fondano queste matematiche e ciò spinge Antonio Baldigiani, che era entrato in scena con Grimaldi ma non aveva ancora parlato, a rivolgersi a Leibniz (§ 6) chiedendogli provocatoriamente che cosa si aspetti da tali principî. È dunque a questo professore di matematiche del Collegio Romano che tocca porre la questione chiave a cui è dedicato il *Phoranomus*: in che cosa consiste la vostra nuova fisica? Leibniz si fa pregare fino a che non vede entrare Adrien Auzout, considerato come una vera e propria autorità in matematica, in presenza del quale si decide a spiegare la nuova fisica, che si fonda sul principio di conservazione delle forze vive (mv^2). Leibniz passa quindi ad affrontare il nodo della questione.

Questa prima parte del *Phoranomus*, in cui Leibniz sceglie di far conversare un certo numero di matematici, ci fa rivivere una seduta (forse immaginaria) dell'Accademia romana. Grimaldi interviene per primo, dal momento che la sua presenza a Roma è rara e i suoi racconti sono in grado di fornire informazioni inedite sulla Cina. In virtú dei riferimenti alla Cina e di quelli all'Accademia parigina, Leibniz sembra voler conferire una dimensione internazionale all'attività matematica che descrive. È esattamente ciò che cercò di realizzare impegnandosi attivamente per sostenere l'idea delle Accademie.

2.6. I progetti accademici di Leibniz.

A partire dal 1670 e fino al termine della sua vita, Leibniz si interessò all'organizzazione internazionale delle scienze e tentò di promuovere, con tutta l'energia di cui disponeva, la creazione di «società» o accademie scientifiche. Il progetto di una *Societas eruditorum Germaniae* che presentò nel 1670, appena ventiduenne, al principe elettore di Magonza era legato alla fondazione di un periodico, il «Nucleus Librarius Semestralis» – che non ottenne il privilegio imperiale –, in cui si sarebbero dovuti recensire tutti

---

’ «Tum ego, quid ipsi de Machina quadam Arithmetica videretur, qua ego effecissem, ut sine labore ac prope sine attentione animi maximae multiplicationes ac divisiones etiam a puello velut ludendo peragi promptissime possent». In un manoscritto del 1680, *Machina arithmeticae dyadicae*, Leibniz considera una macchina che trasforma i numeri decimali in numeri binari, ma non venne mai costruita, diversamente da quella che si fonda sul sistema decimale.

i libri pubblicati nell'impero, elogiandone il contenuto o, all'occorrenza, censurandolo. Regolare il mercato dei libri, scartando quelli ridondanti e superflui, costituire una biblioteca universale, inventariarne il sapere per mezzo di indici: questi dovevano essere i compiti principali della nuova Accademia che avrebbe dovuto aver sede a Francoforte sotto la presidenza del principe elettore in persona [Heinekamp et al. 1994, pp. 121-25].

Questo progetto, cosí come tutti gli altri che si sarebbero succeduti regolarmente negli anni successivi, non ottenne l'assenso delle autorità e quindi nemmeno finanziamenti. Ciò a cui mirava Leibniz, di fatto, era la creazione di istituzioni che si occupassero non solo di scienza, ma anche di economia e di cultura in genere, stabilendo poi dei rapporti con le attività pratiche. I risultati teorici ottenuti, in altre parole, avrebbero dovuto essere utilizzati al servizio del benessere dell'intera umanità. Quest'ottica universalista e filantropica andava ben oltre quella delle Accademie esistenti e le idee leibniziane si sarebbero concretizzate, anche se molto parzialmente, solo nel 1700 con l'istituzione dell'Accademia di Berlino, finanziata dai proventi del monopolio della produzione di calendari e almanacchi. Il 19 marzo 1700 l'elettore di Brandeburgo fece istituire un'Accademia delle scienze e un osservatorio a Berlino, nominando Leibniz presidente a vita. Lo statuto di questa Sozietät der Wissenschaften di Berlino fu ratificato l'11 luglio 1700 «in modo che l'anniversario di fondazione della società coincid[esse] con il genetliaco di Monsignore l'Elettore» [*Akademie-Ausgabe*, I, 18, p. 737]. La società venne ufficialmente inaugurata solo nel 1711, senza il suo presidente che aveva intanto trovato il tempo e le energie per pubblicare nel 1710 il primo volume dei *Miscellanea Berolinensia*, di cui aveva redatto un quinto delle memorie e dove i matematici rivestivano un ruolo non trascurabile: 8 memorie su 60, di cui tre di Leibniz, alcuni contributi di Johann Bernoulli, Jacob Hermann e Philippe Naudé (cui Leibniz aveva chiesto di collaborare allo sviluppo delle applicazioni della sua aritmetica binaria). Lo sviluppo della società venne ostacolato dai ricorrenti problemi di finanziamenti e non riuscí mai a raggiungere la forma «degna della grandezza e della gloria del suo fondatore» [*Akademie-Ausgabe*, I, 18, p. 448] che Leibniz avrebbe voluto offrirgli in dono. Dopo il 1713, con la presa di potere di Federico Guglielmo I, il *Soldatenkönig* (re-sergente), l'Accademia decadde miseramente, e solo le grandi ambizioni di Federico II, grande riformatore dello Stato prussiano e della sua vita culturale, poterono in seguito farla rivivere.

3. *I matematici e la nuova Accademia di San Pietroburgo.*

3.1. L'Accademia come elemento di modernizzazione dello Stato russo.

Negli ultimi anni del XVII secolo, Leibniz si era sempre più interessato alla Russia e al suo zar, sostenitore dell'importanza del ruolo delle scienze nel processo di modernizzazione del suo immenso impero. Fin dal 1696, egli aveva offerto i propri servigi a Pietro il Grande, che incontrò in tre diverse riprese. I rapporti con lo zar rappresentavano per Leibniz un'occasione per riflettere sul modo di creare, sistematicamente e partendo da zero, istituzioni per l'insegnamento e la ricerca. Fra gli specifici programmi di ricerca che si augurava di vedere sviluppati in Russia, si ritrova l'osservazione della declinazione magnetica, che aveva già suggerito senza successo a Sturm e alla Deutsche Akademie der Naturforscher.

Dopo la morte di Leibniz, lo zar si rivolse a Christian Wolff, allora professore di filosofia a Halle, perché diventasse il suo intermediario presso gli intellettuali europei. Il 18 marzo 1723 Wolff gli mandò il suo manuale di fisica, *Vernünfftige Gedancken von den Würckungen der Natur* (Idee ragionevoli sugli effetti della natura), accompagnato da una dedica: «[...] non si può aiutare un paese a svilupparsi, se non favorendo lo studio delle scienze fondamentali e soprattutto delle scienze matematiche e fisiche» [Nagel e Verdun 2005, p. 20], ma rifiutò il posto di consigliere che lo zar gli aveva offerto. Il bibliotecario dello zar viaggiò in Francia, in Germania, in Olanda e in Inghilterra, visitandone le rispettive istituzioni scientifiche, per riuscire a stabilire rapporti di collaborazione con San Pietroburgo. Alla fine, l'8 febbraio 1724, il Senato russo approvò il progetto di Accademia proposto dal medico di corte, Laurentius Blumentrost, che ne divenne il primo presidente. L'Accademia avrebbe dovuto contare su tre elementi costitutivi: l'istituto accademico di ricerca (ispirato al modello delle Accademie di Parigi e Berlino), l'università e il ginnasio per la formazione dei giovani – ma gli ultimi due conobbero un rapido declino. Un resoconto del progetto di questa Accademia venne ampiamente diffuso presso gli ambasciatori russi e gli studiosi europei i quali, in assenza di candidati russi, accorsero numerosi a Pietroburgo[6].

Al suo esordio, l'Accademia contava ventitre membri, sette dei quali erano matematici. Wolff aveva raccomandato Jacob Hermann, allievo di Jacob Bernoulli, pupillo di Leibniz e professore di matematica a Francoforte sull'Oder e anche Johann Bernoulli, il quale declinò l'invito, ma convinse due dei suoi figli, Daniel e Nicolaus (II), a mettersi al servizio dello zar. Il 9 dicembre 1724, Wolff scriveva all'ambasciatore russo in Prussia, il conte Golovkin: «L'affiliazione [di Daniel Bernoulli] all'Accademia imperiale mi sembra importante perché abbiamo bisogno di un uomo che coltivi la *Mathesis sublimior* senza distrarsi con altre attività e che sappia applicarla, all'occorrenza, alla natura e alle arti» [Nagel e Verdun 2005, p. 22]. Sfortunatamente Pietro il Grande, morto il 18 gennaio 1725, non poté vedere compiuta la realizzazione del suo progetto, che fu portato a termine con successo dalla sua vedova, Caterina I. Al termine dell'estate un certo numero di accademici si erano già stabiliti a San Pietroburgo e le sedute di lavoro si tenevano il martedí e il venerdí[7]. Christian Goldbach, che era arrivato, inatteso, in compagnia di Hermann, fu incaricato di redigere i verbali in latino (lo storico Gerhard Müller lo definí, pensando al *secrétaire perpetuel* dell'Académie parigina, il «Fontenelle latinista») e di occuparsi delle pubblicazioni e della corrispondenza, anche se al tempo stesso era membro della classe di matematica. Jacob Hermann ricoprí la cattedra di matematica, Nicolaus Bernoulli quella di meccanica, Daniel Bernoulli fu professore di fisiologia e di anatomia fino a che nel 1731, dopo la partenza di Hermann, ottenne la cattedra di matematica. Ogni giorno insegnava le applicazioni della matematica alla medicina dalle 7 alle 8 del mattino, mentre il fratello Nicolaus insegnava dalle 8 alle 9 la meccanica. Gli studenti, tuttavia, erano poco numerosi, dato che mancava un sistema scolastico in grado di fornire le conoscenze di base necessarie alla comprensione di corsi avanzati. Joseph-Nicolas Delisle, che nel 1722 venne personalmente invitato da Pietro I, assunse la direzione del Dipartimento di Geografia e di Astronomia.

---

[6] Durante il periodo 1725-99, l'Accademia di San Pietroburgo contava 111 membri ordinari, dei quali 55 provenivano dall'impero germanico e solo 35 dai territori russi [Nagel e Verdun 2005, p. 29].

3.2. Un discorso matematico per l'inaugurazione dell'Accademia di Pietroburgo.

La cerimonia d'inaugurazione, che avrebbe dovuto essere presieduta da Caterina I, era stata programmata in coincidenza con il giorno di santa Caterina d'Alessandria (il 25 novembre), ma ebbe effettivamente luogo piú di un mese dopo, il 7 gennaio 1726, in assenza dell'imperatrice. Una seconda seduta pubblica dell'Accademia si tenne il 12 agosto in presenza di Caterina, dei membri della famiglia imperiale, dei rappresentanti del Senato, del Santo Sinodo e della Corte, nonché degli ambasciatori dei paesi stranieri. Dopo un solenne discorso di benvenuto pronunciato in tedesco dal professore di antichità romane, Jacob Hermann presentò una dissertazione in latino sull'origine e lo sviluppo della geometria (pubblicata poi nel 1735 [Le Roy s.d.]). Hermann, convinto che i geometri potessero trovare nella storia nuovi stimoli per le loro ricerche, nella prima parte del suo discorso tracciò la storia della geometria dall'antichità al XVIII secolo. Egli distingue tre epoche principali: l'infanzia della geometria, che comincia con Talete e Pitagora per culminare con Euclide, Archimede e Apollonio; dopo uno *hiatus*, ovvero un periodo di ristagno della geometria, la seconda fase, indicata con *medium ævum*, si apre con Viète ed è dominata dalla figura di Descartes; la terza epoca, inaugurata dalla pubblicazione della *Nova methodus* (1684) di Leibniz e ancora in corso, è quella della *geometria sublimior*.

---

[7] Gli stipendi concessi agli accademici potevano arrivare anche fino al triplo di una quota base. Sebbene in letteratura vengano citate cifre contraddittorie, Delisle e Hermann guadagnavano almeno il triplo di quello che veniva corrisposto a giovani esordienti come Daniel Bernoulli. Il giovanissimo Eulero venne assunto con un salario ancora inferiore.

Hermann sottolinea il rigore dei metodi degli antichi, ma giudicandoli goffi in relazione ai potenti e sbrigativi metodi del calcolo differenziale e integrale, arrivando fino a considerare la *scrupulositas in demonstrando* della geometria greca come un ostacolo all'innovazione:

> Sembra poi che la raffinata scrupolosità dimostrativa degli Antichi abbia costituito un ostacolo che impediva loro di allargare il sacro recinto della Geometria: gli Antichi preferirono infatti una sicura navigazione sotto costa piuttosto che avventurarsi su una piccola zattera nel mare aperto della scienza, a rischio di naufragio [Nagel e Verdun 2005, p. 128][8].

Grazie a Descartes, Pascal, Beaune, Van Schooten, Sluse, Sturm e Barrow, la geometria dell'età di mezzo oltrepassa le coniche apolloniane e la geometria archimedea, ma non raggiunge imprese compiute nell'età matura, quella della *geometria sublimior*, rese possibili dai risultati di Fermat, Wallis e Barrow sul calcolo delle tangenti e il metodo *de maximis et minimis*. Hermann rende omaggio ai *Principia* (1687) di Newton, ma ricorda anche che in quest'opera non c'è molto sul calcolo delle flussioni, reso pubblico solo nel 1704. Viene messa in rilievo l'evoluzione dei metodi di calcolo leibniziano, sviluppati dai fratelli Jacob e Johann Bernoulli, dei quali espone dettagliatamente i risultati. Hermann definisce l'*Analyse des infiniment petits* del marchese de l'Hôpital un «elegantissimum opus» e minimizza la polemica sulla priorità della scoperta del calcolo differenziale. Conclude affermando: «Sicuramente Leibniz ha avuto molto merito nei confronti del pubblico, dal momento che per primo diede alle stampe la sua invenzione e ha cosí offerto, al momento giusto, l'occasione di estendere il recinto sacro della scienza» [*ibid.*, p. 131][9]. Hermann ci offre qui una concezione teleologica della storia, in cui le tappe precedenti sono interpretate unicamente in funzione del livello raggiunto dalla matematica a lui contemporanea.

[8] «Dein exquisita antiquorum scrupulositas in demonstrando obstaculum fuisse videtur, quod Geometriæ pomœria non longius protenderint, maluerunt enim geometriæ ripas tuto peragrare quam ratem alto scientiæ Oceano committere, parum securi a naufragio».

[9] «Et sane Leibnitius de Publico optime meritus est, quod inventum suum primus publicavit atque pomœria Scientiarum extendi occasionem mature præbuit».

Fino alla sua partenza da San Pietroburgo nel 1731, Hermann presentò regolarmente delle memorie sulla risoluzione delle equazioni differenziali, sulla misura delle forze o la teoria dei moti. Insegnava analisi e algebra il lunedí, mercoledí, giovedí e sabato, dalle 11 alle 12; fu incaricato dal vicecancelliere dell'impero russo, Johann Heinrich Ostermann, di redigere un *Abrégé des mathématiques*, apparso nel 1728 in francese e in traduzione russa. Questo manuale, composto in forma di dialogo, doveva contribuire all'istruzione matematica dello zar Pietro II, all'epoca dodicenne, ed era articolato in tre volumi, ciascuno dedicato a un alto dignitario dell'impero. Il primo era consacrato all'aritmetica, alla geometria e alla trigonometria; il terzo alle fortificazioni. Il secondo volume, opera di Delisle, trattava l'astronomia e la geografia. Mi sembra che i meccanismi del mecenatismo che operano in questo contesto siano chiaramente identificabili: un accademico come Hermann, matematico già affermato, può dedicarsi alle proprie ricerche, ma in cambio deve prendere in carico anche l'insegnamento e redigere un manuale da offrire ai suoi protettori.

3.3. Un «paradiso degli eruditi».

Cosí Wolff definiva la situazione a Pietroburgo. E in effetti i giovani, in particolare Daniel Bernoulli (Nicolaus era morto prematuramente nel luglio 1726), Eulero e Johann Georg Krafft, seppero trarre ampio profitto dalle condizioni di lavoro che venivano loro offerte: la possibilità di dedicarsi interamente alla scienza nell'ambito di un circolo di intellettuali con cui potevano discutere e scambiare idee. Anche il giovane Eulero proveniva da Basilea come i due Bernoulli ed era allievo di Johann. Già nel 1725, appena diciottenne, provava «l'indescrivibile desiderio di intraprendere il viaggio per Pietroburgo con i Bernoulli» [Fellmann 1995, p. 12]. Di fatto, grazie alla raccomandazione dei Bernoulli e di Goldbach, dal giugno 1727 poté essere accolto nella nuova Accademia. Arrivò a Pietroburgo il 24 maggio, quando la città era in lutto per la morte recentissima (17 maggio) della zarina Caterina I. Sappiamo che il giovane Eulero andò a pranzo da Hermann e a cena da Daniel Bernoulli, presso cui avrebbe poi abitato fino a quando, nel 1731, poté occupare la cattedra di fisica.

Di che cosa avranno discusso questi due giovani la sera di quel 24 maggio 1727? Forse già di idraulica, il loro campo d'indagine preferito. Tanto Daniel quanto Eulero, buoni allievi di Johann Bernoulli, risolsero alcuni problemi di idraulica applicando il principio delle forze vive (equivalente alla conservazione dell'energia cinetica $\frac{1}{2}mv^2$). I *Commentarii Academiae Petropolitanae* degli anni 1727 e 1729 documentano gli studi di Bernoulli sul flusso d'acqua in uscita da diversi recipienti di forma irregolare, dotati di un foro d'apertura di dimensione finita (e questo rappresentava una novità, dal momento che ci si limitava a considerare fori d'apertura di dimensione infinitamente piccola). Dai verbali sappiamo che anche Eulero lavorava su problemi analoghi, tuttavia i suoi studi non vennero mai pubblicati. L'emulazione fra i due amici era tale che Eulero fu portato a testimoniare che Daniel, accusato di plagio da uno degli altri accademici[10], aveva ottenuto i suoi risultati in idraulica in maniera indipendente dalla sua. Nel giugno 1729, Bernoulli fece trasmettere al presidente dell'Accademia il seguente programma:

> ho iniziato già da 6 mesi un trattato molto completo sulle leggi del moto delle acque, che conterà circa 40 fogli; [...] quest'opera mi terrà impegnato quasi giorno e notte fino alla scadenza dei miei impegni, perché non ho avuto alcun aiuto dagli autori che, fino alla formulazione del nuovo principio di conservazione delle forze vive, non avevano potuto ridurre le suddette leggi alla pura Geometria. Un'altra ragione che ritarderà la conclusione di quest'opera è il gran numero di esperimenti che ci toccherà fare [Nagel e Verdun 2005, p. 139].

Quando partirà da Pietroburgo nel 1733, lascerà un manoscritto di 400 pagine, quello della famosa *Hydrodynamica*[11], che sarà pubblicata poi a Strasburgo. Nel corso di quattro anni, Daniel seppe approfittare della libertà di ricerca che gli venne accordata a Pietroburgo per redigere questo trattato, che divenne il fondamento di una disciplina, cui egli stesso diede il nome, come testimonia in una lettera a Goldbach del 17 luglio 1730:

> Per quanto mi riguarda, mi sono interamente immerso nelle acque che hanno costituito la mia unica occupazione e rinuncio da qualche tempo a occuparmi di tutto ciò che non sia idrostatica o idraulica [...] Ho l'onore di dirvi che, nei giorni scorsi, ho fatto qualche nuova scoperta che può essere proficuamente utilizzata nella struttura dei condotti idraulici, ma che soprattutto inaugurerà una nuova stagione per la fisiologia; fatto sta che ho studiato la statica delle acque correnti, scienza che (a quanto ne so) nessuno aveva mai considerato prima di me e che, se pur se ne fosse intrapreso lo studio, sarebbe risultato molto lacunoso, dal momento che non erano stati ancora formulati i principî di cui mi servo e che sono stati pienamente confermati da un gran numero di esperienze [*ibid.*, p. 140].

Nella *Hydrodynamica*, si trova in particolare l'equazione di Bernoulli che esprime la conservazione dell'energia (*vis viva*) lungo una linea di flusso.

[10] Si tratta del fisico Georg Bernhard Bülfinger (1693-1750), originario di Tubinga. Nei verbali dell'Accademia imperiale, sono conservate notizie di discussioni accese, sulla questione delle forze vive, fra Hermann e Bülfinger da una parte e Bernoulli ed Eulero dall'altra.

FAMILY OF CIRCLES

In this article, we will learn about family of circles, common tangents and angle of intersection of two circles. These are very important concept which are frequently asked in JEE.

Family of Circles

A collection of circles is called a system or family of circles. There can be various types of family of circles. The general equation of a circle is $x^2 + y^2 + 2gx + 2fy + c = 0$. Since, this equation involves three unknowns, *viz.*, g, f and c, so we need atleast three conditions to get a unique circle.

Theorem 1

The equation of a family of circles passing through the intersection of a circle $S \equiv x^2 + y^2 + 2gx + 2fy + c = 0$ and line

$$L \equiv lx + my + n = 0 \text{ is}$$

$$x^2 + y^2 + 2gx + 2fy + c + \lambda(lx + my + n) = 0$$

or $$S + \lambda L = 0$$

where, λ is any real number.

Example 1 The intercept on the line $y = x$ by the circle $x^2 + y^2 - 2x = 0$ is AB. Equation of the circle with AB as a diameter is

(a) $x^2 + y^2 + x + y = 0$ (b) $x^2 + y^2 - x - y = 0$
(c) $x^2 + y^2 - x + y = 0$ (d) $x^2 + y^2 + x - y = 0$

Sol. **(b)** Equation of any circle passing through the point of intersection of $x^2 + y^2 - 2x = 0$ and $y = x$ is

$$S + \lambda L = 0$$

$$\Rightarrow \quad x^2 + y^2 - 2x + \lambda(y - x) = 0$$

$$\Rightarrow \quad x^2 + y^2 - (2 + \lambda)x + \lambda y = 0$$

Now, above circle has centre $\left[\left(\frac{2 + \lambda}{2}\right), \frac{-\lambda}{2}\right]$.

For AB to be the diameter of the required circle, the centre must be on AB.

$$\therefore \quad \frac{2 + \lambda}{2} = \frac{-\lambda}{2} \Rightarrow \lambda = -1$$

Therefore, equation of the required circle is

$$x^2 + y^2 - (2 - 1)x - y = 0$$

$$\Rightarrow \quad x^2 + y^2 - x - y = 0$$

Example 2 Equation of the smallest circle passing through the intersection of the line $x+y=1$ and the circle $x^2+y^2=9$ is

(a) $x^2+y^2-x-y-8=0$
(b) $x^2+y^2+x+y+9=0$
(c) $x^2+y^2+2x+2y+4=0$
(d) $2x^2+2y^2-2x-2y-7=0$

Sol. **Key point** Smallest circle is that circle having given line as diameter.

(a) Any circle passing through the point of intersection of the given line and circle has the equation

$$x^2+y^2-9+\lambda(x+y-1)=0 \qquad \text{...(i)}$$

Its centre is $\left(\frac{-\lambda}{2}, \frac{-\lambda}{2}\right)$.

This circle is the smallest, if $\left(\frac{-\lambda}{2}, \frac{-\lambda}{2}\right)$ is on the chord $x+y-1=0$.

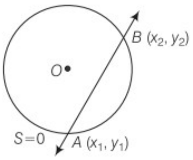
$$\therefore \quad \frac{-\lambda}{2}-\frac{\lambda}{2}-1=0 \Rightarrow \lambda=-1$$

On putting the value of λ in Eq. (i), the equation of the smallest circle is

$$x^2+y^2-9-1(x+y-1)=0$$
$$\Rightarrow \quad x^2+y^2-x-y-8=0$$

Theorem 2

The equation of the family of circles passing through the points $A(x_1, y_1)$ and $B(x_2, y_2)$ is



$$(x-x_1)(x-x_2)+(y-y_1)(y-y_2)+\lambda\begin{vmatrix} x & y & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix}=0$$

or $(x-x_1)(x-x_2)+(y-y_1)(y-y_2)+\lambda L=0$, where $L=0$ represents the line passing through $A(x_1, y_1)$ and $B(x_2, y_2)$ and $\lambda \in R$.

POINTS TO REMEMBER

1. If $x_2 \to x_1$ and $y_2 \to y_1$, then equation of the circle becomes $(x-x_1)^2+(y-y_1)^2+\lambda L=0$.
2. Also, when $x_2 \to x_1$ and $y_2 \to y_1$, then line AB becomes tangent to the circle $S=0$.

Example 3 The circle passing through $(1,-2)$ and touching the axis of X at $(3, 0)$, also passes through the point **[JEE Main 2013]**

(a) $(-5, 2)$ (b) $(2, -5)$ (c) $(5, -2)$ (d) $(-2, 5)$

Sol. **(c)** The equation of the circle touching X-axis, i.e. $y=0$ at $(3, 0)$ is

$$(x-3)^2+(y-0)^2+\lambda y=0 \qquad \text{...(i)}$$

$\because$ It passes through $(1,-2)$.

$$\therefore \quad (1-3)^2+(-2-0)^2-2\lambda=0$$
$$\Rightarrow \quad \lambda=4$$

Putting $\lambda=4$ in Eq. (i), we obtain

$$(x-3)^2+y^2+4y=0$$
$$\Rightarrow \quad x^2+y^2-6x+4y+9=0$$

Clearly, it passes through $(5,-2)$.

Example 4 If C_1, C_2 and C_3 belong to a family of circles through the points (x_1, y_1) and (x_2, y_2), then the ratio of lengths of the tangent from any point on C_1 to the circles is

(a) constant (b) cannot be determined
(c) equal to difference of x-coordinates
(d) equal to difference of y-coordinates

Sol. **(a)** Equation of the family of circles through (x_1, y_1) and (x_2, y_2) is

$$(x-x_1)(x-x_2)+(y-y_1)(y-y_2)+\lambda\begin{vmatrix} x & y & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix}=0$$

Let (h, k) be the point on C_1.

$$\Rightarrow \quad f(h,k)+\lambda_1 g(h,k)=0$$

where, $f(h,k)=(h-x_1)(h-x_2)+(k-y_1)(k-y_2)$

and $$g(h,k)=\begin{vmatrix} h & k & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix}$$

Let T_2 be the length of the tangent from (h,k) to C_2 and T_3 be the length of the tangent from (h, k) to C_3.

Then, $T_2=\sqrt{f(h,k)+\lambda_2 g(h,k)}$

and $T_3=\sqrt{f(h,k)+\lambda_3 g(h,k)}$

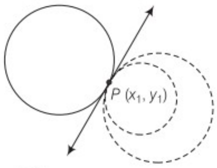
$$\therefore \quad \frac{T_2}{T_3}=\frac{\sqrt{f(h,k)+\lambda_2 g(h,k)}}{\sqrt{f(h,k)+\lambda_3 g(h,k)}}$$

$$\Rightarrow \quad \frac{T_2}{T_3}=\frac{\sqrt{(\lambda_2-\lambda_1)\,g(h,k)}}{\sqrt{(\lambda_3-\lambda_1)\,g(h,k)}}$$

$$\Rightarrow \quad \frac{T_2}{T_3}=\sqrt{\frac{\lambda_2-\lambda_1}{\lambda_3-\lambda_1}}=\text{Constant}$$

Theorem 3

The equation of the family of circles touching the circle $S \equiv x^2+y^2+2gx+2fy+c=0$ at point $P(x_1, y_1)$ is



$$x^2+y^2+2gx+2fy+c + \lambda\,[xx_1+yy_1+g(x+x_1)+f(y+y_1)+c]=0$$

or $S+\lambda L=0$, where $L=0$ is the equation of the tangent to $S=0$ at (x_1, y_1) and $\lambda \in R$.

POINTS TO REMEMBER

1. The equation of a family of circles touching a fixed line $y - y_1 = m(x - x_1)$ at the fixed point (x_1, y_1) is $(x - x_1)^2 + (y - y_1)^2 + k\,[y - y_1 - m(x - x_1)] = 0$, where k is a parameter.
2. In case the line through (x_1, y_1) is parallel to Y-axis, the equation of the family of circles touching it at (x_1, y_1) becomes $(x - x_1)^2 + (y - y_1)^2 + k(x - x_1) = 0$.
3. Also, if the line parallel to X-axis, then the equation of family of circles touching it at $(x_1, y_1) = 0$ becomes $(x - x_1)^2 + (y - y_1)^2 + k(y - y_1) = 0$.

Example 5 The circle passing through the point $(-1, 0)$ and touching the Y-axis at $(0, 2)$, also passes through the point **[IIT JEE 2011]**

(a) $\left(-\frac{3}{2}, 0\right)$ (b) $\left(-\frac{5}{2}, 2\right)$ (c) $\left(-\frac{3}{2}, \frac{5}{2}\right)$ (d) $(-4, 0)$

Sol. **(d)** The equation of the family of circles touching Y-axis at $(0, 2)$ is

$$(x - 0)^2 + (y - 2)^2 + \lambda x = 0$$

It passes through $(-1, 0)$.

$$1 + 4 - \lambda = 0 \Rightarrow \lambda = 5$$

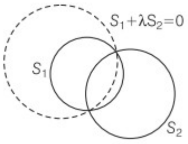
So, the equation of the circle is

$$x^2 + 5x + y^2 - 4y + 4 = 0$$

Clearly, it passes through $(-4, 0)$.

Theorem 4

The equation of a family of circles passing through the intersection of two circles



$$S_1 \equiv x^2 + y^2 + 2g_1x + 2f_1y + c_1 = 0$$

and $$S_2 \equiv x^2 + y^2 + 2g_2x + 2f_2y + c_2 = 0$$

is $$S_1 + \lambda S_2 = 0$$

i.e. $$(x^2 + y^2 + 2g_1x + 2f_1y + c_1) + \lambda\,(x^2 + y^2 + 2g_2x + 2f_2y + c_2) = 0,$$

where $\lambda\ (\neq -1)$ is an arbitrary real number.

Example 6 The equation of the circle passing through $(1, -3)$ and the points common to the two circles $x^2 + y^2 - 6x + 8y - 16 = 0$, $x^2 + y^2 + 4x - 2y - 8 = 0$ is

(a) $x^2 + y^2 - 4x + 6y + 24 = 0$
(b) $2x^2 + 2y^2 + 3x + y - 20 = 0$
(c) $3x^2 + 3y^2 - 5x + 7y - 19 = 0$
(d) None of the above

Sol. **(b)** The equation of circle is

$$(x^2 + y^2 - 6x + 8y - 16) + \lambda(x^2 + y^2 + 4x - 2y - 8) = 0$$

$\because$ It passes through $(1, -3)$.

$$\therefore \quad (1 + 9 - 6 - 24 - 16) + \lambda(1 + 9 + 4 + 6 - 8) = 0$$
$$\Rightarrow \quad -36 + \lambda(12) = 0$$
$$\Rightarrow \quad \lambda = 3$$

So, the equation of the required circle is

$$4x^2 + 4y^2 + 6x + 2y - 40 = 0$$
$$\Rightarrow \quad 2x^2 + 2y^2 + 3x + y - 20 = 0$$

Circle in Contact

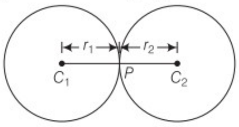
Let us discuss condition for two circles touching each other. Two circles can touch each other externally or internally.

Case I When Circles Touch Externally

When two circles touch each other externally, then distance between their centres is equal to sum of their radii,

i.e. $|C_1C_2| = r_1 + r_2$

In this case, point of contact P divides the line joining C_1 and C_2 internally in the ratio $r_1 : r_2$.



$$\Rightarrow \quad \frac{C_1P}{C_2P} = \frac{r_1}{r_2}$$

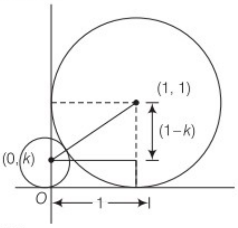
If $C_1(x_1, y_1)$ and $C_2(x_2, y_2)$, then the coordinates of P is

$$\left(\frac{r_1x_2 + r_2x_1}{r_1 + r_2}, \frac{r_1y_2 + r_2y_1}{r_1 + r_2}\right).$$

Example 7 Let C be the circle with centre $(1, 1)$ and radius 1 unit. If T is the circle centred at $(0, y)$ passing through origin and touching the circle C externally, then the radius of T is equal to **[IIT JEE 2014]**

(a) $\frac{\sqrt{3}}{\sqrt{2}}$ (b) $\frac{\sqrt{3}}{2}$ (c) $\frac{1}{2}$ (d) $\frac{1}{4}$

Sol. **(d)** Here, the radius of circle C is 1 unit and the radius of another circle T whose centre is $(0, y)$ and passing through the origin is $y = k$ (say).



From the figure,

Distance between the centres = Sum of radii

$$\sqrt{1+(1-k)^2} = k+1$$

$$\Rightarrow \quad 1+1+k^2-2k = k^2+1+2k$$

$$\Rightarrow \quad 4k = 1 \Rightarrow k = \frac{1}{4}$$

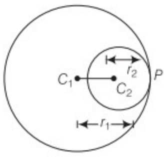
Hence, radius of circle T is $\frac{1}{4}$.

Case II When Circles Touch Internally

When two circles touch each other internally, then distance between their centres is equal to the difference of their radii,

i.e. $\quad |C_1C_2| = |r_1 - r_2|$

In such a case, point of contact P divide the line C_1 and C_2 enternally in the ratio $r_1 : r_2$.



$$\Rightarrow \quad \frac{C_1P}{C_2P} = \frac{r_1}{r_2}$$

If $C_1 \equiv (x_1, y_1)$ and $C_2 \equiv (x_2, y_2)$, then the coordinates of P is $\left(\frac{r_1x_2 - r_2x_1}{r_1 - r_2}, \frac{r_1y_2 - r_2y_1}{r_1 - r_2}\right)$.

Example ⑧ Two circles $x^2 + y^2 + 2ax + c^2 = 0$ and $x^2 + y^2 + 2by + c^2 = 0$ touch each other, then $\frac{1}{a^2} + \frac{1}{b^2}$ is equal to

(a) 1 (b) $\frac{1}{c^2}$

(c) 0 (d) None of these

Sol. **(b)** Given circles are

$$x^2 + y^2 + 2ax + c^2 = 0 \qquad \text{...(i)}$$

and

$$x^2 + y^2 + 2by + c^2 = 0 \qquad \text{...(ii)}$$

Let C_1 and C_2 be the centres of circles (i) and (ii) respectively and r_1, r_2 be their radii, then $C_1(-a, 0)$, $C_2(0, -b)$, $r_1 = \sqrt{a^2 - c^2}$, $r_2 = \sqrt{b^2 - c^2}$. Since, the circles touch each other externally or internally.

$$\therefore \quad |C_1C_2| = |r_1 \pm r_2|$$

$$\Rightarrow \quad \sqrt{a^2 + b^2} = \left|\sqrt{a^2 - c^2} \pm \sqrt{b^2 - c^2}\right|$$

On squaring both the sides, we get

$$a^2 + b^2 = a^2 - c^2 + b^2 - c^2 \pm 2\sqrt{(a^2 - c^2)(b^2 - c^2)}$$

$$\Rightarrow \quad c^2 = \pm\sqrt{(a^2 - c^2)(b^2 - c^2)}$$

$$\Rightarrow \quad c^2 = \pm\sqrt{a^2b^2 - c^2(a^2 + b^2) + c^4}$$

$$\Rightarrow \quad c^4 = a^2b^2 - c^2(a^2 + b^2) + c^4$$

$$\Rightarrow \quad c^2(a^2 + b^2) = a^2b^2 \Rightarrow \frac{1}{a^2} + \frac{1}{b^2} = \frac{1}{c^2}$$

Common Tangents to Two Circles

The number of common tangents depends upon the position of the given circles as discussed below. Let the equations of the two circles be

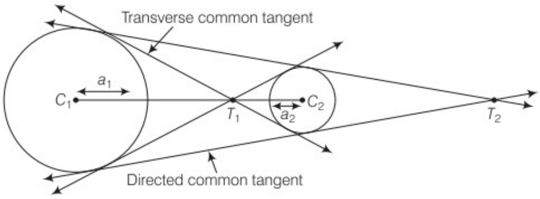
$$(x - h_1)^2 + (y - k_1)^2 = a_1^2 \qquad \text{...(i)}$$

and

$$(x - h_2)^2 + (y - k_2)^2 = a_2^2 \qquad \text{...(ii)}$$

with centres $C_1(h_1, k_1)$ and $C_2(h_2, k_2)$, and radii a_1 and a_2, respectively. Then, the following cases of intersection of these two circles may arises.

Case I When $C_1C_2 > a_1 + a_2$

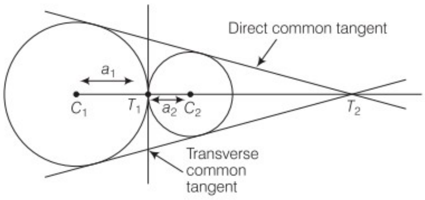


There are four common tangents that can be drawn to two circles. Two of them are direct common tangents and the other two are transverse common tangents. The points of intersection of direct and transverse common tangents always lie on the line joining the centres C_1 and C_2, and divide it internally and externally respectively in the ratio $a_1 : a_2$,

i.e. $\quad \frac{C_1T_2}{C_2T_2} = \frac{a_1}{a_2}$ (externally) and $\frac{C_1T_1}{C_2T_1} = \frac{a_1}{a_2}$ (internally).

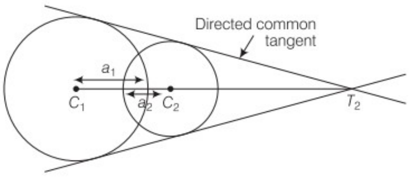
Case II When $C_1C_2 = a_1 + a_2$

In this case, two direct tangents are real and distinct while the transverse tangents are coincident.



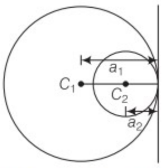
Case III When $C_1C_2 < a_1 + a_2$

In this case, the two direct common tangents are real while the transverse tangents are imaginary.



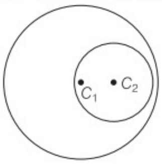
Case IV When $C_1C_2 = a_1 - a_2$

In this case, two tangents are real and coincident while the other two tangents are imaginary.



Case V When $C_1C_2 < a_1 - a_2$

In this case, all the four common tangents are imaginary.



Example 9 How many common tangents can be drawn to the circles $x^2 + y^2 = 6x$ and $x^2 + y^2 + 6x + 2y + 1 = 0$?

(a) 4 (b) 3
(c) 2 (d) 1

Sol. **(a)** The coordinates of the given circles are $C_1(3, 0)$, $C_2(-3, -1)$ and corresponding radii are $r_1 = 3$ and $r_2 = 3$, respectively.

Now, $C_1C_2 = \sqrt{(3+3)^2 + (0+1)^2} = \sqrt{37}$

and $r_1 + r_2 = 3 + 3 = 6$

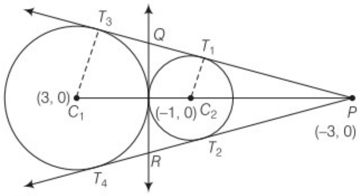
$\therefore$ $C_1C_2 > r_1 + r_2$

So, 4 common tangents can be drawn to the given circles.

Example 10 The common tangents to the circles $x^2 + y^2 + 2x = 0$ and $x^2 + y^2 - 6x = 0$ form a triangle which is

(a) equilateral
(b) isosceles
(c) right angled
(d) None of the above

Sol. **(b)** Clearly, the distance between the centres of the given circles is equal to the sum of their radii. So, two given circles will touch each other externally.



We have,

$$PT_1 = PT_2 \text{ and } PT_3 = PT_4$$

$\Rightarrow$ $T_1T_3 = T_2T_4$

$\Rightarrow$ $2T_1Q = 2T_2R$ $[\because QT_3 = QT_1 \text{ and } RT_4 = RT_2]$

$\Rightarrow$ $T_1Q = T_2R$

$\Rightarrow$ $PT_1 + T_1Q = PT_1 + T_2R$

$\Rightarrow$ $PT_1 + T_1Q = PT_2 + T_2R$

$\Rightarrow$ $PQ = PR$

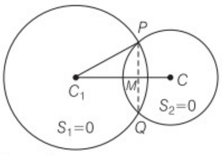
Hence, PQR is an isosceles triangle.

POINTS TO REMEMBER

1. Length of direct common tangent $= \sqrt{d^2 - (r_1 - r_2)^2}$.
2. Length of transverse common tangent $= \sqrt{d^2 - (r_1 + r_2)^2}$ where, d is distance between the circles and r_1, r_2 are radii.

Common Chord

The chord joining the points of intersection of two given circles is called their common chord. The equation of the common chord of two circles



$$S_1 \equiv x^2 + y^2 + 2g_1x + 2f_1y + c_1 = 0$$

and $S_2 \equiv x^2 + y^2 + 2g_2x + 2f_2y + c_2 = 0$

is $2x(g_1 - g_2) + 2y(f_1 - f_2) + c_1 - c_2 = 0$

i.e. $S_1 - S_2 = 0$.

Length of the Common Chord

From above figure, we have

$$PQ = 2\,PM = 2\sqrt{C_1P^2 - C_1M^2}$$

where, C_1P = Radius of the circle $S = 0$

and C_1M = Length of the perpendicular from the centre C_1 to the common chord PQ

Example 11 If the circle $x^2 + y^2 + 6x - 2y + k = 0$ bisect the circumference of the circle $x^2 + y^2 + 2x - 6y - 15 = 0$, then k is equal to

(a) 21 (b) – 21
(c) 23 (d) – 23

Sol. **(d)** The equation of common chord of the given circle is

$$4x + 4y + (k + 15) = 0 \quad \text{...(i)}$$

Since, $x^2 + y^2 + 6x - 2y + k = 0$ bisects the circumference of $x^2 + y^2 + 2x - 6y - 15 = 0$. Therefore, Eq. (i) is a diameter of the circle $x^2 + y^2 + 2x - 6y - 15 = 0$.

$\therefore$ $4(-1) + 4 \times 3 + k + 15 = 0$

$\Rightarrow$ $k = -23$

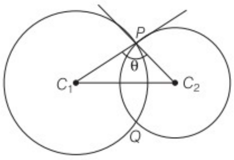
Angle of Intersection of Two Circles

The angle of intersection of two circles is defined as the angle between the tangents to the two circles at their point of intersection.

Let $x^2 + y^2 + 2g_1x + 2f_1y + c_1 = 0$

and $x^2 + y^2 + 2g_2x + 2f_2y + c_2 = 0$

be two circles having their centres at $C_1(-g_1, -f_1)$ and $C_2(-g_2, -f_2)$.



Then, $\cos\theta = \dfrac{C_1P^2 + C_2P^2 - C_1C_2^2}{2C_1P \cdot C_2P}$

Orthogonal Circles

Two circles are said to intersect orthogonally, if their angles of intersection is a right angle.

For two circles $x^2 + y^2 + 2g_1x + 2f_1y + c_1 = 0$ and $x^2 + y^2 + 2g_2x + 2f_2y + c_2 = 0$ cut orthogonally, the necessary condition is $2(g_1g_2 + f_1f_2) = C_1 + C_2$.

Example 12 The angle of intersection of the circles $x^2 + y^2 - 6x + 4y + 11 = 0$ and $x^2 + y^2 - 4x + 6y + 9 = 0$ is

(a) 30° (b) 45°
(c) 60° (d) 90°

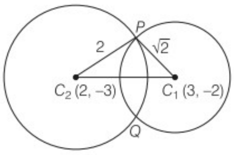
Sol. **(b)** The equations of the circles are

$$x^2 + y^2 - 6x + 4y + 11 = 0 \quad \text{...(i)}$$

and $$x^2 + y^2 - 4x + 6y + 9 = 0 \quad \text{...(ii)}$$

The centres of these circles are $C_1(3, -2)$ and $C_2(2, -3)$, respectively. Let r_1 and r_2 be their radii.

Then, $r_1 = \sqrt{9 + 4 - 11} = \sqrt{2}$ and $r_2 = \sqrt{4 + 9 - 9} = 2$



Also, $C_1C_2 = \sqrt{2}$

Suppose circles (i) and (ii) intersect at P.

Then,

$$\cos(\angle C_1PC_2) = \frac{C_1P^2 + C_2P^2 - C_1C_2^2}{2C_1P \cdot C_2P} = \frac{2 + 4 - 2}{2 \times \sqrt{2} \times 2} = \frac{1}{\sqrt{2}}$$

$$\Rightarrow \quad \angle C_1PC_2 = 45°$$

Smart Practice

1. C_1 and C_2 are circles of unit radius with centres at (0, 0) and (1, 0), respectively. C_3 is a circle of unit radius. It passes through the centres of the circles C_1 and C_2, and its centre above the X-axis. Then, the equation of the common tangent to C_1 and C_3 which does not pass through C_2, is

(a) $\sqrt{3}x + y - 2 = 0$ (b) $\sqrt{3}y + x - 2 = 0$
(c) $\sqrt{3}x - y + 2 = 0$ (d) $\sqrt{3}y - x - 2 = 0$

2. The radius of the smallest circle which touches the straight line $3x - y = 6$ at $(1, -3)$ and also touches the line $y = x$, is (compute upto one place of decimal only)

(a) 2.5 (b) 1.5 (c) 3.5 (d) 4.5

3. A rhombus is inscribed in the region common to the two circles $x^2 + y^2 - 4x - 12 = 0$ and $x^2 + y^2 + 4x - 12 = 0$ with two of its vertices on the line joining the centres of the circles. The area of the rhombus is

(a) $8\sqrt{3}$ sq units (b) $4\sqrt{3}$ sq units
(c) $6\sqrt{3}$ sq units (d) None of these

4. Two circles with radii a and b touch each other externally such that θ is the angle between the direct common tangents $(a > b \geq 2)$. Then,

(a) $\theta = 2\cos^{-1}\left(\dfrac{a - b}{a + b}\right)$

(b) $\theta = 2\tan^{-1}\left(\dfrac{a + b}{a - b}\right)$

(c) $\theta = 2\sin^{-1}\left(\dfrac{a + b}{a - b}\right)$

(d) $\theta = 2\sin^{-1}\left(\dfrac{a - b}{a + b}\right)$

5. The angle at which the circles $(x - 1)^2 + y^2 = 10$ and $x^2 + (y - 2)^2 = 5$ intersect, is

(a) $\dfrac{\pi}{6}$ (b) $\dfrac{\pi}{4}$
(c) $\dfrac{\pi}{3}$ (d) $\dfrac{\pi}{2}$

6. If the line $x\cos\theta + y\sin\theta = 2$ is the equation of a transverse common tangent to the circles $x^2 + y^2 = 4$ and $x^2 + y^2 - 6\sqrt{3}x - 6y + 20 = 0$, then the value of θ is

(a) $\dfrac{5\pi}{6}$ (b) $\dfrac{2\pi}{4}$
(c) $\dfrac{\pi}{3}$ (d) $\dfrac{\pi}{6}$

7. If $C_1 : x^2 + y^2 - 20x + 64 = 0$ and $C_2 : x^2 + y^2 + 30x + 144 = 0$, then the length of the shortest line segment PQ which touches C_1 at P and C_2 at Q, is

(a) 20
(b) 15
(c) 22
(d) 27

8. The coordinates of two points P and Q are (x_1, y_1) and (x_2, y_2) and O is the origin. If the circles are described on OP and OQ as diameters, then the length of their common chord is

(a) $\dfrac{|x_1y_2 + x_2y_1|}{PQ}$
(b) $\dfrac{|x_1y_2 - x_2y_1|}{PQ}$
(c) $\dfrac{|x_1x_2 + y_1y_2|}{PQ}$
(d) $\dfrac{|x_1x_2 - y_1y_2|}{PQ}$

9. The equation of the circle passing through the point of intersection of the circles $x^2 + y^2 - 4x - 2y = 8$ and $x^2 + y^2 - 2x - 4y = 8$ and the point $(-1, 4)$ is

(a) $x^2 + y^2 + 4x + 4y - 8 = 0$
(b) $x^2 + y^2 - 3x + 4y + 8 = 0$
(c) $x^2 + y^2 + x + y - 8 = 0$
(d) $x^2 + y^2 - 3x - 3y - 8 = 0$

10. If the length of the common chord of two circles $x^2 + y^2 + 8x + 1 = 0$ and $x^2 + y^2 + 2\mu y - 1 = 0$ is $2\sqrt{6}$, then the value of μ are

(a) ± 2
(b) ± 3
(c) ± 4
(d) None of these

11. A circle C_1 of radius b touches the circle $x^2 + y^2 = a^2$ externally and has its centre on the positive X-axis, another circle C_2 of radius c touches the circle C_1 externally and has its center on the positive X-axis. Given $a < b < c$, the three circles have a common tangent, if a, b and c are in

(a) AP
(b) GP
(c) HP
(d) None of these

12. Consider a family of circles passing through two fixed points $A(3, 7)$ and $B(6, 5)$. The chords in which the circle $x^2 + y^2 - 4x - 6y - 3 = 0$ cuts the members of the family are concurrent at a point. Then, the coordinates of this point are

(a) $\left(\dfrac{7}{2}, \dfrac{9}{2}\right)$
(b) $\left(\dfrac{9}{2}, \dfrac{7}{2}\right)$
(c) $\left(-\dfrac{7}{2}, \dfrac{9}{2}\right)$
(d) $\left(\dfrac{9}{2}, -\dfrac{7}{2}\right)$

13. If the circles $x^2 + y^2 + 2x + 2ky + 6 = 0$ and $x^2 + y^2 + 2ky + k = 0$ intersect orthogonally, then k is equal to

(a) 2 or $-\dfrac{3}{2}$
(b) -2 or $-\dfrac{3}{2}$
(c) 2 or $\dfrac{3}{2}$
(d) -2 or $\dfrac{3}{2}$

14. The number of common tangents to the circles $x^2 + y^2 - 4x - 6y - 12 = 0$ and $x^2 + y^2 + 6x + 18y + 26 = 0$ is **[JEE Main 2015]**

(a) 3
(b) 4
(c) 1
(d) 2

15. If the circles $x^2 + y^2 + 4x + 22y + c = 0$ bisects the circumference of the circle $x^2 + y^2 - 2x + 8y - d = 0$, then $c + d$ is equal to

(a) 60
(b) 50
(c) 40
(d) 56

16. The circles having radii r_1 and r_2 intersect orthogonally. The length of their common chord is

(a) $\dfrac{2r_1r_2}{\sqrt{r_1^2 + r_2^2}}$
(b) $\dfrac{\sqrt{r_1^2 + r_2^2}}{2r_1r_2}$
(c) $\dfrac{r_1r_2}{\sqrt{r_1^2 + r_2^2}}$
(d) $\dfrac{\sqrt{r_1^2 + r_2^2}}{r_1r_2}$

17. The distance from the centre of the circle $x^2 + y^2 = 2x$ to the common chord of the circles $x^2 + y^2 + 5x - 8y + 1 = 0$ and $x^2 + y^2 - 3x + 7y - 25 = 0$ is

(a) 2
(b) 4
(c) $\dfrac{34}{13}$
(d) $\dfrac{26}{17}$

18. If the radii of the circle $(x - 1)^2 + (y - 2)^2 = 1$ and $(x - 7)^2 + (y - 10)^2 = 4$ are increasing uniformly w.r.t. time as 0.3 unit/s and 0.4 unit/s, then they will touch each other at t equal to

(a) 45 s
(b) 90 s
(c) 11 s
(d) 135 s

19. A circle is given by $x^2 + (y - 1)^2 = 1$. Another circle C touches it externally and also the X-axis. Then, the locus of its centre is

(a) $\{(x, y) : x^2 = 4y\} \cup \{(x, y) : y \le 0\}$
(b) $\{(x, y) : x^2 + (y - 1)^2 = 4\} \cup \{(x, y) : y \le 0\}$
(c) $\{(x, y) : x^2 = y\} \cup \{(0, y) : y \le 0\}$
(d) $\{(x, y) : x^2 = 4y\} \cup \{(0, y) : y \le 0\}$

20. A circle S passes through the point $(0, 1)$ and is orthogonal to the circles $(x - 1)^2 + y^2 = 16$ and $x^2 + y^2 = 1$. Then,

(a) radius of S is 8
(b) radius of S is 7
(c) centre of S is $(-7, 11)$
(d) centre of S is $(-8, 1)$

Do You Know

We all know 0 was invented by Aryabhatt. As far as the invention of digits 1-9 is concerned, these are believed to be invented in Arab. These digits are also known as Arabic Numerals. The first positional numerical system was developed in Babylon in the 2nd Millenium BC.

Answers with Explanation

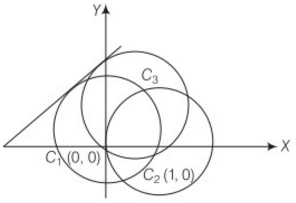
1. ***(c)*** The equation of any circle through (0, 0) and (1, 0) is

$$(x-1)(x-0)+(y-0)(y-0)+\lambda\begin{vmatrix} x & y & 1 \\ 0 & 0 & 1 \\ 1 & 0 & 1 \end{vmatrix}=0$$

$$\Rightarrow \qquad x^2+y^2-x+\lambda y=0$$

If it represents C_3, then its radius is 1.

$$\therefore \qquad 1=\frac{1}{4}+\frac{\lambda^2}{4} \quad \text{or} \quad \lambda=\pm\sqrt{3}$$



As the centre of C_3 lies above the X-axis. We take $\lambda=-\sqrt{3}$. Thus, an equation of C_3 is $x^2+y^2-x-\sqrt{3}y=0$. Since, C_1 and C_3 intersect and are of unit radius, their common tangents are parallel to the line joining their centres (0, 0) and $\left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right)$.

So, let the equation of a common tangent be $\sqrt{3}x-y+k=0$.

It will touch C_1, if $\dfrac{|k|}{\sqrt{3+1}}=1 \Rightarrow k=\pm 2$

2. ***(b)*** The equation of the circle touching the line $3x-y-6=0$ at $(1,-3)$ is given by

$$(x-1)^2+(y+3)^2+\lambda(3x-y-6)=0$$

$$\Rightarrow x^2+y^2+(3\lambda-2)x+(6-\lambda)y+10-6\lambda=0 \qquad \text{...(i)}$$

$\because$ Eq. (i) touches $y=x$. Therefore,

$$2x^2+(2\lambda+4)x+10-6\lambda=0$$

i.e.

$$x^2+(\lambda+2)x+5-3\lambda=0 \qquad \text{...(ii)}$$

has equal roots. Therefore,

$$(\lambda+2)^2-4(5-3\lambda)=\lambda^2+16\lambda-16=0$$

$$\Rightarrow \qquad \lambda=\frac{1}{2}[-16\pm\sqrt{256+64}]=-8\pm\sqrt{80}$$

Now, $(\text{Radius})^2=R^2$

$$=\frac{1}{4}[(3\lambda-2)^2+(6-\lambda)^2-(10-6\lambda)4]$$

$$=\frac{1}{4}[10\lambda^2]$$

$$\Rightarrow \qquad R=\frac{\sqrt{10}\lambda}{2}=\frac{\sqrt{10}}{2}(-8\pm4\sqrt{5})$$

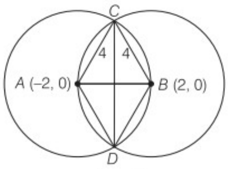
$$=\left|-4\sqrt{10}\pm10\sqrt{2}\right|$$

$\therefore$ Radius of smaller circle $=\left|-4\sqrt{10}+10\sqrt{2}\right|$

$$=1.5 \text{ (approx.)}$$

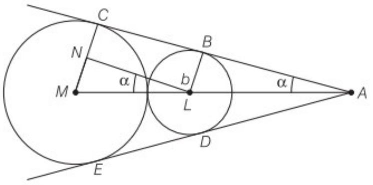
3. ***(a)*** The circles are with centres (2, 0) and (− 2, 0) and radius 4. Therefore, the Y-axis is their common chord.

$\therefore$ ABC is an equilateral triangle.



Hence, area of $ADBC=\dfrac{2\times\sqrt{3}}{4}(4)^2=8\sqrt{3}$ sq units

4. ***(d)***



From ΔMLN,

$$\sin\alpha=\frac{a-b}{a+b}$$

$$\Rightarrow \qquad \alpha=\sin^{-1}\left(\frac{a-b}{a+b}\right)$$

$\therefore$ Angle between AB and $AD=2\alpha=2\sin^{-1}\left(\dfrac{a-b}{a+b}\right)$

5. ***(b)*** For given $r_1=\sqrt{10}$, $C_1\equiv(1,0)$

and for $\qquad r_2=\sqrt{5}$, $C_2\equiv(0,2)$

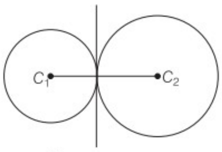
$\therefore \qquad d=C_1C_2=\sqrt{5}$

If θ is the angle between the circles, then

$$\cos\theta=\frac{|d^2-r_1^2-r_2^2|}{2r_1r_2}=\frac{|5-10-5|}{2\sqrt{10}\sqrt{5}}=\frac{1}{\sqrt{2}}$$

Hence, $\qquad \theta=\dfrac{\pi}{4}$

6. ***(d)*** $C_1C_2=r_1+r_2$



$C_1\equiv(0,0)$; $C_2\equiv(3\sqrt{3},3)$ and $r_1=2$, $r_2=4$

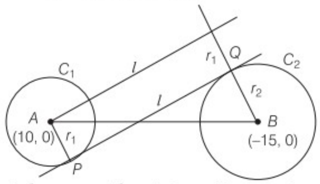
The circles touch each other externally.

The equation of common tangent is $\sqrt{3}x+y-4=0$.

Comparing it with $x\cos\theta+y\sin\theta=2$, we get $\theta=\dfrac{\pi}{6}$.

7. ***(a)*** The centres are $(10, 0)$ and $(-15, 0)$, and the radii are $r_1 = 6$ and $r_2 = 9$.

Also, $d = 25, r_1 + r_2 < d$



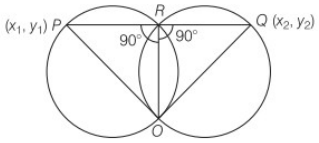
So, the circles are neither intersecting nor touching.

Therefore, $PQ = \sqrt{d^2 - (r_1 + r_2)^2}$

$= \sqrt{625 - 225} = \sqrt{400}$

$= 20$

8. ***(b)*** $OR = \dfrac{2 \times \text{Area of } \Delta OPQ}{PQ}$



$$= \frac{2 \times \left| \frac{1}{2}(x_1y_2 - x_2y_1) \right|}{PQ}$$

$$= \frac{|x_1y_2 - x_2y_1|}{PQ}$$

9. ***(d)*** The equation of any circle through the points of intersection of the given circles is

$$x^2 + y^2 - 4x - 2y - 8 + k(x^2 + y^2 - 2x - 4y - 8) = 0 \quad \text{...(i)}$$

Since, circle (i) passes through $(-1, 4)$, we have $k = 1$

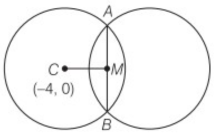
Therefore, the required circle is

$$x^2 + y^2 - 3x - 3y - 8 = 0.$$

10. ***(b)*** The common chord is $S_1 - S_2 = 0$.

i.e. $4x - \mu y + 1 = 0$

$\therefore AC = \text{Radius of first circle} = \sqrt{16}$



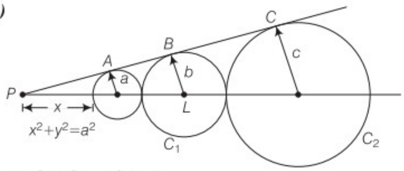
Also, $AM = \dfrac{AB}{2} = \sqrt{6}$

$\therefore \quad CM = 3$

$\Rightarrow \quad \dfrac{|-16 + 1|}{\sqrt{16 + \mu^2}} = 3$

$\Rightarrow \quad \mu = \pm 3$

11. ***(b)***



From the above figure,

$$\frac{a}{x} = \frac{b}{x + a + b} = \frac{c}{x + a + 2b + c}$$

$\therefore \quad ax + a^2 + ab = bx$ [comparing first two terms]

$\Rightarrow \quad x = \dfrac{a^2 + ab}{b - a}$

$\Rightarrow \quad ax + a^2 + 2ab + ac = cx$

[comparing first and third terms]

$\Rightarrow \quad x = \dfrac{a^2 + 2ab + ac}{c - a}$

$\therefore \quad \dfrac{a^2 + ab}{b - a} = \dfrac{a^2 + 2ab + ac}{c - a}$

$\Rightarrow a^2c - a^3 + abc - a^2b = a^2b + 2ab^2 + abc - a^3 - 2a^2 - b - a^2c$

$\Rightarrow \quad ac = b^2$

Therefore, a, b and c are in GP.

12. ***(a)*** The equation of the line passing through the points $A(3, 7)$ and $B(6, 5)$ is

$$y - 7 = -\frac{2}{3}(x - 3) \text{ or } 2x + 3y - 27 = 0$$

Also, the equation of the circle with A and B as the end points of diameter is

$$(x - 3)(x - 6) + (y - 7)(y - 5) = 0$$

Now, the equation of the family of circles through A and B is

$$(x - 3)(x - 6) + (y - 7)(y - 5) + \lambda(2x + 3y - 27) = 0 \quad \text{...(i)}$$

If the circle belonging to this family touches the X-axis.

Then, the equation

$(x - 3)(x - 6) + (0 - 7)(0 - 5) + \lambda\{2x + 3(0) - 27\} = 0$

has two equal roots for which discriminant $D = 0$.

It gives two values of λ.

The equation of the common chord of circle (i) and $x^2 + y^2 - 4x - 6y - 3 = 0$ is the radical axis which is

$$[(x - 3)(x - 6) + (y - 7)(y - 5) + \lambda(2x + 3y - 27)] - [x^2 + y^2 - 4x - 6y - 3] = 0$$

$\Rightarrow \quad (2\lambda - 5)x + (3\lambda - 6)y + (-27\lambda + 56) = 0$

$\Rightarrow \quad (-5x - 6y + 56) + \lambda(2x + 3y - 27) = 0$

This is the family of lines which passes through the point of intersection of $-5x - 6y + 56 = 0$ and $2x + 3y - 27 = 0$, i.e. $\left(2, \dfrac{23}{3}\right)$.

If circle (i) cuts $x^2 + y^2 = 29$ orthogonally, then

$$0 + 0 = -29 + 56 - 27\lambda = 0 \text{ or } \lambda = 1$$

So, the required circle is $x^2 + y^2 - 7x - 9y + 26 = 0$ and the centre is $\left(\dfrac{7}{2}, \dfrac{9}{2}\right)$.

13. ***(a)*** Given circles will intersect orthogonally, if

$$2(1 \times 0 + k \times k) = 6 + k$$

$$\Rightarrow \quad 2k^2 - k - 6 = 0$$

$$\Rightarrow \quad (2k + 3)(k - 2) = 0$$

$$\Rightarrow \quad k = 2, -\frac{3}{2}$$

14. ***(a)*** The coordinates of the centres and radii of the given circles are

$C_1 : (2, 3) \quad C_2 : (-3, -9)$

$r_1 : 5 \quad r_2 : 8$

We find $r_1 + r_2 = C_1C_2 = 13$. So, the two circles touch each other externally. Hence, there are 3 common tangents.

15. ***(b)*** The common chord of the given circles is

$$6x + 14y + c + d = 0 \qquad \text{...(i)}$$

Since, $x^2 + y^2 + 4x + 22y + c = 0$ bisects the circumference of the circle $x^2 + y^2 - 2x + 8y - d = 0$. So, the common chord (i) passes through the centre of the second circle, i.e. $(1, -4)$.

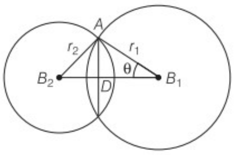
$$\therefore \quad 6 - 56 + c + d = 0 \Rightarrow c + d = 50$$

16. ***(a)*** Let $\angle AB_1B_2 = \theta$. Then,

$$AD = r_1 \sin\theta \text{ and } AD = r_2 \cos\theta$$

$$\therefore \quad AD^2\left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right) = 1$$

$$\Rightarrow \quad AD = \frac{r_1r_2}{\sqrt{r_1^2 + r_2^2}}$$



Thus, length of common chord is $\frac{2r_1r_2}{\sqrt{r_1^2 + r_2^2}}$.

17. ***(a)*** The centre of the circle $x^2 + y^2 = 2x$ is $(1, 0)$. The common chord of the other two circles is

$$8x - 15y + 26 = 0$$

The distance from $(1, 0)$ to $8x - 15y + 26 = 0$ is

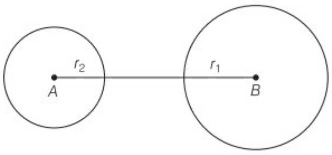
$$\frac{|8 + 26|}{\sqrt{15^2 + 8^2}} = 2$$

18. ***(b)*** Given circles are

$$(x - 1)^2 + (y - 2)^2 = 1 \qquad \text{...(i)}$$

and

$$(x - 7)^2 + (y - 10)^2 = 4 \qquad \text{...(ii)}$$



Let $A \equiv (1, 2), B \equiv (7, 10), r_1 = 1, r_2 = 2,$

$$AB = 10, r_1 + r_2 = 3$$

$$\because \quad AB > r_1 + r_2$$

Hence, the two circles are separated.

The radii of the two circles at time t are $(1 + 0.3t)$ and $(2 + 0.4t)$.

For the two circles to touch each other,

$$AB^2 = [(r_1 + 0.3t) \pm (r_2 + 0.4t)]^2$$

$$\Rightarrow \quad 100 = [(1 + 0.3t) \pm (2 + 0.4t)]^2$$

$$\Rightarrow \quad 100 = (3 + 0.7t)^2, [(0.1)t + 1]^2$$

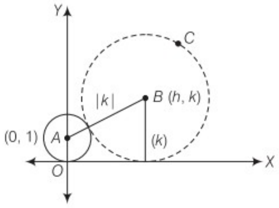
$$\Rightarrow \quad 3 + 0.7t = \pm 10, 0.1t + 1 = \pm 10$$

$$\therefore \quad t = 10, t = 90 \qquad [\because t > 0]$$

The two circles will touch each other externally in 10 s and internally in 90 s.

19. ***(d)*** Let the centre of the circle C be (h, k).

Then, as the circle touches the X-axis, its radius is $|k|$.



Also, it touches the given circle $x^2 + (y - 1)^2 = 1$ with centre $(0, 1)$ and radius 1, externally. Therefore,

Distance between centres = Sum of radii

$$\Rightarrow \quad \sqrt{(h - 0)^2 + (k - 1)^2} = 1 + |k|$$

$$\Rightarrow \quad h^2 + k^2 - 2k + 1 = 1 + 2|k| + k^2$$

$$\Rightarrow \quad h^2 = 2k + 2|k|$$

Therefore, the locus of (h, k) is $x^2 = 2y + 2|y|$.

Now, if $y > 0$, it becomes $x^2 = 4y$.

Also, if $y \le 0$, it becomes $x = 0$.

Combining the two, the required locus is

$$\{(x, y) : x^2 = 4y\} \cup \{(0, y) : y \le 0\}$$

20. ***(b)*** Let the circle S be $x^2 + y^2 + 2gx + 2fy + c = 0$. It is orthogonal to the circles $x^2 + y^2 - 2x - 15 = 0$ and $x^2 + y^2 - 1 = 0$.

Therefore, $2[g(-1) + f \times 0] = c - 15$

and $\quad 2[g \times 0 + f \times 0] = c - 1$

$$\Rightarrow \quad -2g = c - 15 \text{ and } c = 1$$

$$\Rightarrow \quad c = 1, g = 7$$

The circle S passes through $(0, 1)$.

$$\therefore \quad 1 + 2f + c = 0 \Rightarrow f = -1$$

Thus, the centre of the circle S is $(-7, 1)$ and radius is $\sqrt{49 + 1 - 1} = 7$.

‘0’ IS EITHER POSITIVE OR NEGATIVE

Asst. Prof. Naorem Rabei Singh
Pravabati College,
Mayang Imphal (MU)

ABOUT THE CHARACTER OF ZERO

0 is the integer immediately preceding 1. Zero is an even number because it is divisible by 2. Also, 0 is neither positive nor negative. By most definitions, 0 is number which quantifies a count or an amount of null size. In most cultures 0 was identified before the idea of negative things (quantities) that go lower than zero was accepted.

The number 0 is the smallest non-negative/non-positive integer. The natural number following 0 is 1 and no natural number precedes 0. The number 0 may or may not be considered a natural number but it is a whole number and hence a rational number and real number (as well as algebraic number and a complex number)

The number 0 is neither positive nor negative and appears in the middle of a number line.

As a new approach, the following theory is propounded.,

THEORY “0” (zero) has either positive or negative character.

PROOF Let’s discuss a simple division. Say 161 divided by 4

$$\begin{array}{l} 4\overline{\smash{)}161}\big(40 \\ \quad\underline{16} \\ \qquad 1 \\ \qquad \underline{0} \\ \qquad 1 \end{array}$$

Now, the remainder is 1 (one). Let us focus on this remainder. Generally, remainder occurs when something is taken out from something.

Mathematically, ‘Remainder’ occurs when a positive number is subtracted from a bigger positive number.

Then, 1 (one) cannot be called a remainder before subtracting 0 (zero) from 1 (one). But a question : why before or after subtracting 0 (zero) from 1 (one), 1 (one) itself exists arises. The answer to this question should be that 0 (zero) is a positive number, which is negligible. Hence, 0 (zero) has positive character.

Using “Euclid’s Division Lemma” which states as under

Let a and b be any two integers and $b > 0$. Then, there exists unique integers q and r such that $a = bq + r$ and $0 \leq r < b$. Here, q is called the quotient of a with respect to b and r is the remainder of a with respect to b. Any such type of division may be discussed.

Again, **Let us consider another case.**

We know that any positive number divided by zero is undefined.

Say $\frac{2}{0} = \infty$

Now, let us prove $\frac{2}{0} = \infty$

PROOF We get $\frac{2}{0.1} = 20$

$$\frac{2}{0.01} = 200$$

$$\frac{2}{0.001} = 2000$$

$$\frac{2}{0.0001} = 20000$$

....

$$\frac{2}{0.0001\,\ldots\ldots\ldots\,1} = 200\,\ldots\ldots\ldots$$

$$\Rightarrow \qquad \frac{2}{0} = 2000\,\ldots\ldots\ldots = \infty$$

It shows that $0.000\,\ldots\ldots\ldots\,1 = 0$

Therefore, zero is a positive number which is negligible.

Hence, 0 (zero) has positive character.

Also, we know that for any real number x having positive character, there exists number $(-x)$ having negative character. However, $0 = -0$; thereby 0 has negative character also.

Now, the concept, “0 is neither positive nor negative” is to be changed into “0 is either positive or negative”.

Let us, see the two series

(i) 0, 1, 2, 3,.......... (ii) – 0, – 1, – 2, – 3,........

Disclaimer,

This theory is propounded by N. Rabei Singh, Asst. Prof., P.B. College, Mayang Imphal (Manipur University). VECTOR

VECTOR TRIPLE PRODUCT

For any three vectors **a**, **b** and **c** the vectors $\mathbf{a}\times(\mathbf{b}\times\mathbf{c})$ and $(\mathbf{a}\times\mathbf{b})\times\mathbf{c}$ are called vector triple products of **a**, **b**, **c**.

If any three vectors are **a**, **b** and **c**, then

$$\mathbf{a}\times(\mathbf{b}\times\mathbf{c})=(\mathbf{a}\cdot\mathbf{c})\,\mathbf{b}-(\mathbf{a}\cdot\mathbf{b})\,\mathbf{c}$$

AID TO MEMORY

$\mathbf{a}\times(\mathbf{b}\times\mathbf{c})=(\mathbf{a}\cdot\mathbf{c})\,\mathbf{b}-(\mathbf{a}\cdot\mathbf{b})\,\mathbf{c}$ is written as

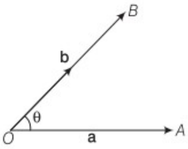
$\text{I}\times(\text{II}\times\text{III})=(\text{I}\cdot\text{III})\,\text{II}-(\text{I}\cdot\text{II})\,\text{III}$

PROPERTIES OF VECTOR TRIPLE PRODUCT

1. The vector triple product $\mathbf{a}\times(\mathbf{b}\times\mathbf{c})$ is a linear combination of those two vectors which are within brackets.

❶ THE SCALAR OR DOT PRODUCT

Let **a** and **b** be two non-zero vectors inclined at an angle θ. Then, the scalar product of **a** with **b** is denoted by $\mathbf{a}\cdot\mathbf{b}$ and is defined as the scalar $|\mathbf{a}||\mathbf{b}|\cos\theta$.



Thus, $\mathbf{a}\cdot\mathbf{b}=|\mathbf{a}||\mathbf{b}|\cos\theta$

REMARK If **a** or **b** or both is a zero vector, then θ is not defined as 0 has no direction. In this case their dot product $\mathbf{a}\cdot\mathbf{b}$ is defined as the scalar zero.

❷ PROJECTION

The projection of a vector is the scalar product of two vectors with the product of modulus of either vector and the projection of the other in its direction.

$\therefore$ Projection of **b** on $\mathbf{a}=\dfrac{\mathbf{a}\cdot\mathbf{b}}{|\mathbf{a}|}=\dfrac{\mathbf{a}}{|\mathbf{a}|}\cdot\mathbf{b}=\hat{\mathbf{a}}\cdot\mathbf{b}$

and projection of **a** on $\mathbf{b}=\dfrac{\mathbf{a}\cdot\mathbf{b}}{|\mathbf{b}|}=\dfrac{\mathbf{a}\cdot\mathbf{b}}{|\mathbf{b}|}=\mathbf{a}\cdot\hat{\mathbf{b}}$

❸ PROPERTIES OF SCALAR PRODUCT

Ⓐ **Property I** The scalar product of two vectors is commutative, i.e. $\mathbf{a}\cdot\mathbf{b}=\mathbf{b}\cdot\mathbf{a}$.

Ⓑ **Property II** The scalar product of vectors is distributive over vector addition, i.e.

(i) $\mathbf{a}\cdot(\mathbf{b}+\mathbf{c})=\mathbf{a}\cdot\mathbf{b}=\mathbf{a}\cdot\mathbf{c}$ [left distributive]

(ii) $(\mathbf{b}+\mathbf{c})\cdot\mathbf{a}=\mathbf{b}\cdot\mathbf{a}+\mathbf{c}\cdot\mathbf{a}$ [right distributive]

Ⓒ **Property III** Let **a** and **b** are two non-zero vectors. Then, $\mathbf{a}\cdot\mathbf{b}=0\Leftrightarrow\mathbf{a}\perp\mathbf{b}$

REMARK Since, $\hat{\mathbf{i}},\hat{\mathbf{j}}$ and $\hat{\mathbf{k}}$ are mutually perpendicular unit vectors along the coordinate axes. Therefore,

$$\hat{\mathbf{i}}\cdot\hat{\mathbf{j}}=\hat{\mathbf{j}}\cdot\hat{\mathbf{i}}=0,\ \hat{\mathbf{j}}\cdot\hat{\mathbf{k}}=\hat{\mathbf{k}}\cdot\hat{\mathbf{j}}=0,\ \hat{\mathbf{k}}\cdot\hat{\mathbf{i}}=\hat{\mathbf{i}}\cdot\hat{\mathbf{k}}=0$$

Ⓓ **Property IV** For any vector **a**, we have $\mathbf{a}\cdot\mathbf{a}=|\mathbf{a}|^2$

REMARK Since, $\hat{\mathbf{i}},\hat{\mathbf{j}}$ and $\hat{\mathbf{k}}$ are unit vectors along the coordinate axes. Therefore,

$\hat{\mathbf{i}}\cdot\hat{\mathbf{i}}=|\hat{\mathbf{i}}|^2=1,\ \hat{\mathbf{j}}\cdot\hat{\mathbf{j}}=|\hat{\mathbf{j}}|^2=1$ and $\hat{\mathbf{k}}\cdot\hat{\mathbf{k}}=|\hat{\mathbf{k}}|^2=1$

Ⓔ **Property V** If m is a scalar and **a**, **b** are any two vectors, then

$$(m\cdot\mathbf{a})\cdot\mathbf{b}=m(\mathbf{a}\cdot\mathbf{b})=\mathbf{a}\cdot(m\cdot\mathbf{b})$$

Ⓕ **Property VI** If m and n are scalars and **a**, **b** are two vectors, then

$m\mathbf{a}\cdot n\mathbf{b}=mn(\mathbf{a}\cdot\mathbf{b})=(mn\mathbf{a})\cdot\mathbf{b}=\mathbf{a}\cdot(mn\mathbf{b})$

Ⓖ **Property VII** For any two vectors **a** and **b**, we have

(i) $\mathbf{a}\cdot(-\mathbf{b})=-(\mathbf{a}\cdot\mathbf{b})=(-\mathbf{a})\cdot\mathbf{b}$

(ii) $(-\mathbf{a})\cdot(-\mathbf{b})=\mathbf{a}\cdot\mathbf{b}$

Ⓗ **Property VIII** For any two vectors **a** and **b**, we have

(i) $|\mathbf{a}+\mathbf{b}|^2=|\mathbf{a}|^2+|\mathbf{b}|^2+2\mathbf{a}\cdot\mathbf{b}$

(ii) $|\mathbf{a}-\mathbf{b}|^2=|\mathbf{a}|^2+|\mathbf{b}|^2-2\mathbf{a}\cdot\mathbf{b}$

(iii) $(\mathbf{a}+\mathbf{b})\cdot(\mathbf{a}-\mathbf{b})=|\mathbf{a}|^2-|\mathbf{b}|^2$

(iv) $|\mathbf{a}+\mathbf{b}|^2+|\mathbf{a}-\mathbf{b}|^2=2(|\mathbf{a}|^2+|\mathbf{b}|^2)$

(v) $|\mathbf{a}+\mathbf{b}|=|\mathbf{a}-\mathbf{b}|\Leftrightarrow\mathbf{a}\perp\mathbf{b}$

(vi) $|\mathbf{a}+\mathbf{b}|=|\mathbf{a}|+|\mathbf{b}|\Leftrightarrow\mathbf{a}$ is parallel to **b**.

(vii) $|\mathbf{a}+\mathbf{b}|^2=|\mathbf{a}|^2+|\mathbf{b}|^2$

$\Leftrightarrow$ **a** and **b** are orthogonal.

Ⓘ **Property IX** If **a**, **b** and **c** are three vectors, then

$$|\mathbf{a}+\mathbf{b}+\mathbf{c}|^2=|\mathbf{a}|^2+|\mathbf{b}|^2+|\mathbf{c}|^2+2(\mathbf{a}\cdot\mathbf{b}+\mathbf{b}\cdot\mathbf{c}+\mathbf{c}\cdot\mathbf{a})$$

❹ SCALAR PRODUCT IN TERMS OF COMPONENTS

Let $\mathbf{a}=a_1\hat{\mathbf{i}}+a_2\hat{\mathbf{j}}+a_3\hat{\mathbf{k}}$ and $\mathbf{b}=b_1\hat{\mathbf{i}}+b_2\hat{\mathbf{j}}+b_3\hat{\mathbf{k}}$.

Then, by using the distributivity of dot products over vector addition, we get

$$\mathbf{a}\cdot\mathbf{b}=a_1b_1+a_2b_2+a_3b_3$$

❺ ANGLE BETWEEN TWO VECTORS

Let **a** and **b** be two vectors inclined at an angle θ.

Then, $\mathbf{a}\cdot\mathbf{b}=|\mathbf{a}||\mathbf{b}|\cos\theta$

$$\Rightarrow\quad\cos\theta=\frac{\mathbf{a}\cdot\mathbf{b}}{|\mathbf{a}|\cdot|\mathbf{b}|}$$

$$\Rightarrow\quad\theta=\cos^{-1}\left[\frac{\mathbf{a}\cdot\mathbf{b}}{|\mathbf{a}|\cdot|\mathbf{b}|}\right]$$

If $\quad\mathbf{a}=a_1\hat{\mathbf{i}}+a_2\hat{\mathbf{j}}+a_3\hat{\mathbf{k}}$

and $\quad\mathbf{b}=b_1\hat{\mathbf{i}}+b_2\hat{\mathbf{j}}+b_3\hat{\mathbf{k}}$,

then $\mathbf{a}\cdot\mathbf{b}=a_1b_1+a_2b_2+a_3b_3$

$$|\mathbf{a}|=\sqrt{a_1^2+a_2^2+a_3^2},\ |\mathbf{b}|=\sqrt{b_1^2+b_2^2+b_3^2}$$

$$\theta=\cos^{-1}\left[\frac{a_1b_1+a_2b_2+a_3b_3}{\sqrt{a_1^2+a_2^2+a_3^2}\,\sqrt{b_1^2+b_2^2+b_3^2}}\right]$$

❻ COMPONENTS OF A VECTOR ALONG AND PERPENDICULAR TO ANOTHER VECTOR

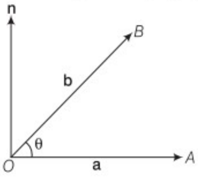
The component of **b** along and perpendicular to **a** are

$$\left\{\frac{\mathbf{a}\cdot\mathbf{b}}{|\mathbf{a}|^2}\right\}\mathbf{a}$$

and $\quad\mathbf{b}-\left\{\dfrac{\mathbf{a}\cdot\mathbf{b}}{|\mathbf{a}|^2}\right\}\mathbf{a}$, respectively.

❼ VECTOR OR CROSS PRODUCT

Let **a** and **b** are two non-zero, non-parallel vectors. Then, the vector product is defined as $\mathbf{a}\times\mathbf{b}$ in order as a vector whose magnitude is $|\mathbf{a}||\mathbf{b}|\sin\theta$.



where θ is the angle between **a** and **b** and whose direction is perpendicular to the plane of **a** and **b** in such a way that **a**, **b** and this direction constitute a right handed system.

$\therefore\quad\mathbf{a}\times\mathbf{b}=|\mathbf{a}||\mathbf{b}|\sin\theta\,\hat{\mathbf{n}}$

where, $\hat{\mathbf{n}}$ is a unit vector perpendicular to the plane of **a** and **b**.

Note
- If one of **a** or **b** or both is **0**, then θ is not defined as **0** has no direction and so $\hat{\mathbf{n}}$ is not defined. In such a case, $\mathbf{a}\times\mathbf{b}=\mathbf{0}$.
- If **a** and **b** are collinear, i.e. if $\theta=0$ or π, then the direction of $\hat{\mathbf{n}}$ is not well-defined and so in this case also $\mathbf{a}\times\mathbf{b}=\mathbf{0}$.

❽ PROPERTIES OF VECTOR PRODUCT

Ⓐ **Property I** Vector product is not commutative,

i.e. $\quad\mathbf{a}\times\mathbf{b}\neq\mathbf{b}\times\mathbf{a}$

However, $\mathbf{a}\times\mathbf{b}=-(\mathbf{b}\times\mathbf{a})$

Ⓑ **Property II** If **a** and **b** are two vectors and m is a scalar, then

$$m\cdot\mathbf{a}\times\mathbf{b}=m(\mathbf{a}\times\mathbf{b})=\mathbf{a}\times m\mathbf{b}$$

Ⓒ **Property III** If **a** and **b** are two vectors and m,n are scalars, then

$$m\mathbf{a}\times n\mathbf{b}=mn(\mathbf{a}\times\mathbf{b})=m(\mathbf{a}\times n\mathbf{b})=n(m\mathbf{a}\times\mathbf{b})$$

Ⓓ **Property IV** Let **a**, **b** and **c** be any three vectors, then

(i) $\mathbf{a}\times(\mathbf{b}+\mathbf{c})=\mathbf{a}\times\mathbf{b}+\mathbf{a}\times\mathbf{c}$ [left distributivity]

(ii) $(\mathbf{b}+\mathbf{c})\times\mathbf{a}=\mathbf{b}\times\mathbf{a}+\mathbf{c}\times\mathbf{a}$ [right distributivity]

Ⓔ **Property V** For any three vectors **a**, **b** and **c**, we have

$$\mathbf{a}\times(\mathbf{b}-\mathbf{c})=\mathbf{a}\times\mathbf{b}-\mathbf{a}\times\mathbf{c}$$

Ⓕ **Property VI** The vector product of two non-zero vectors is zero vector iff they are parallel (collinear),

PT MAP
sion Tool
PRODUCT

2. The vector $\mathbf{r} = \mathbf{a} \times (\mathbf{b} \times \mathbf{c})$ is perpendicular to **a** and lies in the plane **b** and **c**.
3. The formula $\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = (\mathbf{a} \cdot \mathbf{c})\,\mathbf{b} - (\mathbf{a} \cdot \mathbf{b})\,\mathbf{c}$ is true only when the vector outside the bracket is on the left-most side. If it is not we first shift on left by using the properties of cross product and then apply the same formula.
$$\begin{aligned}(\mathbf{b} \times \mathbf{c}) \times \mathbf{a} &= -\{\mathbf{a} \times (\mathbf{b} \times \mathbf{c})\}\\ &= -\{(\mathbf{a} \cdot \mathbf{c})\,\mathbf{b} - (\mathbf{a} \cdot \mathbf{b})\,\mathbf{c}\}\\ &= -(\mathbf{a} \cdot \mathbf{c})\,\mathbf{b} + (\mathbf{a} \cdot \mathbf{b})\,\mathbf{c}\end{aligned}$$
4. For any three vectors **a**, **b** and **c** are the value of $\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) + \mathbf{b} \times (\mathbf{c} \times \mathbf{a}) + \mathbf{c} \times (\mathbf{a} \times \mathbf{b})$ is zero. Thus, $\mathbf{a} \times (\mathbf{b} \times \mathbf{c})$, $\mathbf{b} \times (\mathbf{c} \times \mathbf{a})$, $\mathbf{c} \times (\mathbf{a} \times \mathbf{b})$ are coplanar.

i.e. $\mathbf{a} \times \mathbf{b} = \mathbf{0} \Leftrightarrow \mathbf{a} \,||\, \mathbf{b}$, where **a** and **b** are non-zero vectors.

REMARK It follows from the above property that $\mathbf{a} \times \mathbf{a} = \mathbf{0}$ for every non-zero vector **a**.

Ⓖ **Property VII** Vector product of orthogonal triad of unit vectors $\hat{\mathbf{i}}, \hat{\mathbf{j}}$ and $\hat{\mathbf{k}}$ are $\hat{\mathbf{i}} \times \hat{\mathbf{i}} = \hat{\mathbf{j}} \times \hat{\mathbf{j}} = \hat{\mathbf{k}} \times \hat{\mathbf{k}} = \mathbf{0}$

$$\hat{\mathbf{i}} \times \hat{\mathbf{j}} = \hat{\mathbf{k}}, \hat{\mathbf{j}} \times \hat{\mathbf{k}} = \hat{\mathbf{i}}, \hat{\mathbf{k}} \times \hat{\mathbf{i}} = \hat{\mathbf{j}}$$
$$\hat{\mathbf{j}} \times \hat{\mathbf{i}} = -\hat{\mathbf{k}}, \hat{\mathbf{k}} \times \hat{\mathbf{j}} = -\hat{\mathbf{i}}, \hat{\mathbf{i}} \times \hat{\mathbf{k}} = -\hat{\mathbf{j}}$$

Ⓗ **Property VIII** Let $\mathbf{a} = a_1\hat{\mathbf{i}} + a_2\hat{\mathbf{j}} + a_3\hat{\mathbf{k}}$ and $\mathbf{b} = b_1\hat{\mathbf{i}} + b_2\hat{\mathbf{j}} + b_3\hat{\mathbf{k}}$ be two vectors.

Then, $\mathbf{a} \times \mathbf{b} = \begin{vmatrix} \hat{\mathbf{i}} & \hat{\mathbf{j}} & \hat{\mathbf{k}} \\ a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \end{vmatrix}$

Ⓘ **Property IX** Unit vectors normal to the plane containing two non-zero, non-parallel vectors **a** and **b** are given by $\pm \dfrac{\mathbf{a} \times \mathbf{b}}{|\mathbf{a} \times \mathbf{b}|}$.

Ⓙ **Property X** The area of parallelogram with adjacent sides **a** and **b** is $|\mathbf{a} \times \mathbf{b}|$.

Ⓚ **Property XI** The area of a triangle with adjacent sides **a** and **b** is $\frac{1}{2}|\mathbf{a} \times \mathbf{b}|$.

Ⓛ **Property XII** The area of a ΔABC is $\frac{1}{2}|\mathbf{AB} \times \mathbf{AC}|$ or $\frac{1}{2}|\mathbf{BC} \times \mathbf{BA}|$ or $\frac{1}{2}|\mathbf{CB} \times \mathbf{CA}|$.

Ⓜ **Property XIII** The area of a parallelogram with diagonals **a** and **b** is $\frac{1}{2}|\mathbf{a} \times \mathbf{b}|$.

Ⓝ **Property XIV** The area of a plane quadrilateral *ABCD* is $\frac{1}{2}|\mathbf{AC} \times \mathbf{BD}|$, where **AC** and **BD** are its diagonals.

⑨ SCALAR TRIPLE PRODUCT

Let **a**, **b** and **c** be three vectors. Then, the scalar $(\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c}$ is called the scalar triple product of **a**, **b** and **c** and is denoted by $[\mathbf{a}\ \mathbf{b}\ \mathbf{c}]$.

Thus, $\quad [\mathbf{a}\ \mathbf{b}\ \mathbf{c}] = (\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c}$

The scalar triple product $[\mathbf{a}\ \mathbf{b}\ \mathbf{c}]$ represents the volume of the parallelopiped whose coterminous edges **a**, **b**, **c** form a right handed system of vectors.

⑩ PROPERTIES OF SCALAR TRIPLE PRODUCT

Ⓐ **Property I** If **a**, **b** and **c** are cyclically permuted, then value of scalar triple product remains same, i.e. $(\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c} = (\mathbf{b} \times \mathbf{c}) \cdot \mathbf{a} = (\mathbf{c} \times \mathbf{a}) \cdot \mathbf{b}$

or $\quad [\mathbf{a}\ \mathbf{b}\ \mathbf{c}] = [\mathbf{b}\ \mathbf{c}\ \mathbf{a}] = [\mathbf{c}\ \mathbf{a}\ \mathbf{b}]$

Ⓑ **Property II** The change of cyclic order of vectors in scalar triple product changes the sign of the scalar triple product but not the magnitude, i.e.
$$\begin{aligned}[\mathbf{a}\ \mathbf{b}\ \mathbf{c}] &= -[\mathbf{b}\ \mathbf{a}\ \mathbf{c}]\\ &= -[\mathbf{c}\ \mathbf{b}\ \mathbf{a}]\\ &= -[\mathbf{a}\ \mathbf{c}\ \mathbf{b}]\end{aligned}$$

Ⓒ **Property III** In scalar triple product, the positions of dot and cross can be interchanged provided that the cyclic order of the vectors remain same, i.e.
$$(\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c} = \mathbf{a} \cdot (\mathbf{b} \times \mathbf{c})$$

Ⓓ **Property IV** The scalar triple product of three vectors is zero, if any two of them are equal.

i.e. $\quad [\mathbf{a}\ \mathbf{a}\ \mathbf{c}] = 0$

Ⓔ **Property V** For any three vectors **a**, **b** and **c** and scalars λ, μ and ν, we have
$$[\lambda\mathbf{a}\ \mu\mathbf{b}\ \nu\mathbf{c}] = \lambda\mu\nu\ [\mathbf{a}\ \mathbf{b}\ \mathbf{c}]$$

Ⓕ **Property VI** The scalar triple product of three vectors is zero, if any two of them are parallel or collinear.

Ⓖ **Property VII** If **a**, **b**, **c** and **d** are four vectors, then
$$[\mathbf{a} + \mathbf{b}\ \mathbf{c}\ \mathbf{d}] = [\mathbf{a}\ \mathbf{c}\ \mathbf{d}] + [\mathbf{b}\ \mathbf{c}\ \mathbf{d}]$$

Ⓗ **Property VIII** Let $\mathbf{a} = a_1\hat{\mathbf{i}} + a_2\hat{\mathbf{j}} + a_3\hat{\mathbf{k}}$,
$$\mathbf{b} = b_1\hat{\mathbf{i}} + b_2\hat{\mathbf{j}} + b_3\hat{\mathbf{k}}$$
and $\quad \mathbf{c} = c_1\hat{\mathbf{i}} + c_2\hat{\mathbf{j}} + c_3\hat{\mathbf{k}}$

be the three vectors.

Then, we have
$$[\mathbf{a}\ \mathbf{b}\ \mathbf{c}] = \begin{vmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{vmatrix}$$

Ⓘ **Property IX** The necessary and sufficient condition for three non-zero, non-collinear vectors **a**, **b**, **c** to be coplanar,

i.e. $\quad [\mathbf{a}\ \mathbf{b}\ \mathbf{c}] = 0.$

Ⓙ **Property X** Four points with position vectors **a**, **b**, **c** and **d** will be coplanar, if
$$[\mathbf{d}\ \mathbf{b}\ \mathbf{c}] + [\mathbf{d}\ \mathbf{c}\ \mathbf{a}] + [\mathbf{d}\ \mathbf{a}\ \mathbf{b}] = [\mathbf{a}\ \mathbf{b}\ \mathbf{c}]$$

Ⓚ **Property XI** If **a**, **b**, **c** are three non-coplanar vectors and **A**, **B**, **C** are three vectors such that
$$\mathbf{A} = x_1\mathbf{a} + y_1\mathbf{b} + z_1\mathbf{c},$$
$$\mathbf{B} = x_2\mathbf{a} + y_2\mathbf{b} + z_2\mathbf{c}$$
and $\quad \mathbf{C} = x_3\mathbf{a} + y_3\mathbf{b} + z_3\mathbf{c}$, then
$$\therefore \quad [\mathbf{A}\ \mathbf{B}\mathbf{C}] = \begin{vmatrix} x_1 & y_1 & z_1 \\ x_2 & y_2 & z_2 \\ x_3 & y_3 & z_3 \end{vmatrix} [\mathbf{a}\ \mathbf{b}\ \mathbf{c}]$$

Ⓛ **Property XII** If **a**, **b**, **c** and **l**, **m**, **n** are two trials of vectors, then
$$[\mathbf{a}\ \mathbf{b}\ \mathbf{c}][\mathbf{l}\ \mathbf{m}\ \mathbf{n}] = \begin{vmatrix} \mathbf{a} \cdot \mathbf{l} & \mathbf{b} \cdot \mathbf{l} & \mathbf{c} \cdot \mathbf{l} \\ \mathbf{a} \cdot \mathbf{m} & \mathbf{b} \cdot \mathbf{m} & \mathbf{c} \cdot \mathbf{m} \\ \mathbf{a} \cdot \mathbf{n} & \mathbf{b} \cdot \mathbf{n} & \mathbf{c} \cdot \mathbf{m} \end{vmatrix}$$

Ⓜ **Property XIII** For any three vectors **a**, **b**, **c**,
$$[\mathbf{a}\ \mathbf{b}\ \mathbf{c}]^2 = \begin{vmatrix} \mathbf{a} \cdot \mathbf{a} & \mathbf{a} \cdot \mathbf{b} & \mathbf{a} \cdot \mathbf{c} \\ \mathbf{b} \cdot \mathbf{a} & \mathbf{b} \cdot \mathbf{b} & \mathbf{b} \cdot \mathbf{c} \\ \mathbf{c} \cdot \mathbf{a} & \mathbf{c} \cdot \mathbf{b} & \mathbf{c} \cdot \mathbf{c} \end{vmatrix}$$

Ⓝ **Property XIV** If **a**, **b**, **c**, **l**, **m** are vectors, then
$$[\mathbf{a}\ \mathbf{b}\ \mathbf{c}](\mathbf{l} \times \mathbf{m}) = \begin{vmatrix} \mathbf{a} & \mathbf{b} & \mathbf{c} \\ \mathbf{a} \cdot \mathbf{l} & \mathbf{b} \cdot \mathbf{l} & \mathbf{c} \cdot \mathbf{l} \\ \mathbf{a} \cdot \mathbf{m} & \mathbf{b} \cdot \mathbf{m} & \mathbf{c} \cdot \mathbf{m} \end{vmatrix}$$

⑪ VOLUME OF TETRAHEDRON

The volume of a tetrahedron whose three coterminous edges in the right handed system are **a**, **b** and **c** is $\frac{1}{6}[\mathbf{a}\ \mathbf{b}\ \mathbf{c}]$.

If A, B, C, D are the vertices of a tetrahedron *ABCD*, then its volume is numerically equal to
$$\frac{1}{6}[\mathbf{AB}\ \mathbf{AC}\ \mathbf{AD}]$$
or $\quad \frac{1}{6}[\mathbf{BC}\ \mathbf{BD}\ \mathbf{BA}]$

or $\quad \frac{1}{6}[\mathbf{CD}\ \mathbf{CB}\ \mathbf{CA}].$

RECIPROCAL SYSTEM OF VECTORS

Let **a**, **b** and **c** be three non-coplanar vectors and let
$$\mathbf{a}' = \frac{\mathbf{b} \times \mathbf{c}}{[\mathbf{a}\ \mathbf{b}\ \mathbf{c}]},$$
$$\mathbf{b}' = \frac{\mathbf{c} \times \mathbf{a}}{[\mathbf{a}\ \mathbf{b}\ \mathbf{c}]}$$
and $\quad \mathbf{c}' = \dfrac{\mathbf{a} \times \mathbf{b}}{[\mathbf{a}\ \mathbf{b}\ \mathbf{c}]}$

where, $\mathbf{a}', \mathbf{b}', \mathbf{c}'$ are said to form a reciprocal system of vectors for the vectors **a**, **b**, **c**.

CUBE ROOTS AND *n*th ROOTS OF UNITY

*n*TH ROOTS OF UNITY IS VERY IMPORTANT TOPIC OF COMPLEX NUMBER. SPECIALLY CUBE ROOTS OF UNITY (ω) IS ONE OF THE MOST IMPORTANT TOPIC FROM WHICH EVERY YEAR ATLEAST ONE QUESTION IS ASKED IN IIT JEE MAIN. THIS SECTION WILL COVER BASIC CONCEPT AND VARIOUS PROPERTIES OF CUBE ROOTS OF UNITY.

*n*th Roots of a Complex Number

Let $z = a + ib$ be a complex number and let $r(\cos\theta + i\sin\theta)$ be the polar form of z. Then, by De-Moivre's theorem,

$$z^{1/n} = r^{1/n}\left\{\cos\left(\frac{\theta}{n}\right) + i\sin\left(\frac{\theta}{n}\right)\right\}$$

where, $z^{1/n}$ has n distinct values.

Algorithm to Find the *n*th Roots of a Complex Number

Algorithm

***Step* I** Write the given complex number in polar form.

***Step* II** Add $2r\pi$ to the argument.

***Step* III** Apply De-Moivre's theorem.

***Step* IV** Put $r = 0, 1, 2, \ldots, (n-1)$, i.e. one less than the number in the denominator of the given index in the lowest form.

Example ① The number of roots of the equation $z^6 = -64$ whose real parts are non-negative, is

(a) 2 *(b)* 3 *(c)* 4 *(d)* 5

Sol. **(c)** We have, $z^6 = -64$

$$\Rightarrow \quad z = (-64)^{1/6}$$

$$\Rightarrow \quad z = 2(-1)^{1/6}$$

$$\Rightarrow \quad z = 2(\cos\pi + i\sin\pi)^{1/6}$$

$$\Rightarrow \quad z = 2\{\cos(2r\pi + \pi) + i\sin(2r\pi + \pi)\}^{1/6}, r \in Z$$

$$\Rightarrow z = 2\left\{\cos(2r+1)\frac{\pi}{6} + i\sin(2r+1)\frac{\pi}{6}\right\}; r = 0, 1, 2, 3, 4, 5$$

$$\Rightarrow z = 2\left(\frac{\sqrt{3}}{2} + \frac{i}{2}\right), 2i, 2\left(\frac{-\sqrt{3}}{2} + \frac{i}{2}\right), 2\left(\frac{-\sqrt{3}}{2} - \frac{i}{2}\right), -2i, 2\left(\frac{\sqrt{3}}{2} - \frac{i}{2}\right)$$

Clearly, four of these complex numbers have non-negative real parts.

POINT TO REMEMBER

De-Moivre's Theorem

If $n \in Z$, then $(\cos\theta + i\sin\theta)^n = \cos n\theta + i\sin n\theta$

*n*th Roots of Unity

Let $z = 1^{1/n} \Rightarrow z = (\cos 0 + i\sin 0)^{1/n}$

$\Rightarrow \quad z = (\cos 2r\pi + i\sin 2r\pi)^{1/n}$, where $r \in Z$

$\Rightarrow \quad z = \cos\dfrac{2r\pi}{n} + i\sin\dfrac{2r\pi}{n}$, where $r = 0, 1, 2, \ldots, (n-1)$

$\Rightarrow \quad z = e^{\frac{i2r\pi}{n}}; r = 0, 1, 2, \ldots, (n-1) \quad [\because e^{i\theta} = \cos\theta + i\sin\theta]$

$\Rightarrow \quad z = (e^{i2\pi/n})^r; r = 0, 1, 2, \ldots, (n-1)$

$\Rightarrow \quad z = \alpha^r$, where $\alpha = e^{\frac{i2\pi}{n}}$

Thus, nth roots of unity are

$$1\,(=\alpha^0), \alpha, \alpha^2, \alpha^3, \ldots, \alpha^{n-1},$$

where $\quad \alpha = e^{\frac{i2\pi}{n}} = \cos\left(\dfrac{2\pi}{n}\right) + i\sin\left(\dfrac{2\pi}{n}\right)$

Example 2 If z_1 and z_2 are two nth roots of unity, then $\arg\left(\dfrac{z_1}{z_2}\right)$ is a multiple of

(a) $n\pi$ (b) $\dfrac{3\pi}{n}$ (c) $\dfrac{2\pi}{n}$ (d) None of these

Sol. **(c)** We have, $z_1 = e^{\frac{i2r\pi}{n}}$ and $z_2 = e^{\frac{i2s\pi}{n}}$

where, r and s are integers lying between 0 and n including 0.

$\therefore \quad \arg\left(\dfrac{z_1}{z_2}\right) = \dfrac{2r\pi}{n} - \dfrac{2s\pi}{n} = 2(r-s)\dfrac{\pi}{n}$

Clearly, $\arg\left(\dfrac{z_1}{z_2}\right)$ is a multiple of $\dfrac{2\pi}{n}$.

Properties of *n*th Roots of Unity

Following are the properties of nth roots of unity

Property 1

nth roots of unity form a GP with common ratio $e^{i2\pi/n}$.

Property 2

Sum of nth roots of unity is always zero.

Let nth roots of unity are $1, \alpha, \alpha^2, \ldots, \alpha^{n-1}$.

$\therefore \quad 1 + \alpha + \alpha^2 + \ldots + \alpha^{n-1}$

$$= \frac{1-\alpha^n}{1-\alpha} = \frac{1-e^{i2\pi}}{1-\alpha} \qquad \left[\because \alpha = e^{\frac{i2\pi}{n}} \Rightarrow \alpha^n = e^{i2\pi}\right]$$

$$= \frac{1-1}{1-\alpha} = 0 \qquad [\because e^{i2\pi} = \cos 2\pi + i\sin 2\pi = 1]$$

Example 3 If α is a non-zero fourth root of unity, then the values of $\alpha^{4n-1} + \alpha^{4n-2} + \alpha^{4n-3}$, $n \in N$ is

(a) 0 (b) -1 (c) 3 (d) None of these

Sol. **(b)** $\alpha^{4n-1} + \alpha^{4n-2} + \alpha^{4n-3} = \alpha^{4n}(\alpha^{-1} + \alpha^{-2} + \alpha^{-3})$

$= \alpha^{-1} + \alpha^{-2} + \alpha^{-3} \qquad [\because \alpha^{4n} = 1]$

$= \alpha^3 + \alpha^2 + \alpha \qquad [\because \alpha^4 = 1]$

$= (1 + \alpha + \alpha^2 + \alpha^3) - 1$

$= 0 - 1 \qquad$ [$\because$ sum of nth roots of unity is always zero]

$= -1$

Property 3

Sum of pth powers of nth roots of unity is zero, if p is not a multiple of n.

Let nth roots of unity are $1, \alpha, \alpha^2, \ldots, \alpha^{n-1}$.

$\therefore \quad 1 + \alpha^p + (\alpha^2)^p + (r^3)^p + \ldots + (\alpha^{n-1})^p$

$$= 1 + \alpha^p + \alpha^{2p} + r^{3p} + \ldots + \alpha^{(n-1)p}$$

$$= \frac{1-(\alpha^p)^n}{1-\alpha^p} = \frac{1-(e^{i2\pi p/n})^n}{1-e^{i2\pi p/n}}$$

$$= \frac{1-e^{i2\pi p}}{1-e^{i2\pi p/n}} = \frac{1-1}{1-e^{i2\pi p/n}}$$

$$[\because e^{i2\pi p} = \cos 2\pi p + i\sin 2\pi p = 1]$$

$$= 0$$

Property 4

Sum of pth powers of nth roots of unity is n, if p is a multiple of n.

Let $p = \lambda n$, where $\lambda \in N$.

Then, $\quad \alpha^p = e^{\frac{i2\pi p}{n}} = e^{\frac{i2\pi\lambda n}{n}} = e^{i2\pi\lambda}$

$$= \cos 2\pi\lambda + i\sin 2\pi\lambda = 1$$

$\therefore \quad$ Sum of pth powers of nth roots of unity

$$= 1 + \alpha^p + \alpha^{2p} + \ldots + \alpha^{(n-1)p}$$

$$= 1 + 1 + 1 + \ldots + 1 = n$$

Property 5

Product of nth roots of unity is $(-1)^{n-1}$.

$\therefore$ Product $= 1 \cdot \alpha \cdot \alpha^2 \ldots \alpha^{n-1}$

$$= \alpha^{1+2+3+\ldots+(n-1)} = \alpha^{n(n-1)/2} = (\alpha^{n/2})^{n-1}$$

$$= (e^{i\pi})^{n-1} = (\cos\pi + i\sin\pi)^{n-1} = (-1)^{n-1}$$

Example 4 If $z_r = \cos\left(\dfrac{2r\pi}{5}\right) + i\sin\left(\dfrac{2r\pi}{5}\right)$; $r = 0, 1, 2, 3, 4$, then $z_0z_1z_2z_3z_4$ is equal to

(a) -1 (b) 0 (c) 1 (d) None of these

Sol. **(c)** Clearly, z_0, z_1, z_2, z_3, z_4 are fifth roots of unity. We know that the product of nth roots of unity is $(-1)^{n-1}$.

Therefore, $z_0z_1z_2z_3z_4 = (-1)^{5-1} = 1$

Cube Roots of Unity

Let $z = 1^{1/3}$

Then, $z^3 = 1 \quad \Rightarrow \quad z^3 - 1 = 0$

$\Rightarrow \quad (z-1)(z^2+z+1) = 0$

$\Rightarrow \quad z - 1 = 0 \text{ or } z^2 + z + 1 = 0$

$\Rightarrow \quad z = 1 \text{ or } z = \dfrac{-1 \pm \sqrt{3}i}{2}$

So, the cube roots of unity are 1, $(-1+\sqrt{3}i)/2$ and $(-1-\sqrt{3}i)/2$. Clearly, one of the roots of unity is real and other two are complex.

Note If we denote $\omega = \dfrac{-1+\sqrt{3}i}{2}$, then $\omega^2 = \dfrac{-1-\sqrt{3}i}{2}$.

Therefore, the cube roots of unity are 1, ω, ω^2.

Example 5 If ω is an imaginary cube root of unity, then the value of the expression $1(2-\omega)(2-\omega^2) + 2(3-\omega)(3-\omega^2) + \ldots + (n-1)(n-\omega)(n-\omega^2)$ is **[IIT JEE 2001]**

(a) $\left\{\dfrac{n(n+1)}{2}\right\}^2$ (b) $\left\{\dfrac{n(n+1)}{2}\right\}^2 - n$

(c) $\left\{\dfrac{n(n+1)}{2}\right\}^2 + n$ (d) None of these

Sol. **(b)** We have,

$$(z-1)(z-\omega)(z-\omega^2) = z^3 - 1$$

$$\therefore 1(2-\omega)(2-\omega^2) + 2(3-\omega)(3-\omega^2) + \ldots + (n-1)(n-\omega)(n-\omega^2)$$

$$= \sum_{r=2}^{n} (r-1)(r-\omega)(r-\omega^2)$$

$$= \sum_{r=2}^{n} (r^3 - 1) = \sum_{r=2}^{n} r^3 - \sum_{r=2}^{n} 1 = \sum_{r=1}^{n} r^3 - 1 - \sum_{r=2}^{n} 1$$

$$= \left[\frac{n(n+1)}{2}\right]^2 - 1 - (n-1) = \left\{\frac{n(n+1)}{2}\right\}^2 - n$$

Properties of Cube Roots

Following are the properties of the cube root of unity

(i) Cube roots of unity are 1, ω and ω^2, where $\omega = \dfrac{-1}{2} \pm i\dfrac{\sqrt{3}}{2} = e^{i2\pi/3}$.

(ii) $\arg(\omega) = \dfrac{2\pi}{3}$ and $\arg(\omega^2) = \dfrac{4\pi}{3}$

(iii) $z^3 - 1 = (z-1)(z-\omega)(z-\omega^2)$

(iv) ω and ω^2 are roots of the equation $z^2 + z + 1 = 0$.

(v) Cube roots of unity lie on the unit circle $|z| = 1$ and divide its circumference into three equal parts.

(vi) $1 + \omega^n + \omega^{2n} = \begin{cases} 0, & \text{if } n \text{ is not a multiple of } 3 \\ 3, & \text{if } n \text{ is a multiple of } 3 \end{cases}$

(vii) Cube roots of -1 are $-1, -\omega, -\omega^2$.

(viii) $z^3 + 1 = (z+1)(z+\omega)(z+\omega^2)$

(ix) $-\omega$ and $-\omega^2$ are roots of $z^2 - z + 1 = 0$.

(x) $a^3 + b^3 = (a+b)(a+b\omega)(a+b\omega^2)$

$a^3 - b^3 = (a-b)(a-b\omega)(a-b\omega^2)$

$a^2 + b^2 + c^2 - ab - bc - ca$
$= (a + b\omega + c\omega^2)(a + b\omega^2 + c\omega)$

$a^3 + b^3 + c^3 - 3abc$
$= (a+b+c)(a + b\omega + c\omega^2)(a + b\omega^2 + c\omega)$

Example 6 If ω is an imaginary cube root of unity, then the $(1+\omega-\omega^2)^7$ equals **[IIT JEE 1998]**

(a) 128ω (b) -128ω (c) $128\omega^2$ (d) $-128\omega^2$

Sol. **(d)** $(1+\omega-\omega^2)^7 = (-2\omega^2)^7 = -128\omega^2$

Example 7 If $z(2-2\sqrt{3}i)^2 = i(\sqrt{3}+i)^4$, then $\arg(z)$ is equal to

(a) $\dfrac{5\pi}{6}$ (b) $-\dfrac{\pi}{6}$ (c) $\dfrac{\pi}{6}$ (d) $\dfrac{7\pi}{6}$

Sol. **(b)** We have, $z(2-2\sqrt{3}i)^2 = i(\sqrt{3}+i)^4$

$$\Rightarrow \quad 4z(1-i\sqrt{3})^2 = i^5(1-i\sqrt{3})^4$$

$$\Rightarrow \quad 4z = i(1-i\sqrt{3})^2$$

$$\Rightarrow \quad 4z = i(-2\omega)^2$$

$$\Rightarrow \quad 4z = 4i\omega^2$$

$$\Rightarrow \quad z = i\omega^2 = \frac{\sqrt{3}}{2} - \frac{1}{2}i$$

Clearly, $\arg(z) = \dfrac{-\pi}{6}$

Example 8 Let $\omega\,(\neq 1)$ be a complex cube root of unity. If $(3-3\omega+2\omega^2)^{4n+3} + (2+3\omega-3\omega^2)^{4n+3} + (-3+2\omega+2\omega^2)^{4n+3} = 0$, then the set of possible value(s) of n is(are) **[JEE Advanced 2015]**

(a) N (b) $\{3k : k \in N\}$

(c) $N - \{3k : k \in N\}$ (d) $\{6k : k \in N\}$

Sol. **(c)** We have,

$$(3-3\omega+2\omega^2)^{4n+3} + (2+3\omega-3\omega^2)^{4n+3} + (-3+2\omega+3\omega^2)^{4n+3} = 0$$

$$\Rightarrow \quad (3-3\omega+2\omega^2)^{4n+3} + \{\omega(3-3\omega+2\omega^2)\}^{4n+3} + \{\omega^2(3-3\omega+2\omega^2)\}^{4n+3} = 0$$

$$\Rightarrow \quad (3-3\omega+2\omega^2)^{4n+3}(1+\omega^{4n+3}+\omega^{8n+6}) = 0$$

$$\Rightarrow \quad (3-3\omega+2\omega^2)^{4n+3}(1+\omega^{4n}+\omega^{8n}) = 0$$

$$\Rightarrow \quad (3-3\omega+2\omega^2)^{4n+3}(1+\omega^{n}+\omega^{2n}) = 0$$

$$\Rightarrow \quad 1+\omega^n+\omega^{2n} = 0$$

$\Rightarrow$ n is not a multiple of 3.

Hence, the set of values of n is $N - \{n : n = 3k, k \in N\}$

❶ ANGLE

Measure of an angle is the amount of rotation of a revolving line with respect to a fixed line. If the rotation is in clockwise sense, then the measure of the angle is negative and it is positive, if the rotation is in anti-clockwise sense.

There are three systems of measuring an angle *viz.*

(i) Sexagesimal system or English system
(ii) Circular system (iii) French system

First two of these systems are commonly used. In sexagesimal system, a right angle is divided in 90 equal parts called degrees. Further, each degree is divided into sixty equal parts called minutes and each minute is divided into sixty equal parts called seconds.

Thus, 1 right angle = 90 degrees (90°)

$1° = 60$ minutes $(60')$

$1' = 60$ seconds $(60'')$

In circular system the unit of measurement is radian. One radian is the angle made by an arc of length equal to radius of a given circle at its centre.

❷ RELATION BETWEEN DEGREE AND RADIAN

If D is the degree measure of an angle and R is its measure in radians, then $\frac{D}{90} = \frac{2R}{\pi}$

$\therefore 1 \text{ radian} = \frac{180}{\pi} \text{ degrees} = 57°17'45''$ (approximately)

and 1 degree $= \frac{\pi}{180}$ radian

❸ DOMAIN AND RANGE OF TRIGONOMETRICAL FUNCTIONS

	Domain	Range
$\sin A$	R	$[-1, 1]$
$\cos A$	R	$[-1, 1]$
$\tan A$	$R - \{(2n+1)\pi/2 : n \in Z\}$	R
$\cot A$	$R - \{n\pi : n \in Z\}$	R
$\operatorname{cosec} A$	$R - \{n\pi : n \in Z\}$	$R - (-1, 1)$
$\sec A$	$R - \{(2n+1)\pi/2 : n \in Z\}$	$R - (-1, 1)$

❹ SUM AND DIFFERENCE FORMULAE

1. $\sin(A + B) = \sin A \cos B + \cos A \sin B$
2. $\sin(A - B) = \sin A \cos B - \cos A \sin B$
3. $\cos(A + B) = \cos A \cos B - \sin A \sin B$
4. $\cos(A - B) = \cos A \cos B + \sin A \sin B$
5. $\tan(A + B) = \dfrac{\tan A + \tan B}{1 - \tan A \tan B}$
6. $\tan(A - B) = \dfrac{\tan A - \tan B}{1 + \tan A \tan B}$
7. $\cot(A + B) = \dfrac{\cot A \cot B - 1}{\cot B + \cot A}$
8. $\cot(A - B) = \dfrac{\cot A \cot B + 1}{\cot B - \cot A}$
9. $\cos(A + B)\cos(A - B) = \cos^2 A - \sin^2 B = \cos^2 B - \sin^2 A$
10. $\sin(A + B)\sin(A - B) = \sin^2 A - \sin^2 B = \cos^2 B - \cos^2 A$
11. $\sin 2\theta = 2 \sin\theta\cos\theta = \dfrac{2\tan\theta}{1 + \tan^2\theta}$
12. $\cos 2\theta = \cos^2\theta - \sin^2\theta = 2\cos^2\theta - 1 = 1 - 2\sin^2\theta = \dfrac{1 - \tan^2\theta}{1 + \tan^2\theta}$
13. $\cos^2\theta = \dfrac{1 + \cos 2\theta}{2}, \sin^2\theta = \dfrac{1 - \cos 2\theta}{2}$
14. $\tan 2\theta = \dfrac{2\tan\theta}{1 - \tan^2\theta}$
15. $\dfrac{1 - \cos\theta}{\sin\theta} = \tan\dfrac{\theta}{2}, \dfrac{1 + \cos\theta}{\sin\theta} = \cot\dfrac{\theta}{2}$
16. $\dfrac{1 - \cos\theta}{1 + \cos\theta} = \tan^2\dfrac{\theta}{2}, \dfrac{1 + \cos\theta}{1 - \cos\theta} = \cot^2\dfrac{\theta}{2}$
17. $\sin 3\theta = 3\sin\theta - 4\sin^3\theta$
18. $\cos 3\theta = 4\cos^3\theta - 3\cos\theta$
19. $\tan 3\theta = \dfrac{3\tan\theta - \tan^3\theta}{1 - 3\tan^2\theta}$
20. $\cos A \cos 2A \cos 2^2 A \ldots \cos 2^{n-1} A = \dfrac{\sin 2^n A}{2^n \sin A}$
21. $\sin\theta\sin(60° - \theta)\sin(60° + \theta) = \dfrac{1}{4}\sin 3\theta$
22. $\cos\theta\cos(60° - \theta)\cos(60° + \theta) = \dfrac{1}{4}\cos 3\theta$
23. $\tan\theta\tan(60° - \theta)\tan(60° + \theta) = \tan 3\theta$

❺ SUM AND DIFFERENCE INTO PRODUCTS

1. $\sin A + \sin B = 2\sin\left(\dfrac{A + B}{2}\right)\cos\left(\dfrac{A - B}{2}\right)$
2. $\sin A - \sin B = 2\sin\left(\dfrac{A - B}{2}\right)\cos\left(\dfrac{A + B}{2}\right)$
3. $\cos A + \cos B = 2\cos\left(\dfrac{A + B}{2}\right)\cos\left(\dfrac{A - B}{2}\right)$
4. $\cos A - \cos B = -2\sin\left(\dfrac{A + B}{2}\right)\sin\left(\dfrac{A - B}{2}\right)$

❻ MAXIMUM AND MINIMUM VALUES

We know that $-1 \le \sin x \le 1$, $-1 \le \cos x \le 1$, $-\infty < \tan x < \infty$, $|\sec x| \ge 1$ and $|\operatorname{cosec} x| \ge 1$. If there is a trigonometrical expression of the form $a\sin x + b\cos x$, then by putting $a = r\cos\theta, b = r\sin\theta$, we have

$a\sin x + b\cos x = r\cos\theta\sin x + r\sin\theta\cos x$

$\Rightarrow \quad a\sin x + b\cos x = r\sin(x + \theta)$

where, $r = \sqrt{a^2 + b^2}, \tan\theta = \dfrac{b}{a}$

We have, $-1 \le \sin(x + \theta) \le 1$ for all values of x.

$\Rightarrow \quad -r \le r\sin(x + \theta) \le r$ for all x.

$\Rightarrow \quad -\sqrt{a^2 + b^2} \le a\sin x + b\cos x \le \sqrt{a^2 + b^2}, \forall x$

Hence, the maximum and minimum values of trigonometrical expressions of the form $a\sin x + b\cos x$ are $\sqrt{a^2 + b^2}$ and $-\sqrt{a^2 + b^2}$, respectively.

❼ PROPERTIES OF TRIANGLES

In any ΔABC, the sides BC, opposite to $\angle A$ is denoted by a; CA and AB, opposite to $\angle B$ and $\angle C$ respectively are denoted by b and c, respectively. Semi-perimeter of the triangle is denoted by s and its area by Δ.

GRAPHS OF TRIGONOME

Parent Function	Graph
$y = \sin(x)$ Odd Domain : $(-\infty, \infty)$ Range : $[-1, 1]$ Period : 2π Zeros : $(\pi K, 0)$ $K \in$ Integers	$y = \cos(x)$ Even Domain : $(-\infty, \infty)$ Range : $[-1, 1]$ Period : 2π Zeros : $\left(\dfrac{\pi}{2} + \pi K, 0\right)$	$y = \tan(x)$ Odd Domain : $x \ne \dfrac{\pi}{2} + \pi K$ Range : $(-\infty, \infty)$ Period : π Zeros : $(\pi K, 0)$	
Ⓐ SINE FORMULAE

In any ΔABC, $\dfrac{\sin A}{a} = \dfrac{\sin B}{b} = \dfrac{\sin C}{c}$

i.e. the sines of the angles are proportional to the lengths of the opposite sides.

Ⓑ COSINE FORMULAE

In any ΔABC, $\cos A = \dfrac{b^2 + c^2 - a^2}{2bc}$;

$\cos B = \dfrac{c^2 + a^2 - b^2}{2ac}; \cos C = \dfrac{a^2 + b^2 - c^2}{2ab}$

Ⓒ PROJECTION FORMULAE

In any ΔABC, we have

$a = b\cos C + c\cos B;\quad b = c\cos A + a\cos C$

$c = a\cos B + b\cos A$

Ⓓ AREA OF ΔABC

In a ΔABC, its area Δ is given by

$$\Delta = \frac{1}{2}ab\sin C = \frac{1}{2}bc\sin A = \frac{1}{2}ca\sin B$$

$$\Delta = \sqrt{s(s - a)(s - b)(s - c)}, \text{ where } s = \frac{a + b + c}{2}$$

❽ CIRCLES CONNECTED TO A TRIANGLE

Ⓐ CIRCUMCIRCLE OF A TRIANGLE

The circle which passes through the angular points of a ΔABC is called its circumcircle. The centre of this circle

PT MAP

ision Tool

tions and Identities

TRIC FUNCTION

Parent Function	Graph
$y = \cot(x)$ Odd Domain : $x \neq \pi K$ Range : $(-\infty, \infty)$ Period : π Zeros : $\left(\frac{\pi}{2} + \pi K, 0\right)$	$y = \sec(x)$ Even Domain : $x \neq \frac{\pi}{2} + \pi K$ Range: $(-\infty, -1] \cup [1, \infty)$ Period : 2π Zeros : None	$y = \text{cosec}(x)$ Odd Domain: $x \neq \pi K$ Range: $(-\infty, -1] \cup [1, \infty)$ Period: 2π Zeros: None	
is the ABC is the point of intersection of perpendicular bisectors of the sides and is called the circumcentre. Its radius is always denoted by R.

Ⓑ CIRCUMRADIUS

The radius of the circumcircle of a ΔABC is called the circumradius given by

(i) $R = \frac{a}{2\sin A} = \frac{b}{2\sin B} = \frac{c}{2\sin c}$ (ii) $R = \frac{abc}{4\Delta}$

Ⓒ INSCRIBED CIRCLE OR INCIRCLE OF A TRIANGLE

The circle which can be inscribed within the triangle so as to touch each of its sides is called its inscribed circle or incircle. The centre of this circle is the point of intersection of bisectors of the angles of the triangle. The radius of this circle is always denoted by r. The radius of the inscribed circle of a triangle is called the inradius. It is denoted by r and is given by

(i) $r = \frac{\Delta}{s}$

(ii) $r = (s-a)\tan\frac{A}{2} = (s-b)\tan\frac{B}{2} = (s-c)\tan\frac{C}{2}$

(iii) $r = \frac{a\sin B/2 \sin C/2}{\cos A/2} = \frac{b\sin A/2 \sin C/2}{\cos B/2}$
$= \frac{c\sin B/2 \sin A/2}{\cos C/2}$

(iv) $r = 4R\sin\frac{A}{2}\sin\frac{B}{2}\sin\frac{C}{2}$

Ⓓ ESCRIBED CIRCLES OF A TRIANGLES

The circle which touches the sides BC and two sides AB and AC produced of a ΔABC is called the escribed circle opposite to $\angle A$. Its radius is denoted by r_1. Similarly, r_2 and r_3 denote the radii of the escribed circles opposite to $\angle B$ and $\angle C$, respectively.

The centres of the escribed circles are called the excentres. The centre of the escribed circle opposite to $\angle A$ is the point of intersection of the external bisectors of $\angle B$ and $\angle C$.

In ΔABC,

(i) $r_1 = \frac{\Delta}{s-a}, r_2 = \frac{\Delta}{s-b}, r_3 = \frac{\Delta}{s-c}$

(ii) $r_1 = s\tan A/2,\ r_2 = s\tan B/2,\ r_3 = s\tan C/2$

(iii) $r_1 = \frac{a\cos B/2 \cos C/2}{\cos A/2}; r_2 = \frac{b\cos C/2 \cos A/2}{\cos B/2}$

$r_3 = \frac{c\cos A/2 \cos B/2}{\cos C/2}$

(iv) $r_1 = 4R\sin\frac{A}{2}\cos\frac{B}{2}\cos\frac{C}{2}$

$r_2 = 4R\cos\frac{A}{2}\sin\frac{B}{2}\cos\frac{C}{2}$

$r_3 = 4R\cos\frac{A}{2}\cos\frac{B}{2}\sin\frac{C}{2}$

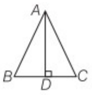
⑨ AREA OF A CYCLIC QUADRILATERAL

A quadrilateral is a cyclic quadrilateral, if its vertices lie on a circle. If s is the semi-perimeter of a cyclic quadrilateral $ABCD$ such that $AB = a, BC = b, CD = c$ and $DA = d$, then its area Δ is given by

$$\Delta = \sqrt{(s-a)(s-b)(s-c)(s-d)}$$

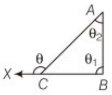
⑩ SOME IMPORTANT FACTS

(i) In an isosceles triangle, the median is perpendicular to the base ΔABC is isosceles and $AD \perp BC$.



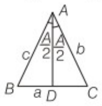
(ii) In similar triangle, the corresponding sides are proportional.

(iii) The exterior angle of a triangle is equal to the sum of interior opposite angles.



In ΔABC, $\theta = \theta_1 + \theta_2$

(iv) In a triangle, the internal bisector of an angle divides the opposite side in the ratio of the arms of the angle.

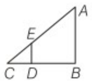


In ΔABC, AD is bisector of $\angle A$.

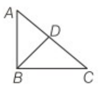
$\therefore \quad \frac{BD}{DC} = \frac{c}{b}$

(v) In a ΔABC, if $DE \parallel AB$, then

$\frac{AB}{DE} = \frac{BC}{DC} = \frac{AC}{EC}$



(vi) In a right angled ΔABC, the mid-point D of hypotenuse AC is equidistant from its vertices A, B and C.

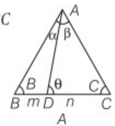


i.e. $AD = BD = CD$

(vii) ***m*-*n* Theorem** In a ΔABC, D divides BC in the ratio $m : n$, then

(a) $(m+n)\cot\theta = n\cot B - m\cot C$

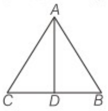
(b) $(m+n)\cot\theta = m\cot\alpha - n\cot\beta$



(viii) **Appolonius Theorem**

If in ΔABC, AD is median, then

$$AB^2 + AC^2 = 2(AD^2 + BD^2)$$



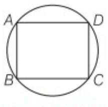
(ix) Angles in the same segment of a circle are equal.

(x) The angle subtended at the centre by an arc is double of the angle subtended at any point of the remaining arc by the same arc.

(xi) **Ptolemy's Theorem**

Incyclic quadrilateral $ABCD$,

$$AB \cdot CD + AD \cdot BC = AC \cdot BD$$



⑪ SOLUTIONS OF TRIGONOMETRIC EQUATIONS

A solution of a trigonometric equation is the value of the unknown angles that satisfies the equation. A solution generalised by means of periodicity is known as the general solution. Solving an equation means to find its general solution. Following are the general solutions of some trigonometric equations

	Equations	General solution
(i)	$\sin\theta = 0$	$\theta = n\pi, n \in Z$
(ii)	$\cos\theta = 0$	$\theta = (2n+1)\pi/2, n \in Z$
(iii)	$\tan\theta = 0$	$\theta = n\pi, n \in Z$
(iv)	$\cot\theta = 0$	$\theta = (2n+1)\pi/2, n \in Z$
(v)	$\sin\theta = \sin\alpha$	$\theta = n\pi + (-1)^n\alpha, n \in Z$
(vi)	$\cos\theta = \cos\alpha$	$\theta = 2n\pi \pm \alpha, n \in Z$
(vii)	$\tan\theta = \tan\alpha$	$\theta = n\pi + \alpha, n \in Z$
(viii)	$\sin^2\theta = \sin^2\alpha$ $\cos^2\theta = \cos^2\alpha$ $\tan^2\theta = \tan^2\alpha$	$\theta = n\pi \pm \alpha, n \in Z$

TRIGONOMETRIC RATIOS OF SOME SPECIAL AND USEFUL ANGLES

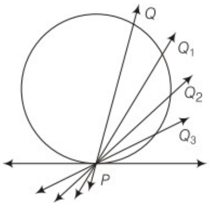
- $\sin 7\frac{1^\circ}{2} = \sqrt{\frac{4-\sqrt{2}-\sqrt{6}}{2\sqrt{2}}}, \cos 7\frac{1^\circ}{2} = \frac{\sqrt{4+\sqrt{2}+\sqrt{6}}}{2\sqrt{2}}$
  $\tan 7\frac{1^\circ}{2} = (\sqrt{3}-\sqrt{2})(\sqrt{2}-1)$
- $\sin 15^\circ = \frac{\sqrt{3}-1}{2\sqrt{2}}, \cos 15^\circ = \frac{\sqrt{3}+1}{2\sqrt{2}}, \tan 15^\circ = 2-\sqrt{3}$
- $\sin 22\frac{1^\circ}{2} = \frac{1}{2}\sqrt{2-\sqrt{2}}, \cos 22\frac{1^\circ}{2} = \frac{1}{2}\sqrt{2+\sqrt{2}}$
  $\tan 22\frac{1^\circ}{2} = \sqrt{2}-1$
- $\sin 18^\circ = \frac{\sqrt{5}-1}{4}, \cos 18^\circ = \frac{\sqrt{10+2\sqrt{5}}}{4}$
  $\tan 18^\circ = \frac{\sqrt{25-10\sqrt{15}}}{5}$
- $\sin 36^\circ = \frac{\sqrt{10-2\sqrt{5}}}{4}, \cos 36^\circ = \frac{\sqrt{5}+1}{4}, \tan 36^\circ = \sqrt{5-2\sqrt{5}}$
- $\sin 9^\circ = \frac{\sqrt{3+\sqrt{5}}-\sqrt{5-\sqrt{5}}}{4}$,
  $\cos 9^\circ = \frac{\sqrt{3+\sqrt{5}}+\sqrt{5-\sqrt{5}}}{4}$

TANGENT TO A CIRCLE

Coverage of special topics for JEE Advanced

In this section, we will learn about various equations of tangent to a circle. We will also discuss the pair of tangent drawn from a point and common tangents. In JEE Advanced, atleast one question is asked every year from this topic.

Tangent to a Circle



Let P be a point on a circle and let PQ be a secant. Now, as the point Q moves along the circle towards P, the line PQ rotates about P and as Q approaches to P, the line PQ coincides with the limiting line PT. This limiting position PT of secant PQ as Q tends to P is called the tangent line to the circle at point P.

Thus, the tangent at a point P is the limiting position of a secant PQ, when Q tends to P along the circle. The point P is called the point of contact of the tangent.

Different Forms of the Equations of Tangents

Following are the different forms of the equations of tangents to a circle.

1. **Slope Form**

The equation of a tangent of slope m to the circle $x^2 + y^2 = a^2$ is $y = mx \pm a\sqrt{1+m^2}$. The coordinates of the point of contact are $\left(\pm \frac{am}{\sqrt{1+m^2}}, \mp \frac{a}{\sqrt{1+m^2}}\right)$

2. **Point Form**

The equation of the tangent at the point $P(x_1, y_1)$ to a circle $x^2 + y^2 + 2gx + 2fy + c = 0$ is

$$xx_1 + yy_1 + g(x + x_1) + f(y + y_1) + c = 0$$

3. **Parametric Form**

The equation of the tangent to the circle $x^2 + y^2 = a^2$ at the point $(a\cos\theta, a\sin\theta)$ is $x\cos\theta + y\sin\theta = a$.

REMEMBER

1. The equations of the tangents of slope m to the circle $(x-a)^2 + (y-b)^2 = r^2$ are given by $y - b = m(x-a) \pm r\sqrt{1+m^2}$ and the coordinates of the point of contact are
$$\left(a \pm \frac{mr}{\sqrt{1+m^2}}, b \mp \frac{r}{\sqrt{1+m^2}}\right)$$
2. The equations of the tangents of slope m to the circle $x^2 + y^2 + 2gx + 2fy + c = 0$ are
$$y + f = m(x+y) \pm \sqrt{(g^2 + f^2 - c)(1+m^2)}$$
3. The equation of the tangent to the circle $(x-a)^2 + (y-b)^2 = r^2$ at the point $(a + r\cos\theta, b + r\sin\theta)$ is
$$(x-a)\cos\theta + (y-b)\sin\theta = r$$

Example ① The centre of circle inscribed in square formed by the lines $x^2 - 8x + 12 = 0$ and $y^2 - 14y + 45 = 0$, is

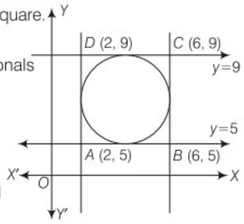
[JEE Main 2003]

(a) (4, 7)
(b) (7, 4)
(c) (9, 4)
(d) (4, 9)

Sol. **(a)** Given, circle is inscribed in square formed by the lines $x^2 - 8x + 12 = 0$ and $y^2 - 14y + 45 = 0$

$\Rightarrow x = 6, x = 2, y = 5, y = 9$

which could be plotted shown as figure where, $ABCD$ clearly forms a square.



$\therefore$ Centre of inscribed circle

= Point of intersection of diagonals

= Mid-point of AC or BD

$= \left(\frac{2+6}{2}, \frac{5+9}{2}\right)$

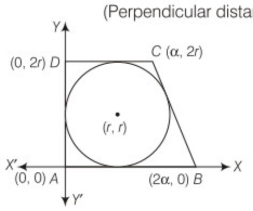
$= (4, 7)$

Hence, the centre of inscribed circle is (4, 7).

Example 2 Let $ABCD$ be a quadrilateral with area 18, with side AB parallel to the side CD and $AB = 2CD$. Let AD be perpendicular to AB and CD. If a circle is drawn inside the quadrilateral $ABCD$ touching all the sides, then its radius, is **[JEE Main 2007]**

(a) 3 (b) 2 (c) 3/2 (d) 1

Sol. (b) $\because$ Area of trapezium $ABCD = 1/2$ (Sum of parallel sides) (Perpendicular distance between them)



Then, $18 = \frac{1}{2}(3\alpha)(2r) \Rightarrow \alpha r = 6$ ...(i)

Also, line $y = -\frac{2r}{\alpha}(x - 2\alpha)$ is tangent to circle

$$(x - r)^2 + (y - r)^2 = r^2 \Rightarrow 2\alpha = 3r \quad \text{...(ii)}$$

From Eqs. (i) and (ii), we get

$$r = 2$$

Example 3 The lines $3x - 4y + 4 = 0$ and $6x - 8y - 7 = 0$ tangents to the same circle. The radius of this circle is .... **[JEE Main 1984]**

Sol. Since, $3x - 4y + 4 = 0$ and $3x - 4y - \frac{7}{2} = 0$ are two parallel tangents. Thus, distance between them is diameter of circle.

$$\therefore \text{Diameter} = \frac{\left|4 + \frac{7}{2}\right|}{\sqrt{3^2 + 4^2}} = \frac{15}{2 \times 5} = \frac{3}{2}$$

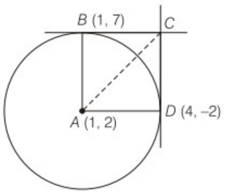
$$\therefore \quad \text{Radius} = \frac{3}{4}$$

Example 4 Let A be the centre of the circle $x^2 + y^2 - 2x - 4y - 20 = 0$. Suppose that, the tangents at the points $B(1, 7)$ and $D(4, -2)$ on the circle meet at the point C. Find the area of the quadrilateral $ABCD$. **[IIT JEE 1981]**

Sol. Equations of tangents at (1, 7) and (4, −2) are

$$x + 7y - (x + 1) - 2(y + 7) - 20 = 0$$

$$\Rightarrow \quad y = 7$$



and $4x - 2y - (x + 4) - 2(y - 2) - 20 = 0$

$$\Rightarrow \quad 3x - 4y = 20$$

$\therefore$ Point C is (16, 7).

$\therefore$ Vertices of a quadrilateral are

$A(1, 2)$, $B(1, 7)$, $C(16, 7)$ and $D(4, -2)$.

$\therefore$ Area of quadrilateral $ABCD$

$$= \text{Area of } \Delta ABC + \text{Area of } \Delta ACD$$

$$= \frac{1}{2} \times 15 \times 5 + \frac{1}{2} \times 15 \times 5 = 75 \text{ sq units}$$

Example 5 Find the equations of the circles passing through $(-4, 3)$ and touching the lines $x + y = 2$ and $x - y = 2$. **[IIT JEE 1982]**

Sol. Let the equation of the required circle be

$$x^2 + y^2 + 2gx + 2fy + c = 0 \quad \text{...(i)}$$

It passes through (−4, 3).

$$\therefore \quad 25 - 8g + 6f + c = 0 \quad \text{...(ii)}$$

Since, circle touches the lines $x + y = 2$ and $x - y = 2$.

$$\therefore \quad \left|\frac{-g - f - 2}{\sqrt{2}}\right| = \left|\frac{-g + f - 2}{\sqrt{2}}\right| = \sqrt{g^2 + f^2 - c} \quad \text{...(iii)}$$

$$\text{Now,} \quad \left|\frac{-g - f - 2}{\sqrt{2}}\right| = \left|\frac{-g + f - 2}{\sqrt{2}}\right|$$

$$\Rightarrow \quad -g - f - 2 = \pm(-g + f - 2)$$

$$\Rightarrow \quad -g - f - 2 = -g + f - 2$$

$$\text{or} \quad -g - f - 2 = g - f + 2$$

$$\Rightarrow \quad g = -2 \text{ or } f = 0$$

***Case* I** When $f = 0$

From Eq. (iii), we get

$$\left|\frac{-g - 2}{\sqrt{2}}\right| = \sqrt{g^2 - c}$$

$$\Rightarrow \quad (g + 2)^2 = 2(g^2 - c)$$

$$\Rightarrow \quad g^2 - 4g - 4 - 2c = 0 \quad \text{...(iv)}$$

On putting $f = 0$ in Eq. (ii), we get

$$25 - 8g + c = 0 \quad \text{...(v)}$$

From Eqs. (iv) and (v), we get

$$g^2 - 4g - 4 - 2(8g - 25) = 0$$

$$\Rightarrow \quad g^2 - 4g - 4 - 16g + 50 = 0$$

$$\Rightarrow \quad g^2 - 20g + 46 = 0 \Rightarrow g = 10 \pm 3\sqrt{6}$$

$$\text{and} \quad c = 55 \pm 24\sqrt{6}$$

On substituting the values of g, f and c in Eq. (i), we get

$$x^2 + y^2 + 2(10 \pm 3\sqrt{6})x + (55 \pm 24\sqrt{6}) = 0$$

***Case* II** When $g = -2$

From Eq. (iii), we get

$$\Rightarrow \quad f^2 = 2(4 + f^2 - c) \Rightarrow f^2 - 2c + 8 = 0 \quad \text{...(vi)}$$

On putting $g = -2$ in Eq. (ii), we get

$$c = -6f - 41$$

On substituting the value of c in Eq. (vi), we get

$$f^2 + 12f + 90 = 0$$

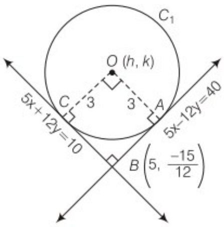
This equation gives imaginary values of f. Thus, there is no circle in this case. Hence, the required equation of the circles are $x^2 + y^2 + 2(10 \pm 3\sqrt{6})x + (55 \pm 24\sqrt{6}) = 0$

Example ⑥ Lines $5x+12y-10=0$ and $5x-12y-40=0$ touch a circle C_1 of diameter 6. If the centre of C_1 lie in the first quadrant, then find the equation of the circle C_2 which is concentric with C_1 and cuts intercepts of length 8 on these lines.

Sol. Since, $5x+12y-10=0$ and $5x-12y-40=0$ are both perpendicular tangents to the circle C_1.

$\therefore$ $OABC$ forms a square.

Let the centre coordinates be (h, k), where $OC = OA = 3$ and $OB = 6\sqrt{2}$.



$$\Rightarrow \frac{|5h+12k-10|}{13} = 3$$

$$\text{and } \frac{|5h-12k-40|}{13} = 3$$

$$\Rightarrow \quad 5h+12k-10 = \pm 39$$

$$\text{and } \quad 5h-12k-40 = \pm 39$$

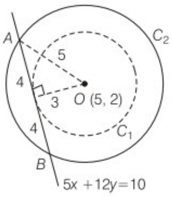
On solving above equations.

The coordinates which lie in I quadrant, are (5, 2).

$\therefore$ Centre for C_1 (5, 2).

To obtain equation of circle concentric with C_1 and making an intercept of length 8 on $5x+12y=10$ and $5x-12y=40$

So, required equation of circle C_2 has centre (5, 2) and radius 5.



$$\Rightarrow \quad (x-5)^2 + (y-2)^2 = 5^2$$

Pairs of Tangents

From a given point, two tangents can be drawn to a circle which are real and distinct, coincident or imaginary according to as the given point lies outside, on or inside the circle. The combined equation of the pair of tangents drawn from a point $P(x_1, y_1)$ to the circle $x^2+y^2=a^2$ is

$$(x^2+y^2-a^2)\,(x_1^2+y_1^2-a^2) = (xx_1+yy_1-a^2)^2$$

or $$SS' = T^2$$

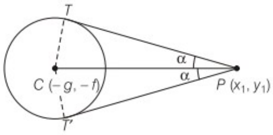
where, $S = x^2+y^2-a^2$, $S' = x_1^2+y_1^2-a^2$

$$T = xx_1+yy_1-a^2$$

Length of the Tangents

The length of the tangent from the point $P(x_1, y_1)$ to the circle $x^2+y^2+2gx+2fy+c=0$ is equal to

$$\sqrt{s_1} = \sqrt{x_1^2+y_1^2+2gx_1+2fy_1+c}$$



REMEMBER

If PT is the length of the tangent from a point P to a given circle, then PT^2 is called the power of the point with respect to the given circle.

Example ⑦ The angle between a pair of tangents drawn from a point P to the circle $x^2+y^2+4x-6y+9\sin^2\alpha+13\cos^2\alpha=0$ is 2α. The equation of the locus of the point P is **[IIT JEE 1996]**

(a) $x^2+y^2+4x-6y+4=0$

(b) $x^2+y^2+4x-6y-9=0$

(c) $x^2+y^2+4x-6y-4=0$

(d) $x^2+y^2+4x-6y+9=0$

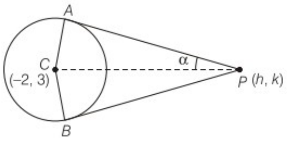
Sol. (d) Centre of the circle

$x^2+y^2+4x-6y+9\sin^2\alpha+13\cos^2\alpha=0$ is $C(-2, 3)$

and radius $\sqrt{(-2)^2+(3)^2-9\sin^2\alpha-13\cos^2\alpha}$

$= \sqrt{13-9\sin^2\alpha-13\cos^2\alpha} = \sqrt{13(1-\cos^2\alpha)-9\sin^2\alpha}$

$= \sqrt{13\sin^2\alpha-9\sin^2\alpha} = \sqrt{4\sin^2\alpha} = 2\sin\alpha$



Let (h, k) be any point P and $\angle APC = \alpha$, $\angle PAC = \frac{\pi}{2}$

i.e. $\Delta\ APC$ is a right triangle.

$$\therefore \sin\alpha = \frac{AC}{PC} = \frac{2\sin\alpha}{\sqrt{(h+2)^2+(k-3)^2}}$$

$$\Rightarrow \quad (h+2)^2+(k-3)^2 = 4$$

$$\Rightarrow \quad h^2+4+4h+k^2+9-6k = 4$$

$$\Rightarrow \quad h^2+k^2+4h-6k+9 = 0$$

Thus, required equation of the locus is

$$x^2+y^2+4x-6y+9=0$$

Example ⑧ If the tangent at the point P on the circle $x^2+y^2+6x+6y=2$ meets the straight line $5x-2y+6=0$ at a point Q on the Y-axis, then the length of PQ, is **[JEE Main 2002]**

(a) 4 (b) $2\sqrt{5}$ (c) 5 (d) $3\sqrt{5}$

Sol. (c) The line $5x-2y+6=0$ meets the Y-axis at the point (0, 3) and therefore the tangent has to pass through the point (0, 3) and required length

$$= \sqrt{x_1^2+y_1^2+6x_1+6y_1-2}$$

$$= \sqrt{0^2+3^2+6(0)+6(3)-2}$$

$$= \sqrt{25}$$

$$= 5$$

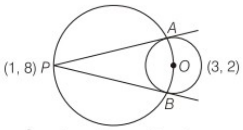
Example 9 Tangents drawn from the point $P(1, 8)$ to the circle $x^2 + y^2 - 6x - 4y - 11 = 0$ touch the circle at the points A and B. The equation of the circumcircle of the ΔPAB, is **[JEE Main 2009]**

(a) $x^2 + y^2 + 4x - 6y + 19 = 0$
(b) $x^2 + y^2 - 4x - 10y + 19 = 0$
(c) $x^2 + y^2 - 2x + 6y - 29 = 0$
(d) $x^2 + y^2 - 6x - 4y + 19 = 0$

Sol. ***(b)*** For required circle, $P(1, 8)$ and $O(3, 2)$ will be the end points of its diameter.

∴ Equation of required circle is

$$(x-1)(x-3) + (y-8)(y-2) = 0$$



$$\Rightarrow \quad x^2 + y^2 - 4x - 10y + 19 = 0$$

Example 10 Tangents are drawn from the point $(17, 7)$ to the circle $x^2 + y^2 = 169$.

Statement I The tangents are mutually perpendicular.

Statement II The locus of the points from which a mutually perpendicular tangents can be drawn to the given circle is $x^2 + y^2 = 338$. **[IIT JEE 2007]**

(a) Statement I is true, Statement II is also true; Statement II is the correct explanation of Statement I
(b) Statement I is true, Statement II is also true; Statement II is not the correct explanation of Statement I
(c) Statement I is true, Statement II is false
(d) Statement I is false; Statement II is true

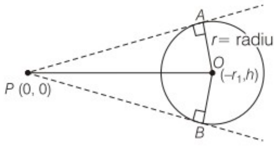
Sol. ***(a)*** Since, the tangents are perpendicular. So, locus of perpendicular tangents to circle $x^2 + y^2 = 169$ is a director circle having equation $x^2 + y^2 = 338$.

Example 11 The equations of the tangents drawn from the origin to the circle $x^2 + y^2 + 2rx + 2hy + h^2 = 0$, are **[IIT JEE 1988]**

(a) $x = 0$ (b) $y = 0$
(c) $(h^2 - r^2)x - 2rhy = 0$ (d) $(h^2 - r^2)x + 2rhy = 0$

Sol. ***(a, c)*** Since, tangents are drawn from origin. So,the equation of tangent is given by $y = mx$.

⇒ Length of perpendicular from origin = Radius



$$\Rightarrow \quad \frac{|mr + h|}{\sqrt{m^2+1}} = r \Rightarrow m^2r^2 + h^2 + 2mrh = r^2(m^2+1)$$

$$\Rightarrow \quad m = \left|\frac{r^2 - h^2}{2rh}\right|, m = \infty$$

∴ Equations of tangents are

$$y = \left|\frac{r^2 - h^2}{2rh}\right| x \text{ and } x = 0$$

∴ $(h^2 - r^2)x - 2rhy = 0$ and $x = 0$

Example 12 Let $x^2 + y^2 - 4x - 2y - 11 = 0$ be a circle. A pair of tangents from the point $(4, 5)$ with a pair of radii form a quadrilateral of area .... **[JEE Main 1985]**

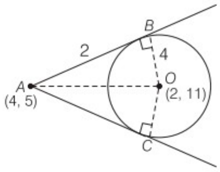
Sol. Centre of circle is (2, 1) and radius

$$= \sqrt{(-2)^2 + (-1)^2 - (-11)} = 4$$

Here, length of tangent AB

$$= \sqrt{4^2 + 5^2 - 4(4) - 2(5) - 11}$$

$$= 2$$



∴ Area of quadrilateral $ABOC$ = 2 × Area of ΔABO

$$= 2 \times \frac{1}{2}(AB)(OB)$$

$$= 2 \times \frac{1}{2} \times 2 \times 4$$

$$= 8 \text{ sq units}$$

Example 13 The area of the triangle formed by the tangents from the point $(4, 3)$ to the circle $x^2 + y^2 = 9$ and the line joining their points of contact is .... **[IIT JEE 1987]**

Sol. Area of triangle formed by the tangents from the point (h, k) to the circle $x^2 + y^2 = a^2$ and their chord of contact

$$= \frac{a(h^2 + k^2 - a^2)^{3/2}}{h^2 + k^2}$$

Thus, area of triangle formed by tangents from (4, 3) to the circle $x^2 + y^2 = 9$ and their chord of contact

$$= \frac{3(4^2 + 3^2 - 9)^{3/2}}{4^2 + 3^2}$$

$$= \frac{3(16 + 9 - 9)^{3/2}}{25} = \frac{3(64)}{25}$$

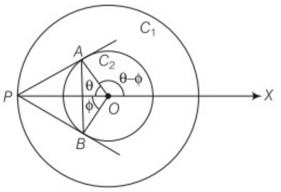
$$= \frac{192}{25} \text{ sq units}$$

Example 14 C_1 and C_2 are two concentric circles, the radius of C_2 being twice that of C_1. From a point P on C_2, tangents PA and PB are drawn to C_1. Prove that the centroid of ΔPAB lies on C_1. [JEE Main 1998]

Sol. Let the coordinates of point P be $(2r\cos\theta, 2r\sin\theta)$.

We have, $OA = r, OP = 2r$

Since, ΔOAP is a right angled triangle.



$$\cos\phi = \frac{1}{2} \Rightarrow \phi = \frac{\pi}{3}$$

$\therefore$ Coordinates of A are $\{r\cos(\theta - \pi/3), r\sin(\theta - \pi/3)\}$ and that of B are $[r\cos(\theta + \pi/3), r\sin(\theta + \pi/3)]$.

If p, q is the centroid of ΔPAB, then

$$p = \frac{1}{3}[r\cos(\theta - \pi/3) + r\cos(\theta + \pi/3) + 2r\cos\theta]$$

$$= \frac{1}{3}[r\{\cos(\theta - \pi/3) + \cos(\theta + \pi/3)\} + 2r\cos\theta]$$

$$= \frac{1}{3}\left[r\left\{\begin{matrix} 2\cos\left(\dfrac{\theta - \frac{\pi}{3} + \theta + \frac{\pi}{3}}{2}\right) \\ \cos\left(\dfrac{\theta - \frac{\pi}{3} - \theta - \frac{\pi}{3}}{2}\right)\end{matrix}\right\} + 2r\cos\theta\right]$$

$$= \frac{1}{3}[r\{2\cos\theta\cos\pi/3\} + 2r\cos\theta]$$

$$= \frac{1}{3}[r\cos\theta + 2r\cos\theta] = r\cos\theta$$

and
$$q = \frac{1}{3}\left[r\sin\left(\theta - \frac{\pi}{3}\right) + r\sin\left(\theta + \frac{\pi}{3}\right) + 2r\sin\theta\right]$$

$$= \frac{1}{3}\left[r\left\{\sin\left(\theta - \frac{\pi}{3}\right) + \sin\left(\theta + \frac{\pi}{3}\right)\right\} + 2r\sin\theta\right]$$

$$= \frac{1}{3}\left[r\left\{\begin{matrix} 2\sin\left(\dfrac{\theta - \frac{\pi}{3} + \theta + \frac{\pi}{3}}{2}\right) \\ \cos\left(\dfrac{\theta - \frac{\pi}{3} - \theta - \frac{\pi}{3}}{2}\right)\end{matrix}\right\} + 2r\sin\theta\right]$$

$$= \frac{1}{3}[r(2\sin\theta\cos\pi/3) + 2r\sin\theta]$$

$$= \frac{1}{3}[r\sin\theta + 2r\sin\theta] = r\sin\theta$$

Now, $(p, q) = (r\cos\theta, r\sin\theta)$ lies on $x^2 + y^2 = r^2$ which is called C_1.

Common Tangents to Two Circles

The number of common tangents depends upon the positions of the given circle as discussed below

Let the equations of the two circles be

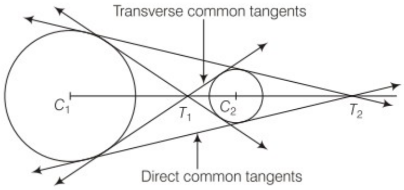
$$(x - h_1)^2 + (y - k_1)^2 = a_1^2 \quad \ldots(i)$$

and
$$(x - h_2)^2 + (y - k_2)^2 = a_2^2 \quad \ldots(ii)$$

with centres $C_1(h_1, k_1)$, $C_2(h_2, k_2)$ and radii a_1, a_2 respectively. Then, the following cases of intersection of these two circles may arises.

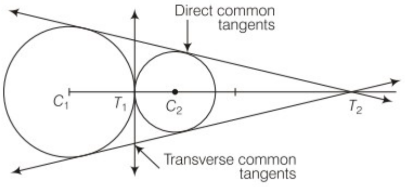
***Case* I** When $C_1C_2 > a_1 + a_2$

In this case, the two circles do not intersect with each other and four common tangents can be drawn to two circles. Two of them are direct and other two are transverse common tangents.



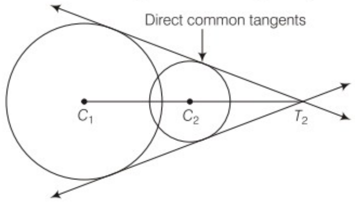
***Case* II** When $C_1C_2 = a_1 + a_2$

In this case, two direct tangents are real and distinct while the transverse tangents are coincident.



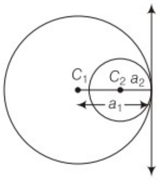
***Case* III** When $C_1C_2 < a_1 + a_2$

In this case, the two direct common tangents are real while the transverse tangents are imaginary.



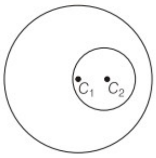
***Case* IV** When $C_1C_2 = a_1 - a_2$

In this case, two tangents are real and coincident while the other two tangents are imaginary.



***Case* V** When $C_1C_2 < a_1 - a_2$

In this case, all the four common tangents are imaginary.



Example 15 The number of common tangents to the circles $x^2 + y^2 = 4$ and $x^2 + y^2 - 6x - 8y = 24$, is/are **[IIT JEE 1998]**

(a) 0 (b) 1 (c) 3 (d) 4

Sol. **(b)** Given, $x^2 + y^2 = 4$

Centre, $C_1 \equiv (0, 0)$ and $R_1 = 2$

Again, $x^2 + y^2 - 6x - 8y - 24 = 0$

Then, $C_2 \equiv (3, 4)$ and $R_2 = 7$

Again, $C_1C_2 = 5 = R_2 - R_1$

Therefore, the given circles touch internally such that they can have just one common tangent at the point of contact.

Example 16 A tangent PT is drawn to the circle $x^2 + y^2 = 4$ at the point $P(\sqrt{3}, 1)$. A straight line L, perpendicular to PT is a tangent to the circle $(x-3)^2 + y^2 = 1$. **[IIT JEE 2012]**

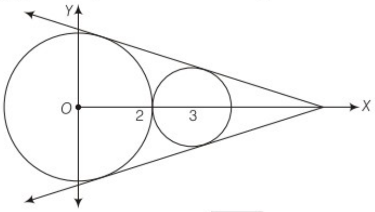
(i) A common tangent of the two circles is

(a) $x = 4$ (b) $y = 2$
(c) $x + \sqrt{3}y = 4$ (d) $x + 2\sqrt{2}y = 6$

(ii) A possible equation of L is

(a) $x - \sqrt{3}y = 1$ (b) $x + \sqrt{3}y = 1$
(c) $x - \sqrt{3}y = -1$ (d) $x + \sqrt{3}y = 5$

Sol. (i) **(d)** Here, equation of common tangent is



$$y = mx \pm 2\sqrt{1 + m^2}$$

which is also the tangent to

$$(x-3)^2 + y^2 = 1$$

$$\Rightarrow \frac{|3m - 0 + 2\sqrt{1 + m^2}|}{\sqrt{m^2 + 1}} = 1$$

$$\Rightarrow 3m + 2\sqrt{1 + m^2} = \pm \sqrt{1 + m^2}$$

$$\Rightarrow 3m = -3\sqrt{1 + m^2} \text{ or } 3m = -\sqrt{1 + m^2}$$

$$\Rightarrow m^2 = 1 + m^2 \text{ or } 9m^2 = 1 + m^2$$

$$\Rightarrow m \in \phi \text{ or } m = \pm \frac{1}{2\sqrt{2}}$$

$$\therefore y = \pm \frac{1}{2\sqrt{2}} x \pm 2\sqrt{1 + \frac{1}{8}}$$

$$\Rightarrow y = \pm \frac{x}{2\sqrt{2}} \pm \frac{6}{2\sqrt{2}}$$

$$\Rightarrow 2\sqrt{2}y = \pm (x + 6)$$

(ii) **(a)** Here, tangent to $x^2 + y^2 = 4$ at $(\sqrt{3}, 1)$ is $\sqrt{3}x + y = 4$.

As, L is perpendicular to $\sqrt{3}x + y = 4$.

$\therefore$ $x - \sqrt{3}y = \lambda$, which is tangent to $(x-3)^2 + y^2 = 1$

$$\Rightarrow \frac{|3 - 0 - \lambda|}{\sqrt{1 + 3}} = 1 \Rightarrow |3 - \lambda| = 2$$

$$\Rightarrow 3 - \lambda = 2, -2$$

$$\therefore \lambda = 1, 5$$

$$\Rightarrow L : x - \sqrt{3}y = 1, x - \sqrt{3}y = 5$$

Example 17 Match the conditions/expressions in Column I with statement in Column II. **[IIT JEE 2007]**

Column I	Column II
A. Two intersecting circles	p. have a common tangent
B. Two mutually external circles	q. have a common normal
C. Two circles, one strictly inside the other	r. do not have a common tangent
D. Two branches of a hyperbola	s. do not have a common normal

Sol. A $\to$ p, q; B $\to$ p, q; C $\to$ q, r; D $\to$ q, r

A. When two circles are intersecting they have a common normal and common tangent.

B. Two mutually external circles have a common normal and common tangent.

C. When one circle lies inside the other, then they have a common normal but no common tangent.

D. Two branches of a hyperbola have a common normal but no common tangent.

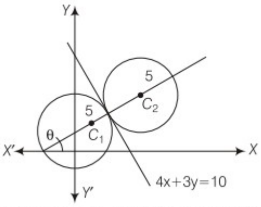
Example 18 Two circles, each of radius 5 units, touch each other at (1, 2). If the equation of their common tangent is $4x + 3y = 10$, then find the equations of the circles. **[IIT JEE 1991]**

Sol. We have, slope of the common tangent $= -\frac{4}{3}$

$\therefore$ Slope of $C_1C_2 = \frac{3}{4}$

If C_1C_2 makes an angle θ with X-axis,

then $\cos\theta = \frac{4}{5}$ and $\sin\theta = \frac{3}{5}$.



So, the equation of C_1C_2 in parametric form is

$$\frac{x-1}{4/5}=\frac{y-2}{3/5} \quad \text{...(i)}$$

Since, C_1 and C_2 are points on Eq. (i) at a distance of 5 units from P.

So, the coordinates of C_1 and C_2 are given by

$$\frac{x-1}{4/5}=\frac{y-2}{3/5}=\pm 5$$

$$\Rightarrow \quad x = 1 \pm 4 \text{ and } y = 2 \pm 3$$

Thus, the coordinates of C_1 and C_2 are (5, 5) and (–3, – 1) respectively.

Hence, the equations of the two circles are

$$(x-5)^2+(y-5)^2=5^2 \text{ and } (x+3)^2+(y+1)^2=5^2$$

Example 19 Three circles touch one another externally. The tangents at their point of contact meet at a point whose distance from a point of contact is 4. Find the ratio of the product of the radii to the sum of the radii of the circles.
[IIT JEE 1992]

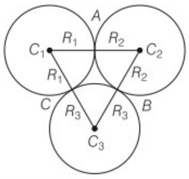
Sol. Suppose the circles have centres at C_1, C_2 and C_3 with radii R_1, R_2 and R_3 respectively. Let the circles touch at A, B and C. Let the common tangents at A, B and C meet at O. We have,

$$OA = OB = OC = 4 \quad \text{[given]}$$

Now, the circle with centre at O and passing through A, B and C is the incircle of $\Delta C_1C_2C_3$ (because $OA \perp C_1C_2$).

Therefore, the inradius of $\Delta C_1C_2C_3$ is 4.

$$\text{and} \quad r=\frac{\Delta}{s} \quad \text{...(i)}$$



Now, perimeter of a triangle,

$$2s = R_1+R_2+R_2+R_3+R_3+R_1$$

$$\Rightarrow \quad 2s = 2(R_1+R_2+R_3)$$

$$\Rightarrow \quad s = R_1+R_2+R_3$$

$$\text{and} \quad \Delta = \sqrt{s(s-a)(s-b)(s-c)}$$

$$= \sqrt{(R_1+R_2+R_3)(R_3)(R_2)(R_1)}$$

$$\text{From Eq. (i),} \quad 4=\frac{\sqrt{R_1R_2R_3(R_1+R_2+R_3)}}{R_1+R_2+R_3}$$

$$\Rightarrow 16=\frac{R_1R_2R_3(R_1+R_2+R_3)}{(R_1+R_2+R_3)^2} \Rightarrow 16=\frac{R_1R_2R_3}{R_1+R_2+R_3}$$

Example 20 Find the coordinates of the point at which the circles $x^2-y^2-4x-2y+4=0$ and $x^2+y^2-12x-8y+36=0$ touch each other. Also, find equation of common tangents touching the circles at distinct points.
[IIT JEE 1993]

Sol. Two circles touch each other externally, if $C_1C_2=r_1+r_2$ and internally, if $C_1C_2=r_1 \sim r_2$.

Given circles are $x^2-y^2-4x-2y+4=0$, whose centre $C_1(2, 1)$ and radius, $r_1=1$.

$$\text{and} \quad x^2+y^2-12x-8y+36=0$$

whose centre C_2 (6, 4) and radius, $r_2=4$

∴ Distance between the centres

$$=\sqrt{(6-2)^2+(4-1)^2}=\sqrt{16+9}=5$$

$$\Rightarrow \quad C_1C_2=r_1+r_2$$

Therefore, the circles touch each other externally and at the point of touching the point divides the line joining the two centres internally in the ratio of their radii, i.e. 1 : 4.

$$\text{Therefore,} \quad x_1=\frac{1\times 6+4\times 2}{1+4}=\frac{14}{5}$$

$$\text{and} \quad y_1=\frac{1\times 4+4\times 1}{1+4}=\frac{8}{5}$$

Again, to determine the equations of common tangents touching the circles in distinct points, we know that, the tangents pass through a point which divides the line joining the two centres externally in the ratio of their radii, i.e. 1 : 4.

$$\text{Therefore,} \quad x_2=\frac{1\times 6-4\times 2}{1-4}=\frac{-2}{-3}=\frac{2}{3}$$

$$\text{and} \quad y_2=\frac{1\times 4-4\times 1}{1-4}=0$$

Now, let m be the slope of the tangent and this line passing through $\left(\frac{2}{3}, 0\right)$ is

$$y-0=m\left(x-\frac{2}{3}\right) \Rightarrow y-mx+\frac{2}{3}m=0$$

This is tangent to the first circle, if perpendicular distance from centre = radius.

$$\therefore \quad \frac{1-2m+(2/3)m}{\sqrt{1+m^2}}=1 \quad [\because C_1 \equiv (2, 1) \text{ and } r_1=1]$$

$$\Rightarrow 1-2m+\left(\frac{2}{3}\right)m=\sqrt{1+m^2} \Rightarrow 1-\frac{4}{3}m=\sqrt{1+m^2}$$

$$\Rightarrow 1+\frac{16}{9}m^2-\frac{8}{3}m=1+m^2 \Rightarrow \frac{7}{9}m^2-\frac{8}{3}m=0$$

$$\Rightarrow \quad m\left(\frac{7}{9}m-\frac{8}{3}\right)=0$$

$$\Rightarrow \quad m=0, m=\frac{24}{7}$$

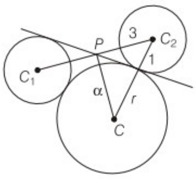
Hence, the equations of the two tangents are

$$y=0 \quad \text{and} \quad y=\frac{24}{7}\left(x-\frac{2}{3}\right)$$

$$\Rightarrow \quad y=0 \quad \text{and} \quad 7y-24x+16=0$$

Example 21 The centres of two circles C_1 and C_2 each of unit radius are at a distance of 6 units from each other. Let P be the mid- point of the line segment joining the centres of C_1 and C_2 and C be a circle touching circles C_1 and C_2 externally. If a common tangents to C_1 and C passing through P is also a common tangent to C_2 and C, then the radius of the circle C is ..... . **[IIT JEE 2009]**

Sol. $\because (r+1)^2 = \alpha^2 + 9$



$$r^2 + 8 = \alpha^2$$

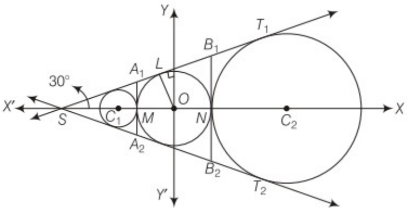
$$\Rightarrow \quad r^2 + 2r + 1 = r^2 + 8 + 9$$

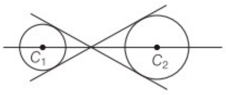
$$\Rightarrow \quad 2r = 16$$

$$\Rightarrow \quad r = 8 \text{ units}$$

Example 22 Let T_1 and T_2 be two tangents drawn from $(-2, 0)$ on the circle $C: x^2 + y^2 = 1$. Determine the circles touching C and having T_1, T_2 as their pair of tangents. Further, find the equations of all possible common tangents to these circles when taken two at a time. **[IIT JEE 1999]**

Sol.





From figure, it is clear that, ΔOLS is a right angled triangle with right angle at L.

Also, $\quad OL = 1$ and $OS = 2$

$$\therefore \quad \sin(\angle LSO) = \frac{1}{2}$$

$$\Rightarrow \quad \angle LSO = 30^\circ$$

Since, $SA_1 = SA_2$, so ΔSA_1A_2 is an equilateral triangle.

The circle with centre at C_1 is a circle inscribed in ΔSA_1A_2.

Therefore, centre C_1 is centroid of ΔSA_1A_2. Thus, C_1 divides SM in the ratio 2 : 1. Therefore, coordinates of C_1 are $(-4/3, 0)$ and its radius $= C_1M = \frac{1}{3}$.

$$\therefore \text{ Its equation is } \left(x + \frac{4}{3}\right)^2 + y^2 = \left(\frac{1}{3}\right)^2 \qquad \text{...(i)}$$

The other circle touches the equilateral ΔSB_1B_2 externally. Its radius r is given by $r = \dfrac{\Delta}{s-a}$

where, $\quad B_1B_2 = a$

But $\quad \Delta = \frac{1}{2}(a)(SN) = \frac{3}{2}a$

and $\quad s = a = \frac{3}{2}a - a = \frac{a}{2}$

Thus, $\quad r = 3$

$\Rightarrow$ Coordinates of C_2 are (4, 0).

$\therefore$ Equation of circle with centre at C_2 is

$$(x-4)^2 + y^2 = 3^2 \qquad \text{...(ii)}$$

Equations of common tangents to circle (i) and circle C are

$$x = -1$$

and $\quad y = \pm \frac{1}{\sqrt{3}}(x+2) \qquad [T_1 \text{ and } T_2]$

Equations of common tangents to circle (ii) and circle C are

$$x = 1$$

and $\quad y = \pm \frac{1}{\sqrt{3}}(x+2) \qquad [T_1 \text{ and } T_2]$

Two tangents common to circles (i) and (ii) are T_1 and T_2 at O. To find the remaining two transverse tangents to circles (i) and (ii), we find a point I which divides the joint of C_1C_2 in the ratio

$$r_1 : r_2 = \frac{1}{3} : 3 = 1 : 9$$

$\therefore$ Coordinates of I are $\left(-\frac{4}{5}, 0\right)$.

Equation of any line through I is $y = m\left(x + \frac{4}{5}\right)$. It will touch circle (i), if

$$\frac{\left|m\left(-\frac{4}{3} + \frac{4}{5}\right) - 0\right|}{\sqrt{1+m^2}} = \frac{1}{3}$$

$$\Rightarrow \quad \left|-\frac{8m}{15}\right| = \frac{1}{3}\sqrt{1+m^2}$$

$$\Rightarrow \quad 64m^2 = 25(1+m^2)$$

$$\Rightarrow \quad 39\,m^2 = 25$$

$$\Rightarrow \quad m = \pm \frac{5}{\sqrt{39}}$$

Hence, these tangents are

$$y = \pm \frac{5}{\sqrt{39}}\left(x + \frac{4}{5}\right).$$

Smart Practice

Single Option Correct Type

1. The line $2x - y + 1 = 0$ is tangent to the circle at the point $(2, 5)$ and the centre of the circle lies on $x - 2y = 4$. The radius of the circle is

(a) $3\sqrt{5}$ (b) $5\sqrt{3}$ (c) $2\sqrt{5}$ (d) $5\sqrt{2}$

2. If O is the origin and OP, OQ are the tangents from the origin to the circle $x^2 + y^2 - 6x + 4y + 8 = 0$, then the circumcentre of ΔOPQ is

(a) $(3, -2)$ (b) $\left(\frac{3}{2}, -1\right)$ (c) $\left(\frac{3}{4}, -\frac{1}{2}\right)$ (d) $\left(-\frac{3}{2}, 1\right)$

3. If (α, β) is a point on the circle whose centre is on the X-axis and which touches the line $x + y = 0$ at $(2, -2)$, then the greatest value of α is

(a) $4 - \sqrt{2}$ (b) 6 (c) $4 + 2\sqrt{2}$ (d) $4 + 2$

4. There are two circles whose equations are $x^2 + y^2 = 9$ and $x^2 + y^2 - 8x - 6y + n^2 = 0$, $n \in Z$. If the two circles have exactly two common tangents, then the number of possible values of n is

(a) 2 (b) 8
(c) 9 (d) None of these

5. The equation of the tangent to the circle $x^2 + y^2 + a^2$, which makes a triangle of area a^2 with the coordinate axes, is

(a) $x \pm y = a\sqrt{2}$ (b) $x \pm y = \pm a\sqrt{2}$
(c) $x \pm y = 2a$ (d) $x \pm y = \pm 2a$

One or More than One Option Correct Type

6. The equation of the tangent to the circle $x^2 + y^2 = 25$ passing through $(-2, 11)$, is/are

(a) $4x + 3y = 25$
(b) $3x + 4y = 38$
(c) $24x - 7y + 125 = 0$
(d) $7x + 24y = 250$

7. The circles $x^2 + y^2 - 2x - 4y + 1 = 0$ and $x^2 + y^2 + 4x + 4y - 1 = 0$

(a) touch internally
(b) touch externally
(c) have $3x + 4y - 1 = 0$ as the common tangent at the point of contact
(d) have $3x + 4y + 1 = 0$ as the common tangent at the point of contact

8. The range of values of a such that angle θ between the pair of tangents drawn from $(a, 0)$ to the circle $x^2 + y^2 + 1$ satisfies $\frac{\pi}{2} < \theta < \pi$, is

(a) $(1, 2)$ (b) $(1, \sqrt{2})$
(c) $(-\sqrt{2}, -1)$ (d) $(-2, -1)$

Linked Comprehension Type

Passage (Q. Nos. 9-11) A circle C whose radius is 1 unit, touches the X-axis at point A. The centre Q of C lies in the first quadrant. The tangent from the origin O to the circle touches it at T and a point P lies on it such that ΔOAP is a right angled triangle at A and its perimeter is 8 units.

9. The length of PQ is

(a) $\frac{1}{2}$ (b) $\frac{4}{3}$
(c) $\frac{5}{3}$ (d) $\frac{7}{3}$

10. The equation of circle C is

(a) $\{x - (2 + \sqrt{3})\}^2 + (y - 1)^2 = 1$
(b) $\{x - (\sqrt{3} - \sqrt{2})\}^2 + (y - 1)^2 = 1$
(c) $(x - \sqrt{3})^2 + (y - 1)^2 = 1$
(d) None of the above

11. The equation of tangent OT is

(a) $x - \sqrt{3}\,y = 0$ (b) $x - \sqrt{2}\,y = 0$
(c) $y - \sqrt{3}\,x = 0$ (d) $y - \sqrt{2}\,x = 0$

Single Integer Type

12. The sum of the slopes of the lines tangent to both the circles $x^2 + y^2 = 1$ and $(x - 6)^2 + y^2 = 4$, is …… .

13. The length of a common internal tangent to two circles is 7 and that of a common external tangent is 11. If the product of the radii of the two circles is P, then the value of $\frac{P}{2}$ is ……… .

14. If two perpendicular tangents can be drawn from the origin to the circle $x^2 - 6x + y^2 - 2py + 17 = 0$, then the value of $|p|$ is ……… .

Match the Column

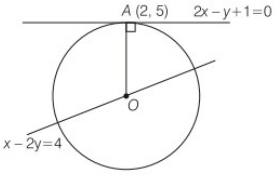
15. Match the Column I items with Column II items.

	Column I		Column II
A.	The number of circles touching the given three non-concurrent lines is	p.	1
B.	The number of circles touching $y = x$ at (2, 2) and also touching the line $x + 2y - 4 = 0$, is	q.	2
C.	The number of circles touching the lines $x \pm y = 2$ and passing through the point (4, 3), is	r.	4
D.	The number of circles intersecting the given three circles orthogonally, is	s.	infinite

Answers with **Explanation**

1. ***(a)*** We have, $2x - y + 1 = 0$ is a tangent. Slope of line $OA = -\frac{1}{2}$. The equation of line OA is $y - 5 = -\frac{1}{2}(x - 2)$ or $x + 2y = 12$

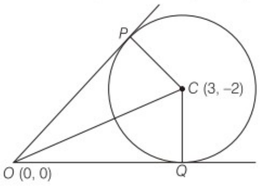
Therefore, intersection with $x - 2y = 4$ will give the coordinates of centre as (8, 2).



Hence,

$$r = OA = \sqrt{(8-2)^2 + (2-5)^2}$$
$$= 3\sqrt{5}$$

2. ***(b)*** Clearly, $OPCQ$ is a cyclic quadrilateral. Then, the circumcircle of ΔOPQ passes through the point C.



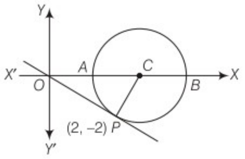
For this, OC is diameter.

Then, the circumcentre is the mid-point of OC,

i.e. $$\left(\frac{0+3}{2}, \frac{0-2}{2}\right) = \left(\frac{3}{2}, -1\right)$$

3. ***(c)*** If $(a, 0)$ is the centre C and P is $(2, -2)$, then $\angle COP = 45°$. Since, the equation of OP is $x + y = 0$, so we have $OP = 2\sqrt{2} = CP$.

Hence, $OC = \sqrt{OP^2 + CP^2} = \sqrt{(2\sqrt{2})^2 + (2\sqrt{2})^2} = 4$



The point on the circle with the greatest x-coordinate is B.

$$\therefore \quad \alpha = OB = OC + CB = OC + PC = 4 + 2\sqrt{2}$$

4. ***(c)*** For $x^2 + y^2 = 9$, the centre is (0, 0) and the radius is 3. For $x^2 + y^2 - 8x - 6y + n^2 = 0$, the centre is (4, 3) and the radius is $\sqrt{4^2 + 3^2 - n^2}$.

Now, $4^2 + 3^2 - n^2 > 0$ or $n^2 < 5^2$ or $-5 < n < 5$. The circles should cut externally to have exactly two common tangents. So, $r_1 + r_2 > d$ (distance between centres)

$$\therefore \quad 3 + \sqrt{25 - n^2} > \sqrt{4^2 + 3^2}$$
$$\Rightarrow \quad \sqrt{25 - n^2} > 2 \Rightarrow 25 - n^2 > 4$$
$$\therefore \quad n^2 < 21 \Rightarrow -\sqrt{21} < n < \sqrt{21}$$

Therefore, the common values of n should satisfy

$$-\sqrt{21} < n < \sqrt{21}$$

But $n \in Z$. So, $n = -4, -3, \ldots, 4$

$\therefore$ The number of possible values of n is 9.

5. ***(b)*** Let the tangent be of the form $\frac{x}{x_1} + \frac{y}{y_1} = 1$ and the area of triangle formed by it with the coordinate axes be

$$\frac{1}{2}x_1y_1 = a^2 \qquad \ldots(\text{i})$$

Again, $y_1x + x_1y - x_1y_1 = 0$

On applying the conditions of tangency, we get

$$\frac{|-x_1y_1|}{\sqrt{x_1^2 + y_1^2}} = a \text{ or } x_1^2 + y_1^2 = \frac{x_1^2y_1^2}{a^2} \qquad \ldots(\text{ii})$$

From Eqs. (i) and (ii), we get the values of x_1 and y_1, which gives the equation of tangent as $x \pm y = \pm a\sqrt{2}$.

6. ***(a, c)*** The equation of any tangent to the circle $x^2 + y^2 = 25$ is of the form

$$y = mx + 5\sqrt{1 + m^2}, \text{ where } m \text{ is the slope.}$$

It passes through (−2, 11).

$$\therefore \quad 11 = -2m + 5\sqrt{1 + m^2}$$
$$\Rightarrow \quad (11 + 2m)^2 = 25(1 + m^2)$$
$$\Rightarrow \quad m = \frac{24}{7}, \frac{-4}{3}$$

Therefore, the equation of tangents are

$$24x - 7y + 125 = 0$$

and $$4x + 3y = 25$$

7. ***(b, c)*** For the given circles

$$S_1 : x^2 + y^2 - 2x - 4y + 1 = 0$$

and $$S_2 : x^2 + y^2 + 4x + 4y - 1 = 0,$$

$$C_1 \equiv (1, 2), r_1 = 2; C_2 \equiv (-2, -2), r_2 = 3$$

Now, $r_1 + r_2 = 5$ and $C_1C_2 = 5$

Hence, the circles touch externally. Also, the common tangent at the point of contact is $S_1 - S_2 = 0$ or $3x + 4y - 1 = 0$.

8. ***(b, c)*** The equation of the pair of tangents given by $SS' = T^2$ is

$$(ax + 0 - 1)^2 = (x^2 + y^2 - 1)(a^2 + 0 - 1)$$
$$\Rightarrow \quad (a^2 - 1)y^2 - x^2 + 2ax - a^2 = 0$$

If θ is the angle between the tangents, then

$$\tan\theta = \frac{2\sqrt{H^2 - AB}}{A + B} = \frac{2\sqrt{-(a^2 - 1)(-1)}}{a^2 - 2}$$
$$= \frac{2\sqrt{a^2 - 1}}{a^2 - 2}$$

If θ lies in the second quadrant, then $\tan\theta < 0$.

METICULOUS ANALYSIS

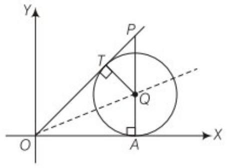
$$\therefore \quad \frac{2\sqrt{a^2-1}}{a^2-2} < 0$$

$$\Rightarrow \quad a^2 - 1 > 0 \text{ and } a^2 - 2 < 0$$

$$\Rightarrow \quad |a| > 1 \text{ and } |a| < \sqrt{2}$$

$\therefore\ a \in (-\sqrt{2}, -1) \cup (1, \sqrt{2})$

9. ***(c)*** Given, $QT = QA = 1$



Let $\quad PQ = x$. Then, $PT = \sqrt{x^2-1}$

ΔTQP and ΔAPO are similar triangles.

Then, $\quad OT = OA = \dfrac{x+1}{\sqrt{x^2-1}}$

$$\Rightarrow \quad 1 + x + \frac{2(x+1)}{\sqrt{x^2-1}} + \sqrt{x^2-1} = 8$$

$$\therefore \quad x = \frac{5}{3}$$

10. ***(a)*** Here, $AP = \dfrac{8}{3}$ and $OP = \dfrac{16}{3}$

Let $\quad \angle AOP = 2\theta,$

then $\quad \sin 2\theta = \dfrac{1}{2}$

In ΔOAQ,

$$\tan\theta = \frac{1}{OA} \Rightarrow OA = \frac{1}{\tan\theta}$$

Also, $\quad \sin 2\theta = \dfrac{2\tan\theta}{1+\tan^2\theta} = \dfrac{1}{2}$

$$\therefore \quad \tan\theta = 2 - \sqrt{3}$$

Thus, $\quad OA = 2 + \sqrt{3}$

Hence, the equation of circle is

$$\{x - (2+\sqrt{3})\}^2 + (y-1)^2 = 1$$

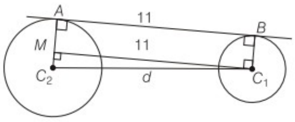
11. ***(a)*** The equation of tangent OT is

$$\frac{x-0}{\cos 2\theta} = \frac{y-0}{\sin 2\theta}$$

$$\therefore \quad x - \sqrt{3}y = 0$$

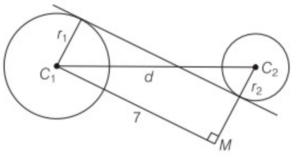
12. ***(0)*** Since, both circles are symmetric about X-axis, so the sum of slopes of tangent is 0.

13. ***(9)***



From the figure,

$$d^2 = 11^2 + (r_1 - r_2)^2 \qquad \text{...(i)}$$



From the figure,

$$d^2 = 7^2 + (r_1 + r_2)^2 \qquad \text{...(ii)}$$

From Eqs. (i) and (ii), we get

$$4r_1r_2 = 72$$

$$\Rightarrow \quad r_1r_2 = 18 = P \qquad \text{[given]}$$

$$\therefore \quad \frac{P}{2} = \frac{18}{2} = 9$$

14. ***(5)*** The equation of the given circle is

$$x^2 + y^2 - 6x - 2py + 17 = 0$$

$$\Rightarrow \quad (x-3)^2 + (y-p)^2 = (p^2 - 8) \qquad \text{...(i)}$$

Also, (0, 0) lies outside the circle.

The equation of director circle of $S = 0$ will be

$$(x-3)^2 + (y-p)^2 = 2(p^2-8) \qquad \text{...(ii)}$$

Tangents drawn from (0, 0) to circle (i) are perpendicular to each other. Therefore, (0, 0) must lie on director circle.

$$\therefore \quad (0-3)^2 + (0-p)^2 = 2(p^2-8)$$

$$\Rightarrow \quad p^2 = 25$$

$$\Rightarrow \quad p = \pm 25$$

$$\Rightarrow \quad |p| = 5$$

Chapter 3
Early Works in the Field of Contact Geometry of Surfaces

The investigation of the contact geometry of curves and surfaces can be traced back to the eighteenth century. The study of the contact of curves and surfaces was undertaken in considerable detail by *J.L. Lagrange*[1] in his "*Theorié des Fonctions Analytiques*" (1797) [1], and *A.L. Cauchy*[2] in his "*Leçons sur les Applications du Calcul Infinitésimal á la Geometrie*" (1826) [2]. Later, in the twentieth century, an investigation in the realm of contact geometry of curves and surfaces was undertaken by *J. Favard*[3] in his "*Course de Gèomètrie Diffèrentialle Locale*" (1957) [3]. A few more names of the researchers to be mentioned.

Contacts of curves and surfaces of two different kinds are distinguished. Speaking more generally, the contact of surfaces with "*different order of tangency*" is investigated in differential geometry of surfaces. As a particular case, the conditions of contact of two smooth regular part surfaces in the "*first order of tangency*" are investigated in engineering geometry of surfaces.

Let us begin the discussion from the analysis of the results of the research obtained so far in differential geometry of surfaces.

3.1 Order of Contact

Order of contact of two smooth regular surfaces can be specified in terms of the order of contact of two smooth regular planar curves. It is understood there that:

- the curves are within a common plane;
- the curves are passing through the point of contact of the surfaces; and

---

[1] *Joseph-Louis* ***Lagrange*** (January 25, 1736–April 10, 1813)—an Italian born [born *Giuseppe Lodovico (Luigi)* ***Lagrangia***] famous French mathematician and mechanician.

[2] *Augustin-Louis* ***Cauchy*** (August 21, 1789–May 23, 1857)—a famous French mathematician.

[3] *Jean* ***Favard*** (August 28, 1902–January 21, 1965)—a French mathematician.

S. P. Radzevich, *Geometry of Surfaces*,
https://doi.org/10.1007/978-3-030-22184-3_3

- the plane is through the direction of the common perpendicular to the contacting surfaces at a point of interest.

Under such an investigation scenario, the contact geometry of two surfaces can be reduced to investigation of the geometry of contact of the two curves when the section plane spins about the straight line along the common perpendicular to the contacting surfaces. One application of such an approach is in fitting a local model to a shape if we want the contact to be as tight as possible. This requirement can be formulated in other words, that is, if we want the highest possible degree of conformity of the contacting surfaces in a particular plane through the common perpendicular. Another application is in the interaction of probes with a shape. For instance, a light ray may graze a surface in many different ways, the degree of contact varying enormously from case to case.

Planar curves have no contact if they have no point in common. Contact of order zero is observed when two smooth regular curves have a common intersection. Then, the order-one contact of the curves occurs when—at the point in common—the tangents to the curves align with one another. Ultimately, it is said that two curves have contact of the order n if all their derivatives with respect to arc length up to the nth-order are aligned, whereas the $(n+1)$th-order is different. The order thus amounts to the order of the common initial part of a *Taylor*[4] series.[5]

Similarly, it is said for the case of two surfaces that the order of contact is n if all mixed partial derivatives up to the nth-order for some mutual parameterization $[\mathbf{r}_{P1}(U_P,\ V_P)$, and $\mathbf{r}_{P2}(U_P,\ V_P)]$ align, whereas this is not the case for the $(n+1)$th-order.

Thus, first-order contact means:

$$\frac{\partial \mathbf{r}_{P1}}{\partial U_P}(U_P,\ V_P) = \frac{\partial \mathbf{r}_{P2}}{\partial U_P}(U_P,\ V_P) \tag{3.1}$$

$$\frac{\partial \mathbf{r}_{P1}}{\partial V_P}(U_P,\ V_P) = \frac{\partial \mathbf{r}_{P2}}{\partial V_P}(U_P,\ V_P) \tag{3.2}$$

and at least one of the equalities:

$$\frac{\partial^2 \mathbf{r}_{P1}}{\partial U_P^2}(U_P,\ V_P) = \frac{\partial^2 \mathbf{r}_{P2}}{\partial U_P^2}(U_P,\ V_P) \tag{3.3}$$

$$\frac{\partial^2 \mathbf{r}_{P1}}{\partial U_P^2}(U_P,\ V_P) = \frac{\partial^2 \mathbf{r}_{P2}}{\partial U_P^2}(U_P,\ V_P) \tag{3.4}$$

$$\frac{\partial^2 \mathbf{r}_{P1}}{\partial U_P \partial V_P}(U_P,\ V_P) = \frac{\partial^2 \mathbf{r}_{P2}}{\partial U_P \partial V_P}(U_P,\ V_P) \tag{3.5}$$

---

[4] *Brook* ***Taylor*** (August 18, 1685–December 29, 1731)—a well known English mathematician.

[5] It can be found out in the book by *Favard* [3] that two curves having infinite degree of contact cannot be congruent to one another.

is not true; that is to say, the tangent planes coincide but the osculating quadrics differ.

In Eq. (3.1) through Eq. (3.5), the position vector of a point of the first of the contacting surfaces P_1 is designated $\mathbf{r}_{P1}$, and the position vector of a point of the second of the contacting surface P_2 is denoted $\mathbf{r}_{P2}$. Both the contacting surfaces P_1 and P_2 must be parameterized so as to have common "*Gaussian coordinates*" U_P and V_P. In a case the part surfaces P_1 and P_2 are expressed in different U_P- and V_P-coordinates, then it is required to re-parameterize them to common U_P- and V_P-parameters (see Appendix C).

A "*curve*" has contact of at least order n with a "*surface*" if there exists a curve in the surface, which has nth-order contact with the curve. One defines the contact of space curves in the same way as the contact of planar curves mentioned earlier.

3.2 Contact Geometry of Part Surfaces

When solving problems in engineering geometry of surfaces, an appropriate method for analytical description of the contact geometry of part surfaces—say of a part surface P_1 and a part surface P_2—is required. The problem of analytical description of the contact geometry of two smooth regular part surfaces in the first order of tangency is a sophisticated one. It can be solved on the premise of analysis of geometry of the contacting surfaces in the differential vicinity of the point of their contact.

Various methods for analytical description of the contact geometry of smooth regular surfaces have been developed. An overview of the known methods can be found in the monograph by Prof. *Radzevich* [4]. The latest achievements in the field are discussed in the papers [5, 6] and in the monograph [7]. In these publications as well as in other works, two part surfaces P_1 and P_2 that make contact at a point K are considered. Locally, each of the contacting surfaces is represented by a corresponding quadric. Owing to the fact that only differential vicinity of the contacting surfaces is considered below, that same designation P_1 and P_2 is applied to the quadrics as to the surfaces P_1 and P_2 themselves.

Generally speaking, at the point of contact K, the contacting part surfaces P_1 and P_2 may feature an arbitrary configuration. Namely, the local part surface patches P_1 and P_2 may be turned around a common perpendicular through a certain angle. Thus, it makes sense to begin the discussion from the analytical description of local relative orientation of the part surfaces P_1 and P_2 (in the differential vicinity of the point of contact of the surfaces).

3.3 Local Relative Orientation of Contacting Part Surfaces

Consider two local part surface patches P_1 and P_2, which make contact at a point K as illustrated in Fig. 3.1. At the contact point K, the surfaces P_1 and P_2 share a

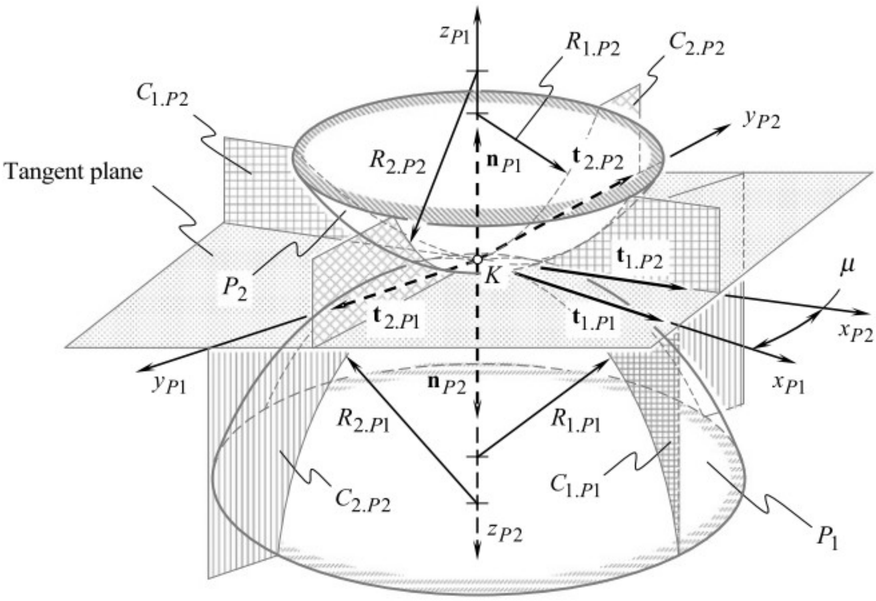

Fig. 3.1 Local configuration of two smooth regular part surface patches P_1 and P_2 at a point K of their contact

common tangent plane. Tangency of the surfaces imposes a kind of restrictions on the relative configuration (location and orientation) of these surfaces, and on their relative motion, if any. In engineering geometry of surface generation, a quantitative measure of the surfaces P_1 and P_2 relative orientation is established.

Relative orientation of the contacting part surfaces P_1 and P_2 is specified by the angle μ of the surfaces "*local relative orientation*".[6] By definition [5, 8, and 9], the angle μ is equal to the angle that the unit tangent vector $\mathbf{t}_{1.P1}$ of the first principal direction of the part surface P_1 forms with the unit tangent vector $\mathbf{t}_{1.P2}$ of the first principal direction of the part surface P_2. That same angle μ can also be specified as the angle made by the unit tangent vectors $\mathbf{t}_{2.P1}$ and $\mathbf{t}_{2.P2}$ of the second principal directions of the part surfaces P_1 and P_2 at a point K of their contact. This immediately yields the equations for the calculation of the angle μ of the surfaces local relative orientation:

$$\sin\mu = |\mathbf{t}_{1.P1} \times \mathbf{t}_{1.P2}| = |\mathbf{t}_{2.P1} \times \mathbf{t}_{2.P2}| \tag{3.6}$$

$$\cos\mu = \mathbf{t}_{1.P1} \cdot \mathbf{t}_{1.P2} = \mathbf{t}_{2.P1} \cdot \mathbf{t}_{2.P2} \tag{3.7}$$

---

[6] Orientation of the surfaces P_1 and P_2 is "*local*" in nature as it is related only to the differential vicinity of point K of contact of the surfaces.

$$\tan \mu = \frac{|\mathbf{t}_{1.P1} \times \mathbf{t}_{1.P2}|}{\mathbf{t}_{1.P1} \cdot \mathbf{t}_{1.P2}} \equiv \frac{|\mathbf{t}_{2.P1} \times \mathbf{t}_{2.P2}|}{\mathbf{t}_{2.P1} \cdot \mathbf{t}_{2.P2}} \tag{3.8}$$

Here, we define:

$\mathbf{t}_{1.P1}$, $\mathbf{t}_{2.P1}$	Are the unit vectors of principal directions on the first part surface P_1 of two contacting surfaces
$\mathbf{t}_{1.P2}$, $\mathbf{t}_{2.P2}$	Are the unit vectors of principal directions on the second part surface P_2 of two contacting surfaces.

In case of point contact of the part surfaces P_1 and P_2, the actual value of the angle μ is calculated at the point K of contact of the surfaces. If the part surfaces P_1 and P_2 are in line contact, then the actual value of the angle μ of the surfaces' local relative orientation can be calculated at every point within the line of contact.[7] The reason for why the angle μ is referred to as the angle of "*local*" surfaces' orientation is clearly illustrated with this.

The determination of the angle μ of the surfaces' P_1 and P_2 local relative orientation is illustrated in Fig. 3.2.

Unit tangent vectors of the principal directions $\mathbf{t}_{1.P1}$ and $\mathbf{t}_{1.P2}$ at a point of contact of the part surfaces P_1 and P_2 are employed for the purpose of calculation of the angle μ of the surfaces' local relative orientation.

Consider two part surfaces P_1 and P_2 in point contact that are represented in a common reference system. The surfaces make contact at point K. For further analysis, an equation of the common tangent plane to the surfaces P_1 and P_2 at the point K is necessary (Figs. 3.1 and 3.3):

$$(\mathbf{r}_{\text{tp}} - \mathbf{r}_K) \cdot \mathbf{u}_{P1} \cdot \mathbf{v}_{P1} = 0 \tag{3.9}$$

Here, we define:

$\mathbf{r}_{\text{tp}}$	Is the position vector of a point of the common tangent plane
$\mathbf{r}_K$	Is the position vector of the contact point K
$\mathbf{u}_{P1}$ and $\mathbf{v}_{P1}$	are the unit vectors tangent to U_{P1}- and V_{P1}-coordinate lines on the surface P_1 at the point K.

An equation similar to Eq. (3.9) can also be expressed in terms of parameters of geometry of the other contacting surface P_2.

The actual value of the angle ω_{P1} between the vectors $\mathbf{v}_{P1}$ and $\mathbf{v}_{P1}$ can be calculated from one of the following equations:

$$\sin \omega_{P1} = \frac{\sqrt{E_{P1} G_{P1} - F_{P1}^2}}{\sqrt{E_{P1} G_{P1}}} \tag{3.10}$$

---

[7] It is worth pointing out here that for line contact, the relative orientation of the surfaces P_1 and P_2 is predetermined in global sense. However, the actual value of the angle μ of the surfaces' P_1 and P_2 "*local*" relative orientation at different points of the line of contact is different.

$$\tan \omega_{P1} = \frac{\sqrt{E_{P1} G_{P1} - F_{P1}^2}}{F_{P1}} \tag{3.12}$$

Equations similar to Eq. (3.9) through Eq. (3.12) are also valid for the calculation of the angle ω_{P2} of the other contacting surface P_2.

The unit tangent vectors $\mathbf{u}_{P1}$ and $\mathbf{v}_{P1}$, which are tangent to the U_{P1}- and V_{P1}-coordinate lines on the part surface P_1, and the unit tangent vectors $\mathbf{u}_{P2}$ and $\mathbf{v}_{P2}$, which are tangent to the U_{P2}- and V_{P2}-coordinate lines on the surface P_2, are specified by the angles θ and ε. The actual values of the angles θ and ε can be calculated from the following equations:

$$\cos \theta = \mathbf{u}_{P1} \cdot \mathbf{u}_{P2} \tag{3.13}$$

$$\cos\varepsilon = \mathbf{v}_{P1} \cdot \mathbf{v}_{P2} \tag{3.14}$$

Angle ξ_P is the angle that the first principal direction $\mathbf{t}_{1.P}$ on the surface P forms with the unit tangent vector $\mathbf{u}_P$ (see Fig. 3.3). The equation for the calculation of the actual value of the angle ξ_P is derived by Prof. *Radzevich* [5, 8, and 9]:

$$\sin\xi_{P1} = \frac{\eta_{P1}}{\sqrt{\eta_{P1}^2 - 2\eta_{P1}\cos\omega_{P1} + 1}}\sin\omega_{P1} \tag{3.15}$$

where the ratio $\partial U_{P1}/\partial V_{P1}$ is denoted by η_{P1}, ($\eta_{P1} = \partial U_{P1}/\partial V_{P1}$).

In the event $F_{P1} = 0$, the equality $\tan\xi_{P1} = \eta_{P1}$ is observed. Here, the ratio η_{P1} is calculated as the root of the quadratic equation:

$$\begin{aligned}(F_{P1}L_{P1} - E_{P1}M_{P1})\eta_{P1}^2 + (G_{P1}L_{P1} - E_{P1}N_{P1})\eta_{P1} \\ + (G_{P1}M_{P1} - F_{P1}N_{P1}) = 0\end{aligned} \tag{3.16}$$

that follows immediately from Eq. (1.68).

The equation for calculation of the actual value of the angle ξ_{P1} yields another representation. Following the chain rule, $\mathrm{d}\mathbf{r}_{P1}$ can be represented in the form:

$$\mathrm{d}\mathbf{r}_{P1} = \mathbf{U}_{P1}\mathrm{d}U_{P1} + \mathbf{V}_{P1}\mathrm{d}V_{P1} \tag{3.17}$$

By definition, $\tan\xi_{P1} = \frac{\sin\xi_{P1}}{\cos\xi_{P1}}$. The functions $\sin\xi_{P1}$ and $\cos\xi_{P1}$ yield representation in the form:

$$\sin\xi_{P1} = \frac{|\mathbf{U}_{P1} \times \mathrm{d}\mathbf{r}_{P1}|}{|\mathbf{U}_{P1}| \cdot |\mathrm{d}\mathbf{r}_{P1}|} \tag{3.18}$$

$$\cos\xi_{P1} = \frac{\mathbf{U}_{P1} \cdot \mathrm{d}\mathbf{r}_{P1}}{|\mathbf{U}_{P1}| \cdot |\mathrm{d}\mathbf{r}_{P1}|} \tag{3.19}$$

The last expressions make it possible the formula:

$$\begin{aligned}\tan\xi_{P1} &= \frac{\sin\xi_{P1}}{\cos\xi_{P1}} = \frac{|\mathbf{U}_{P1} \times \mathrm{d}\mathbf{r}_{P1}|}{\mathbf{U}_{P1} \cdot \mathrm{d}\mathbf{r}_{P1}} = \frac{|\mathbf{U}_{P1} \times \mathrm{d}\mathbf{r}_{P1}|}{\mathbf{U}_{P1} \cdot (\mathbf{U}_{P1}\mathrm{d}U_{P1} + \mathbf{V}_{P1}\mathrm{d}V_{P1})} \\ &= \frac{|\mathbf{U}_{P1} \times \mathrm{d}\mathbf{r}_{P1}| \cdot \mathrm{d}V_{P1}}{\mathbf{U}_{P1} \cdot \mathbf{U}_{P1}\mathrm{d}U_{P1} + \mathbf{U}_{P1} \cdot \mathbf{V}_{P1}\mathrm{d}V_{P1}}\end{aligned} \tag{3.20}$$

By definition,

$$\mathbf{U}_{P1} \cdot \mathbf{U}_{P1} = E_{P1} \tag{3.21}$$

$$\mathbf{U}_{P1} \cdot \mathbf{V}_{P1} = F_{P1} \tag{3.22}$$

$$\mathbf{V}_{P1} \cdot \mathbf{V}_{P1} = G_{P1} \tag{3.23}$$

$$|\mathbf{U}_{P1} \times \mathbf{V}_{P1}| = \sqrt{E_{P1}G_{P1} - F_{P1}^2} \tag{3.24}$$

Then, Eq. (3.17) through Eq. (3.24) yield the formula:

$$\tan\xi_{P1} = \frac{\sqrt{E_{P1}G_{P1} - F_{P1}^2}}{\eta_P \cdot E_{P1} + F_{P1}} \tag{3.25}$$

for calculation of the actual value of the angle ξ_{P1}.

Equations, similar to those above Eqs. (3.15) and (3.25), are also valid for the calculation of the actual value of the angle ξ_{P2} that the first principal direction $\mathbf{t}_{1.P2}$ on the part surface P_2 makes with the unit tangent vector $\mathbf{u}_{P2}$.

The analysis performed above yields the following equations for the calculation of the unit tangent vectors $\mathbf{t}_{1.P1}$, $\mathbf{t}_{2.P1}$ of the principal directions:

$$\mathbf{t}_{1.P1} = \mathbf{Rt}(\xi_{P1}, \mathbf{n}_{P1}) \cdot \mathbf{u}_{P1} \tag{3.26}$$

$$\mathbf{t}_{2.P1} = \mathbf{Rt}\Big[\Big(\xi_{P1} + \frac{\pi}{2}\Big), \mathbf{n}_{P1}\Big] \cdot \mathbf{u}_{P1} \tag{3.27}$$

for the first part surface P_1, and similar equations for the calculation of the unit tangent vectors $\mathbf{t}_{1.T}$, $\mathbf{t}_{2.T}$ of the principal directions:

$$\mathbf{t}_{1.P2} = \mathbf{Rt}(\xi_{P2},\ \mathbf{n}_{P2}) \cdot \mathbf{u}_{P2} \tag{3.28}$$

$$\mathbf{t}_{2.P2} = \mathbf{Rt}\Big[\Big(\xi_{P2} + \frac{\pi}{2}\Big),\ \mathbf{n}_{P2}\Big] \cdot \mathbf{u}_{P2} \tag{3.29}$$

for the second part surface P_2.

See Appendix B for the calculation of the operators of rotation $\mathbf{Rt}(\xi_{P1},\ \mathbf{n}_{P1})$, $\mathbf{Rt}\big[\big(\xi_{P1} + \frac{\pi}{2}\big),\ \mathbf{n}_{P1}\big]$, and $\mathbf{Rt}(\xi_{P2},\ \mathbf{n}_{P2})$, $\mathbf{Rt}\big[\big(\xi_{P2} + \frac{\pi}{2}\big),\ \mathbf{n}_{P2}\big]$ in Eq. (3.26) through Eq. (3.29) accordingly.

3.4 First-Order Analysis: Common Tangent Plane

Various methods can be implemented for analytical description of the contact geometry of two smooth regular part surfaces in the first order of tangency. The first-order analysis is the simplest among all of them.

First-order analysis is the simplest method used for the analysis of geometry of contact of two smooth regular part surfaces P_1 and P_2 at a point K of their contact. Implementation of the first-order analysis returns limited information on the contact geometry of the surfaces in the differential vicinity of the point of contact. Accurate analytical description of the geometry of contact of two smooth regular part surfaces is possible only when the first-order analysis is used together with a kind of higher-order analysis. Under such a scenario, the first-order analysis is incorporated as a first step of a higher-order analysis of the contact geometry of two smooth regular part surfaces P_1 and P_2.

The common tangent plane can be defined as a plane through the contact point K. This plane is perpendicular to the common unit normal vector $\mathbf{n}_P$ to the part surfaces P_1 and P_2 at K. For an analytical description of the common tangent plane, vector equation [see Eq. (1.15)]:

$$(\mathbf{r}_{\mathrm{tp}} - \mathbf{r}_K) \cdot \mathbf{u}_{P1} \cdot \mathbf{v}_{P1} = 0 \tag{3.30}$$

can be employed.

Any pair of unit vectors chosen from the set of vectors, namely from the set of vectors $\mathbf{u}_{P1}$, $\mathbf{v}_{P1}$, $\mathbf{u}_{P2}$, $\mathbf{v}_{P2}$, $\mathbf{t}_{1.P1}$, $\mathbf{t}_{2.P1}$, $\mathbf{t}_{1.P2}$, $\mathbf{t}_{2.P2}$ can be used as a replacement for the unit tangent vectors $\mathbf{u}_{P1}$ and $\mathbf{v}_{P1}$ in Eq. (3.30).

The first-order analysis provides very limited information about the contact geometry of two smooth regular part surfaces in first order of tangency. Hence, the first-order analysis itself has limited application. However, the importance of the first-order analysis becomes valuable as it is incorporated into the second-order analysis, and/or into a higher-order analysis.

3.5 Second-Order Analysis

For a more accurate analytical description of the contact geometry of two part surfaces P_1 and P_2, consideration of the second-order parameters is required. Elements of both of the first order and second order are taken into consideration when the second-order analysis undertaken. To perform the second-order analysis, familiarity with "*Dupin indicatrix*" is highly desirable. The "*Dupin indicatrix*" is a perfect starting point for consideration of the second-order analysis.

It makes sense to begin the discussion of the contact geometry of two smooth regular part surfaces in the first order of tangency from the assumptions those made by the founder of contact mechanics of materials, German physicist *Heinrich Hertz*. The theory proposed by *Hertz* is based on the implementation of an imaginary surface, which (after *Hertz*) is referred to as "*surface of relative curvature*."

3.5.1 Comments on Analytical Description of Local Geometry of Contacting Surfaces Loaded by a Normal Force: "Hertz Proportional Assumption"

Investigation of the geometry of interacting surfaces under an applied normal load can be traced back to the fundamental research by *H. Hertz*[8] on contact of solid elastic bodies (*Hertz*, 1881–1896).

In 1886–1889, *Hertz* published two articles on what was to become known as the field of "*contact mechanics*" of materials. His work basically summarizes how two axisymmetric objects placed in contact will behave under loading. The developed theory is based on *Hertz's* observation of elliptical "*Newton's rings*" formed upon placing a glass sphere upon a lens as the basis of assuming that the pressure exerted by the sphere follows an elliptical distribution.

---

[8] *Heinrich Rudolf* ***Hertz*** (February 22, 1857–January 1, 1894), a famous German physicist.

is not true; that is to say, the tangent planes coincide but the osculating quadrics differ.

In Eq. (3.1) through Eq. (3.5), the position vector of a point of the first of the contacting surfaces P_1 is designated $\mathbf{r}_{P1}$, and the position vector of a point of the second of the contacting surface P_2 is denoted $\mathbf{r}_{P2}$. Both the contacting surfaces P_1 and P_2 must be parameterized so as to have common "*Gaussian coordinates*" U_P and V_P. In a case the part surfaces P_1 and P_2 are expressed in different U_P- and V_P-coordinates, then it is required to re-parameterize them to common U_P- and V_P-parameters (see Appendix C).

A "*curve*" has contact of at least order n with a "*surface*" if there exists a curve in the surface, which has nth-order contact with the curve. One defines the contact of space curves in the same way as the contact of planar curves mentioned earlier.

3.2 Contact Geometry of Part Surfaces

When solving problems in engineering geometry of surfaces, an appropriate method for analytical description of the contact geometry of part surfaces—say of a part surface P_1 and a part surface P_2—is required. The problem of analytical description of the contact geometry of two smooth regular part surfaces in the first order of tangency is a sophisticated one. It can be solved on the premise of analysis of geometry of the contacting surfaces in the differential vicinity of the point of their contact.

Various methods for analytical description of the contact geometry of smooth regular surfaces have been developed. An overview of the known methods can be found in the monograph by Prof. *Radzevich* [4]. The latest achievements in the field are discussed in the papers [5, 6] and in the monograph [7]. In these publications as well as in other works, two part surfaces P_1 and P_2 that make contact at a point K are considered. Locally, each of the contacting surfaces is represented by a corresponding quadric. Owing to the fact that only differential vicinity of the contacting surfaces is considered below, that same designation P_1 and P_2 is applied to the quadrics as to the surfaces P_1 and P_2 themselves.

Generally speaking, at the point of contact K, the contacting part surfaces P_1 and P_2 may feature an arbitrary configuration. Namely, the local part surface patches P_1 and P_2 may be turned around a common perpendicular through a certain angle. Thus, it makes sense to begin the discussion from the analytical description of local relative orientation of the part surfaces P_1 and P_2 (in the differential vicinity of the point of contact of the surfaces).

3.3 Local Relative Orientation of Contacting Part Surfaces

Consider two local part surface patches P_1 and P_2, which make contact at a point K as illustrated in Fig. 3.1. At the contact point K, the surfaces P_1 and P_2 share a

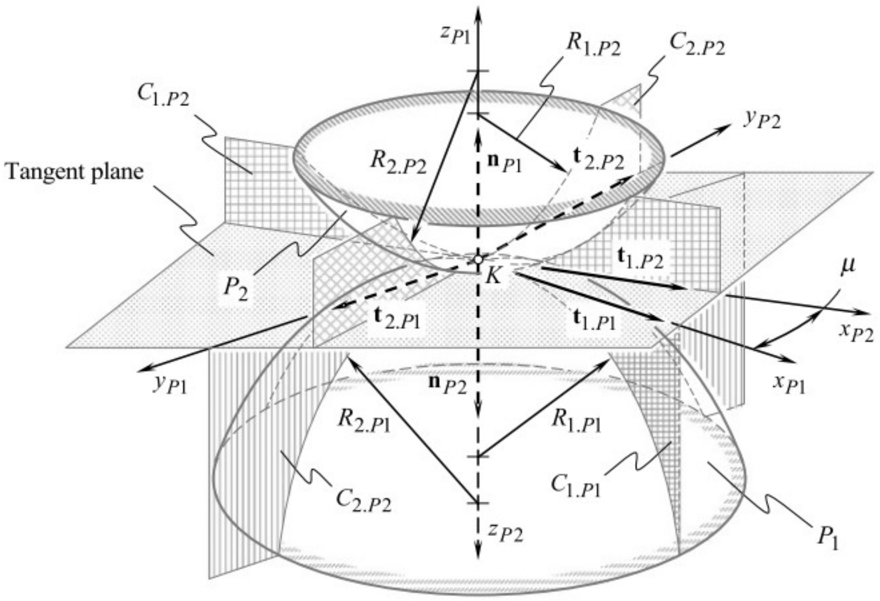

Fig. 3.1 Local configuration of two smooth regular part surface patches P_1 and P_2 at a point K of their contact

common tangent plane. Tangency of the surfaces imposes a kind of restrictions on the relative configuration (location and orientation) of these surfaces, and on their relative motion, if any. In engineering geometry of surface generation, a quantitative measure of the surfaces P_1 and P_2 relative orientation is established.

Relative orientation of the contacting part surfaces P_1 and P_2 is specified by the angle μ of the surfaces "*local relative orientation*".[6] By definition [5, 8, and 9], the angle μ is equal to the angle that the unit tangent vector $\mathbf{t}_{1.P1}$ of the first principal direction of the part surface P_1 forms with the unit tangent vector $\mathbf{t}_{1.P2}$ of the first principal direction of the part surface P_2. That same angle μ can also be specified as the angle made by the unit tangent vectors $\mathbf{t}_{2.P1}$ and $\mathbf{t}_{2.P2}$ of the second principal directions of the part surfaces P_1 and P_2 at a point K of their contact. This immediately yields the equations for the calculation of the angle μ of the surfaces local relative orientation:

$$\sin\mu = |\mathbf{t}_{1.P1} \times \mathbf{t}_{1.P2}| = |\mathbf{t}_{2.P1} \times \mathbf{t}_{2.P2}| \tag{3.6}$$

$$\cos\mu = \mathbf{t}_{1.P1} \cdot \mathbf{t}_{1.P2} = \mathbf{t}_{2.P1} \cdot \mathbf{t}_{2.P2} \tag{3.7}$$

---

[6] Orientation of the surfaces P_1 and P_2 is "*local*" in nature as it is related only to the differential vicinity of point K of contact of the surfaces.

$$\tan \mu = \frac{|\mathbf{t}_{1.P1} \times \mathbf{t}_{1.P2}|}{\mathbf{t}_{1.P1} \cdot \mathbf{t}_{1.P2}} \equiv \frac{|\mathbf{t}_{2.P1} \times \mathbf{t}_{2.P2}|}{\mathbf{t}_{2.P1} \cdot \mathbf{t}_{2.P2}} \tag{3.8}$$

Here, we define:

$\mathbf{t}_{1.P1}$, $\mathbf{t}_{2.P1}$	Are the unit vectors of principal directions on the first part surface P_1 of two contacting surfaces
$\mathbf{t}_{1.P2}$, $\mathbf{t}_{2.P2}$	Are the unit vectors of principal directions on the second part surface P_2 of two contacting surfaces.

In case of point contact of the part surfaces P_1 and P_2, the actual value of the angle μ is calculated at the point K of contact of the surfaces. If the part surfaces P_1 and P_2 are in line contact, then the actual value of the angle μ of the surfaces' local relative orientation can be calculated at every point within the line of contact.[7] The reason for why the angle μ is referred to as the angle of "*local*" surfaces' orientation is clearly illustrated with this.

The determination of the angle μ of the surfaces' P_1 and P_2 local relative orientation is illustrated in Fig. 3.2.

Unit tangent vectors of the principal directions $\mathbf{t}_{1.P1}$ and $\mathbf{t}_{1.P2}$ at a point of contact of the part surfaces P_1 and P_2 are employed for the purpose of calculation of the angle μ of the surfaces' local relative orientation.

Consider two part surfaces P_1 and P_2 in point contact that are represented in a common reference system. The surfaces make contact at point K. For further analysis, an equation of the common tangent plane to the surfaces P_1 and P_2 at the point K is necessary (Figs. 3.1 and 3.3):

$$(\mathbf{r}_{\text{tp}} - \mathbf{r}_K) \cdot \mathbf{u}_{P1} \cdot \mathbf{v}_{P1} = 0 \tag{3.9}$$

Here, we define:

$\mathbf{r}_{\text{tp}}$	Is the position vector of a point of the common tangent plane
$\mathbf{r}_K$	Is the position vector of the contact point K
$\mathbf{u}_{P1}$ and $\mathbf{v}_{P1}$	are the unit vectors tangent to U_{P1}- and V_{P1}-coordinate lines on the surface P_1 at the point K.

An equation similar to Eq. (3.9) can also be expressed in terms of parameters of geometry of the other contacting surface P_2.

The actual value of the angle ω_{P1} between the vectors $\mathbf{v}_{P1}$ and $\mathbf{v}_{P1}$ can be calculated from one of the following equations:

$$\sin \omega_{P1} = \frac{\sqrt{E_{P1}G_{P1} - F_{P1}^2}}{\sqrt{E_{P1}G_{P1}}} \tag{3.10}$$

---

[7] It is worth pointing out here that for line contact, the relative orientation of the surfaces P_1 and P_2 is predetermined in global sense. However, the actual value of the angle μ of the surfaces' P_1 and P_2 "*local*" relative orientation at different points of the line of contact is different.

$$\tan \omega_{P1} = \frac{\sqrt{E_{P1} G_{P1} - F_{P1}^2}}{F_{P1}} \tag{3.12}$$

Equations similar to Eq. (3.9) through Eq. (3.12) are also valid for the calculation of the angle ω_{P2} of the other contacting surface P_2.

The unit tangent vectors $\mathbf{u}_{P1}$ and $\mathbf{v}_{P1}$, which are tangent to the U_{P1}- and V_{P1}-coordinate lines on the part surface P_1, and the unit tangent vectors $\mathbf{u}_{P2}$ and $\mathbf{v}_{P2}$, which are tangent to the U_{P2}- and V_{P2}-coordinate lines on the surface P_2, are specified by the angles θ and ε. The actual values of the angles θ and ε can be calculated from the following equations:

$$\cos \theta = \mathbf{u}_{P1} \cdot \mathbf{u}_{P2} \tag{3.13}$$

$$\cos \varepsilon = \mathbf{v}_{P1} \cdot \mathbf{v}_{P2} \tag{3.14}$$

Angle ξ_P is the angle that the first principal direction $\mathbf{t}_{1.P}$ on the surface P forms with the unit tangent vector $\mathbf{u}_P$ (see Fig. 3.3). The equation for the calculation of the actual value of the angle ξ_P is derived by Prof. *Radzevich* [5, 8, and 9]:

$$\sin \xi_{P1} = \frac{\eta_{P1}}{\sqrt{\eta_{P1}^2 - 2\eta_{P1}\cos\omega_{P1} + 1}} \sin \omega_{P1} \tag{3.15}$$

where the ratio $\partial U_{P1}/\partial V_{P1}$ is denoted by η_{P1}, ($\eta_{P1} = \partial U_{P1}/\partial V_{P1}$).

In the event $F_{P1} = 0$, the equality $\tan \xi_{P1} = \eta_{P1}$ is observed. Here, the ratio η_{P1} is calculated as the root of the quadratic equation:

$$\begin{aligned}&(F_{P1}L_{P1}-E_{P1}M_{P1})\eta_{P1}^2+(G_{P1}L_{P1}-E_{P1}N_{P1})\eta_{P1}\\&\quad+(G_{P1}M_{P1}-F_{P1}N_{P1})=0\end{aligned}\tag{3.16}$$

that follows immediately from Eq. (1.68).

The equation for calculation of the actual value of the angle ξ_{P1} yields another representation. Following the chain rule, $\mathrm{d}\mathbf{r}_{P1}$ can be represented in the form:

$$\mathrm{d}\mathbf{r}_{P1}=\mathbf{U}_{P1}\mathrm{d}U_{P1}+\mathbf{V}_{P1}\mathrm{d}V_{P1}\tag{3.17}$$

By definition, $\tan\xi_{P1}=\frac{\sin\xi_{P1}}{\cos\xi_{P1}}$. The functions $\sin\xi_{P1}$ and $\cos\xi_{P1}$ yield representation in the form:

$$\sin\xi_{P1}=\frac{|\mathbf{U}_{P1}\times\mathrm{d}\mathbf{r}_{P1}|}{|\mathbf{U}_{P1}|\cdot|\mathrm{d}\mathbf{r}_{P1}|}\tag{3.18}$$

$$\cos\xi_{P1}=\frac{\mathbf{U}_{P1}\cdot\mathrm{d}\mathbf{r}_{P1}}{|\mathbf{U}_{P1}|\cdot|\mathrm{d}\mathbf{r}_{P1}|}\tag{3.19}$$

The last expressions make it possible the formula:

$$\begin{aligned}\tan\xi_{P1}&=\frac{\sin\xi_{P1}}{\cos\xi_{P1}}=\frac{|\mathbf{U}_{P1}\times\mathrm{d}\mathbf{r}_{P1}|}{\mathbf{U}_{P1}\cdot\mathrm{d}\mathbf{r}_{P1}}=\frac{|\mathbf{U}_{P1}\times\mathrm{d}\mathbf{r}_{P1}|}{\mathbf{U}_{P1}\cdot(\mathbf{U}_{P1}\mathrm{d}U_{P1}+\mathbf{V}_{P1}\mathrm{d}V_{P1})}\\&=\frac{|\mathbf{U}_{P1}\times\mathrm{d}\mathbf{r}_{P1}|\cdot\mathrm{d}V_{P1}}{\mathbf{U}_{P1}\cdot\mathbf{U}_{P1}\mathrm{d}U_{P1}+\mathbf{U}_{P1}\cdot\mathbf{V}_{P1}\mathrm{d}V_{P1}}\end{aligned}\tag{3.20}$$

By definition,

$$\mathbf{U}_{P1}\cdot\mathbf{U}_{P1}=E_{P1}\tag{3.21}$$

$$\mathbf{U}_{P1}\cdot\mathbf{V}_{P1}=F_{P1}\tag{3.22}$$

$$\mathbf{V}_{P1}\cdot\mathbf{V}_{P1}=G_{P1}\tag{3.23}$$

$$|\mathbf{U}_{P1}\times\mathbf{V}_{P1}|=\sqrt{E_{P1}G_{P1}-F_{P1}^2}\tag{3.24}$$

Then, Eq. (3.17) through Eq. (3.24) yield the formula:

$$\tan\xi_{P1}=\frac{\sqrt{E_{P1}G_{P1}-F_{P1}^2}}{\eta_P\cdot E_{P1}+F_{P1}}\tag{3.25}$$

for calculation of the actual value of the angle ξ_{P1}.

Equations, similar to those above Eqs. (3.15) and (3.25), are also valid for the calculation of the actual value of the angle ξ_{P2} that the first principal direction $\mathbf{t}_{1.P2}$ on the part surface P_2 makes with the unit tangent vector $\mathbf{u}_{P2}$.

The analysis performed above yields the following equations for the calculation of the unit tangent vectors $\mathbf{t}_{1.P1}$, $\mathbf{t}_{2.P1}$ of the principal directions:

$$\mathbf{t}_{1.P1} = \mathbf{Rt}(\xi_{P1}, \mathbf{n}_{P1}) \cdot \mathbf{u}_{P1} \tag{3.26}$$

$$\mathbf{t}_{2.P1} = \mathbf{Rt}\Big[\Big(\xi_{P1} + \frac{\pi}{2}\Big), \mathbf{n}_{P1}\Big] \cdot \mathbf{u}_{P1} \tag{3.27}$$

for the first part surface P_1, and similar equations for the calculation of the unit tangent vectors $\mathbf{t}_{1.T}$, $\mathbf{t}_{2.T}$ of the principal directions:

$$\mathbf{t}_{1.P2} = \mathbf{Rt}(\xi_{P2},\ \mathbf{n}_{P2}) \cdot \mathbf{u}_{P2} \tag{3.28}$$

$$\mathbf{t}_{2.P2} = \mathbf{Rt}\Big[\Big(\xi_{P2} + \frac{\pi}{2}\Big),\ \mathbf{n}_{P2}\Big] \cdot \mathbf{u}_{P2} \tag{3.29}$$

for the second part surface P_2.

See Appendix B for the calculation of the operators of rotation $\mathbf{Rt}(\xi_{P1},\ \mathbf{n}_{P1})$, $\mathbf{Rt}\big[\big(\xi_{P1} + \frac{\pi}{2}\big),\ \mathbf{n}_{P1}\big]$, and $\mathbf{Rt}(\xi_{P2},\ \mathbf{n}_{P2})$, $\mathbf{Rt}\big[\big(\xi_{P2} + \frac{\pi}{2}\big),\ \mathbf{n}_{P2}\big]$ in Eq. (3.26) through Eq. (3.29) accordingly.

3.4 First-Order Analysis: Common Tangent Plane

Various methods can be implemented for analytical description of the contact geometry of two smooth regular part surfaces in the first order of tangency. The first-order analysis is the simplest among all of them.

First-order analysis is the simplest method used for the analysis of geometry of contact of two smooth regular part surfaces P_1 and P_2 at a point K of their contact. Implementation of the first-order analysis returns limited information on the contact geometry of the surfaces in the differential vicinity of the point of contact. Accurate analytical description of the geometry of contact of two smooth regular part surfaces is possible only when the first-order analysis is used together with a kind of higher-order analysis. Under such a scenario, the first-order analysis is incorporated as a first step of a higher-order analysis of the contact geometry of two smooth regular part surfaces P_1 and P_2.

The common tangent plane can be defined as a plane through the contact point K. This plane is perpendicular to the common unit normal vector $\mathbf{n}_P$ to the part surfaces P_1 and P_2 at K. For an analytical description of the common tangent plane, vector equation [see Eq. (1.15)]:

$$(\mathbf{r}_{\text{tp}} - \mathbf{r}_K) \cdot \mathbf{u}_{P1} \cdot \mathbf{v}_{P1} = 0 \tag{3.30}$$

can be employed.

Any pair of unit vectors chosen from the set of vectors, namely from the set of vectors $\mathbf{u}_{P1}$, $\mathbf{v}_{P1}$, $\mathbf{u}_{P2}$, $\mathbf{v}_{P2}$, $\mathbf{t}_{1.P1}$, $\mathbf{t}_{2.P1}$, $\mathbf{t}_{1.P2}$, $\mathbf{t}_{2.P2}$ can be used as a replacement for the unit tangent vectors $\mathbf{u}_{P1}$ and $\mathbf{v}_{P1}$ in Eq. (3.30).

The first-order analysis provides very limited information about the contact geometry of two smooth regular part surfaces in first order of tangency. Hence, the first-order analysis itself has limited application. However, the importance of the first-order analysis becomes valuable as it is incorporated into the second-order analysis, and/or into a higher-order analysis.

3.5 Second-Order Analysis

For a more accurate analytical description of the contact geometry of two part surfaces P_1 and P_2, consideration of the second-order parameters is required. Elements of both of the first order and second order are taken into consideration when the second-order analysis undertaken. To perform the second-order analysis, familiarity with "*Dupin indicatrix*" is highly desirable. The "*Dupin indicatrix*" is a perfect starting point for consideration of the second-order analysis.

It makes sense to begin the discussion of the contact geometry of two smooth regular part surfaces in the first order of tangency from the assumptions those made by the founder of contact mechanics of materials, German physicist *Heinrich Hertz*. The theory proposed by *Hertz* is based on the implementation of an imaginary surface, which (after *Hertz*) is referred to as "*surface of relative curvature*."

3.5.1 *Comments on Analytical Description of Local Geometry of Contacting Surfaces Loaded by a Normal Force:* "Hertz Proportional Assumption"

Investigation of the geometry of interacting surfaces under an applied normal load can be traced back to the fundamental research by *H. Hertz*[8] on contact of solid elastic bodies (*Hertz*, 1881–1896).

In 1886–1889, *Hertz* published two articles on what was to become known as the field of "*contact mechanics*" of materials. His work basically summarizes how two axisymmetric objects placed in contact will behave under loading. The developed theory is based on *Hertz's* observation of elliptical "*Newton's rings*" formed upon placing a glass sphere upon a lens as the basis of assuming that the pressure exerted by the sphere follows an elliptical distribution.

3.5.3 "Dupin Indicatrix" at a Point of Surface of Relative Normal Curvature ✡

It is of importance to stress here again that all of three normal curvatures $k_{\mathscr{R}}$, k_{P1}, and k_{P2} in Eq. (4.36) are taken in a common normal plane section through the point[10] of contact K of the surfaces P_1, P_2, and $\mathscr{R}$.

Based on the calculated values of the principal curvatures $k_{1.\mathscr{R}}$ and $k_{2.\mathscr{R}}$, the implicit equation of the surface of relative curvature yields representation in the form:

$$2Z_{\mathscr{R}} = k_{1.\mathscr{R}} X_{\mathscr{R}}^2 + k_{2.\mathscr{R}} Y_{\mathscr{R}}^2 \tag{3.47}$$

A characteristic surface similar to the surface $\mathscr{R}$ of relative normal curvature can be defined as the surface for which the equality $R_{\mathscr{R}} = R_{P1} - R_{P2}$ is observed. Evidently, this equality is similar in nature to the equality Eq. (4.36).

3.5.3 "Dupin Indicatrix" *at a Point of Surface of Relative Normal Curvature*

Consider an intersection of the surface of relative normal curvature by a plane, parallel to the tangent plane at the point K, but only at a small distance away from it. Then, project the intersection on the tangent plane. In the coordinate plane $x_P y_P$, principal part of the intersection will be given by the equation of "*Dupin indicatrix*"[11] [2]

$$\mathrm{Dup}(\mathscr{R}) \Rightarrow \frac{L_{\mathscr{R}}}{E_{\mathscr{R}}} x_{\mathscr{R}}^2 + \frac{2M_{\mathscr{R}}}{\sqrt{E_{\mathscr{R}} G_{\mathscr{R}}}} x_{\mathscr{R}} y_{\mathscr{R}} + \frac{N_{\mathscr{R}}}{G_{\mathscr{R}}} y_{\mathscr{R}}^2 = \pm 1 \tag{3.48}$$

which describes the distribution of normal relative curvature within the differential vicinity of the point K.

Here, $E_{\mathscr{R}}$, $F_{\mathscr{R}}$, and $G_{\mathscr{R}}$ designate fundamental magnitudes of the first order, and $L_{\mathscr{R}}$, $M_{\mathscr{R}}$, and $N_{\mathscr{R}}$ designate fundamental magnitudes of the second order at the point K of the surface $\mathscr{R}$.

If the axes $x_{\mathscr{R}}$ and $y_{\mathscr{R}}$ of the local coordinate system $x_{\mathscr{R}} y_{\mathscr{R}}$ align with the principal directions $\mathbf{t}_{1.\mathscr{R}}$ and $\mathbf{t}_{2.\mathscr{R}}$ of the surface of relative curvature $\mathscr{R}$, then Eq. (3.48) reduces to:

$$\mathrm{Dup}(\mathscr{R}) \Rightarrow k_{1.\mathscr{R}} x_{\mathscr{R}}^2 + k_{2.\mathscr{R}} y_{\mathscr{R}}^2 = \pm 1 \tag{3.49}$$

---

[10] In a case of line contact of the surfaces P_1 and P_2, point K is the point on the line of the surfaces' contact at which the normal curvatures $k_{\mathscr{R}}$, k_{P1}, and k_{P2} are required to be calculated.

[11] To be more exact, the distribution of normal relative radii of curvature $R_{\mathscr{R}}$, and not of normal relative curvature $k_{\mathscr{R}}$ itself, is reflected by the "*Dupin indicatrix*, $\mathrm{Dup}(\mathscr{R})$". Thus, it could be designated as $\mathrm{Dup}_R(\mathscr{R})$. However, the equation of the indicatrix $\mathrm{Dup}_k(\mathscr{R})$ of a surface normal curvature could also be composed.

Similarly, the corresponding equations for the normalized $\mathrm{Dup}_R(\mathscr{R})$ indicatrix of relative normal radius of curvature, and the indicatrix of normal curvature $\mathrm{Dup}_k(\mathscr{R})$ could also easily be derived.

An important intermediate conclusion follows immediately from Eq. (3.48):

Conclusion 3.2 *The direction* $\mathbf{t}_{1.\mathscr{R}}$ *for the maximum* $k_{1.\mathscr{R}}$*, and the direction* $\mathbf{t}_{2.\mathscr{R}}$ *for the minimum* $k_{2.\mathscr{R}}$ *values of normal curvature at a point of the surface of relative normal curvature are always orthogonal to one another, and, therefore, the condition* $\mathbf{t}_{1.\mathscr{R}} \perp \mathbf{t}_{2.\mathscr{R}}$ *is always observed.*

The major axes of the "*Dupin indicatrix*, Dup($\mathscr{R}$)" make the angles φ_{min} and φ_{max} with the principal directions $\mathbf{t}_{1.\mathscr{R}}$ and $\mathbf{t}_{2.\mathscr{R}}$.

3.5.4 Matrix Representation of Equation of "Dupin Indicatrix" *at a Point of Surface of Relative Normal Curvature*

Like any other quadratic form, Eq. (3.48) of the "*Dupin indicatrix*" of the surface of normal relative curvature $\mathscr{R}$ can be represented in matrix form

$$\text{Dup}(\mathscr{R}) \Rightarrow [\,x_P \;\; y_P \;\; 0 \;\; 0\,] \cdot \begin{bmatrix} \frac{L_{\mathscr{R}}}{E_{\mathscr{R}}} & \frac{2M_{\mathscr{R}}}{\sqrt{E_{\mathscr{R}}G_{\mathscr{R}}}} & 0 & 0 \\ \frac{2M_{\mathscr{R}}}{\sqrt{E_{\mathscr{R}}G_{\mathscr{R}}}} & \frac{N_{\mathscr{R}}}{G_{\mathscr{R}}} & 0 & 0 \\ 0 & 0 & \mp 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} x_P \\ y_P \\ 0 \\ 0 \end{bmatrix} = \pm 1 \tag{3.50}$$

In "*Darboux trihedron,*" this equation reduces to:

$$\text{Dup}(\mathscr{R}) \Rightarrow [\,x_P \;\; y_P \;\; 0 \;\; 0\,] \cdot \begin{bmatrix} L_{\mathscr{R}} & M_{\mathscr{R}} & 0 & 0 \\ M_{\mathscr{R}} & N_{\mathscr{R}} & 0 & 0 \\ 0 & 0 & \mp 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} x_P \\ y_P \\ 0 \\ 0 \end{bmatrix} = \pm 1 \tag{3.51}$$

It is convenient to implement matrix representation of the equation of the "*Dupin indicatrix*, Dup($\mathscr{R}$)" (see above), for instance, when multiple coordinate system transformations need to be performed.

The equation of the "*Dupin indicatrix*, $Dup(\mathscr{R})$" can be represented in the form:

$$r_{\text{Dup}}(\varphi) = \sqrt{|R_{\mathscr{R}}(\varphi)|} \cdot \text{sgn}\Phi_{2.\mathscr{R}}^{-1} \tag{3.52}$$

This last equation reveals that the position vector of a point of the indicatrix Dup($\mathscr{R}$) in any direction is equal to the square root of the radius of curvature in that same direction.[12]

---

[12] Similar to *Dupin* indicatrix Dup($\mathscr{R}$), a planar characteristic curve of another kind can be introduced as well. The equation of this characteristic curve can be postulated in the form $r_{\text{Dup}.k}(\varphi) = \sqrt{|k_{\mathscr{R}}(\varphi)|} \cdot \text{sgn}\Phi_{2.\mathscr{R}}^{-1}$. Application of curvature indicatrix in the form $r_{\text{Dup}.k}(\varphi)$ yields

3.5.5 Surface of Relative Normal Radii of Curvature

The normal curvature $k_{\mathscr{R}}$ of the surface of normal relative curvature $\mathscr{R}$, the normal curvatures k_{P1}, and k_{P2} of the part surfaces P_1 and P_2 can be represented in the form: $k_{\mathscr{R}} = R_{\mathscr{R}}^{-1}$, $k_{P1} = R_{P1}^{-1}$, and $k_{P2} = R_{P2}^{-1}$ correspondingly, where $R_{\mathscr{R}}$, R_{P1}, and R_{P2} are the corresponding radii of normal curvature of the surfaces $\mathscr{R}$, P_1, and P_2. They are also taken in a common normal plane section through the point of contact K of these surfaces $\mathscr{R}$, P_1, and P_2.

The radius of relative normal curvature is another widely known tool that is used in contemporary practice for the purposes of analytical description of the geometry of contact when performing second-order analysis. The radius $R_{\mathscr{R}}$ of relative normal curvature can be defined by the expression:

$$R_{\mathscr{R}} = R_{P1} - R_{P2} \tag{3.53}$$

In many applications, Eq. (3.53) for the radius of relative normal of curvature $R_{\mathscr{R}}$ is equivalent to Eq. (3.46) for the relative normal curvature $k_{\mathscr{R}}$.

3.5.6 Normalized Relative Normal Curvature

Usually, it is preferable to deal with unitless values when performing second-order analysis rather than with values having units. In order to eliminate unit values, it is recommended to use a normalized relative normal curvature $\bar{k}_{\mathscr{R}}$ of the contacting surfaces P_1 and P_2. The normalized relative normal curvature $\bar{k}_{\mathscr{R}}$ of the surfaces P_1 and P_2 is referred to as the value determined by the equation

$$\bar{k}_{\mathscr{R}} = \frac{k_{P1} + k_{P2}}{|k_{1.P}|} \tag{3.54}$$

Similarly, the normalized radius of relative normal curvature $\bar{R}_{\mathscr{R}}$ of the surfaces P_1 and P_2 can be introduced here based on Eq. (3.53). The normalized relative radius of normal curvature $\bar{R}_{\mathscr{R}}$ of the surfaces P_1 and P_2 is referred to as the value determined by the equation:

$$\bar{R}_{\mathscr{R}} = \frac{R_{P1} - R_{P2}}{|R_{1.P1}|} \tag{3.55}$$

Implementation of the unitless parameters $\bar{k}_{\mathscr{R}}$, $\bar{R}_{\mathscr{R}}$, as well as others makes it possible avoiding dealing with unit values. Equations comprised of unitless parameters are often more convenient in applications.

---

avoiding of uncertainty in cases of a plane. For a plane surface Dup($\mathscr{R}$) exists, while $r_{\text{Dup}.k}(\varphi)$ shrinks to the point K.

A corresponding "*Dupin indicatrix*" can be constructed for all of the above-considered characteristic surfaces. Namely for:

(a) the surface of normal relative radii of curvature $\mathrm{Dup}_R(\mathscr{R})$,
(b) the normalized surface of normal relative curvature $\mathrm{Dup}(\bar{\mathscr{R}})$, and
(c) the normalized surface of normal radii of relative curvature $\mathrm{Dup}_R(\bar{\mathscr{R}})$.

3.5.7 Curvature Indicatrix of Surface of Relative Normal Curvature

The curvature indicatrix of the surface of relative normal curvature $\mathscr{R}$ can be introduced similar to already done for a smooth regular part P. This planar characteristic curve is designated as $\mathrm{Crv}(\mathscr{R})$. The curvature indicatrix $\mathrm{Crv}(\mathscr{R})$ can be implemented to make clear whether or not two smooth regular part surfaces P_1 and P_2 make physically feasible contact.

The curvature indicatrices $\mathrm{Crv}(\mathscr{R})$ those shown in Fig. 3.6 correspond to physically feasible kinds of contact of the part surfaces. Two part surfaces P_1 and P_2 can contact one another physically if the curvature indicatrix $\mathrm{Crv}(\mathscr{R})$ is either of convex elliptic type (Fig. 3.6a), or of convex umbilic type (Fig. 3.6b), or finally of convex parabolic type (Fig. 3.6c). Under such circumstances, the curvature indicatrix $\mathrm{Crv}(\mathscr{R})$ of the surface $\mathscr{R}$ of relative normal curvature can be described analytically by the inequality:

$$\mathrm{Crv}(\mathscr{R}) \Rightarrow \frac{L_{\mathscr{R}}}{E_{\mathscr{R}}} x_P^2 + \frac{2M_{\mathscr{R}}}{\sqrt{E_{\mathscr{R}} G_{\mathscr{R}}}} x_P y_P + \frac{N_{\mathscr{R}}}{G_{\mathscr{R}}} y_P^2 > 1 \tag{3.56}$$

In all of these cases, the mean curvature $\mathscr{M}_{\mathscr{R}}$ of the surface $\mathscr{R}$ of relative curvature is of a positive value ($\mathscr{M}_{\mathscr{R}} > 0$).

In a particular case, the surface of relative normal curvature can be reduced either to a point or a line. These degenerated cases of the surface $\mathscr{R}$ are illustrated schematically in Fig. 3.7a, b correspondingly.

In case contact of two smooth regular surfaces P_1 and P_2 is physically impossible, the curvature indicatrix $\mathrm{Crv}(\mathscr{R})$ of the surface of relative normal curvature $\mathscr{R}$ is bounded by the corresponding "*Dupin indicatrix* $\mathrm{Dup}(\mathscr{R})$" position vector of a point of which has negative value [at least for one point for the characteristic curve $\mathrm{Dup}(\mathscr{R})$]. Curvature indicatrices $\mathrm{Crv}(\mathscr{R})$ for such cases are schematically illustrated in Fig. 3.8.

Curvature indicatrices $\mathrm{Crv}(\mathscr{R})$ of a surface of relative normal curvature $\mathscr{R}$ are represented by three concave local patches of the surface $\mathscr{R}$, namely:

(a) concave elliptic (Fig. 3.8a),
(b) concave umbilic (Fig. 3.8b), and
(c) concave parabolic (Fig. 3.8c)

local surface patches.

In addition to concave local patches, three saddle-like local patches of the surface of relative normal curvature $\mathscr{R}$ are represented by three local patches having:

(d) pseudo-convex (Fig. 3.8d),
(e) minimal (Fig. 3.8e), and
(f) pseudo-concave (Fig. 3.8f)

local surface patches.

Ultimately, two degenerate kinds of the curvature indicatrices Crv($\mathscr{R}$) of a surface of relative normal curvature $\mathscr{R}$ are represented in Fig. 3.8g, h.

All the indicatrices Crv($\mathscr{R}$) in Fig. 3.8 fulfill the following inequality:

$$\mathrm{Crv}(\mathscr{R}) \Rightarrow \frac{L_{\mathscr{R}}}{E_{\mathscr{R}}} x_P^2 + \frac{2M_{\mathscr{R}}}{\sqrt{E_{\mathscr{R}} G_{\mathscr{R}}}} x_P y_P + \frac{N_{\mathscr{R}}}{G_{\mathscr{R}}} y_P^2 < 1 \tag{3.57}$$

Again, the curvature indicatrices Crv($\mathscr{R}$) shown in Fig. 3.8 indicate that the surfaces P_1 and P_2 cannot contact one another physically.

curve of the second order. In the case under consideration, it is always convex with uniform change of curvature. The "$\mathscr{A}n_R(P_1)$-*indicatrix*" is also a planar smooth regular curve. However, the points of inflection are inherent to this curve. This is due to the fact that the "$\mathscr{A}n_R(P_1)$-*indicatrix*" is a curve of fourth order. The higher order enhances the capabilities of the characteristic curve $\mathscr{A}n_R(P_1)$.

Owing to the higher order of the equation, the "$\mathscr{A}n_R(P_1)$-*indicatrix*" reflects the distribution of normal radii of curvature, while the "*Dupin indicatrix*, $Dup(P_1)$" reflects the distribution of square roots of normal radii of curvature of a part surface P_1 at the surface point m. In order to make the difference clear, it is sufficient to represent the equation of the "*Dupin indicatrix*" in the form similar to that for "$\mathscr{A}n_R(P_1)$-*indicatrix*" [see Eq. (6.37)]:

$$Dup(P_1) \quad \Rightarrow \quad \mathbf{r}_{Dup}(\varphi) = \begin{bmatrix} \sqrt{|R_{P1}(\varphi)|}\cos\varphi \operatorname{sgn} R_{P1}(\varphi) \\ \sqrt{|R_{P1}(\varphi)|}\sin\varphi \operatorname{sgn} R_{P1}(\varphi) \\ 0 \\ 0 \end{bmatrix} \tag{6.39}$$

It is evident from the above consideration that Eqs. (6.37) and (6.39) are similar.

6.3 Relative Characteristic Curve

The considered properties of the "*Plücker conoid*" can be employed for the derivation of the equation of a planar characteristic curve for analytical description of the contact geometry of two smooth regular part surfaces for the needs of engineering geometry of surfaces.

6.3.1 On a Possibility of Implementation of Two "Plücker Conoids"

At first glimpse, implementation of two "*Plücker conoids*" sounds promising for the purpose of solving the problem of analytical description of contact geometry of two smooth regular part surfaces.

In order to develop an appropriate solution to the problem under consideration, the characteristic surface $\mathbf{Pl}_R(P_1/P_2)$ that reflects the "*summa*" of the corresponding normal radii of curvature at a point of contact of the part surfaces P_1 and P_2 could be introduced. The following matrix representation of the equation of the surface $\mathbf{Pl}_R(P_1/P_2)$ follows immediately:

$$\mathbf{Pl}_R(P_1/P_2) \quad \Rightarrow \quad \mathbf{R}_R^*(\varphi) = \begin{bmatrix} (R_{P1} + R_{P2}) \cos\varphi \\ (R_{P1} + R_{P2}) \sin\varphi \\ 2 \sin\varphi \cos\varphi \\ 0 \end{bmatrix} \tag{6.40}$$

The characteristic surface $\mathbf{Pl}_R(P_1/P_2)$ is referred to as the "*Plücker relative conoid*."

Because the centers $C_{1.P1}$ and $C_{2.P1}$ of the principal curvature of the part surfaces P_1, and the centers $C_{1.P2}$ and $C_{2.P2}$ of the principal curvatures of the part surface P_2 in general case do not coincide with one another, the actual reciprocation of the straight-line segment of length $(R_{P1} - R_{P2})$ could be restricted by different pairs of the limiting points $C_{1.P1}$, $C_{2.P1}$, $C_{1.P2}$, $C_{2.P2}$. Various locations of the limiting points on the axis through the unit normal vector $\mathbf{n}_{P1}$ result in "*deformation*" of the characteristic surface $\mathbf{Pl}_R(P_1/P_2)$ in its axial direction. A deformation of such type does not affect the surface appearance in the direction of $(R_{P1} + R_{P2})$ that is of critical importance for engineering geometry of surfaces.

The characteristic surface $\mathbf{Pl}_R(P_1/P_2)$ is described analytically by Eq. (6.40). This indicates that the "*Plücker relative conoid*" correctly reflects the degree of conformity at a point of contact K of the part surfaces P_1 and P_2. However, the surface $\mathbf{Pl}_R(P_1/P_2)$ itself is inconvenient for implementation in engineering geometry of surfaces. In order to fix this undesired particular problem, the "*Plücker relative indicatrix* $\mathbf{Pl}_R(P_1/P_2)$" at a point of contact K of two surfaces P_1 and P_2 is introduced. The equation of this 3*D* characteristic curve immediately follows immediately from Eq. (6.40):

$$\mathbf{Pl}_R(P_1/P_2) \quad \Rightarrow \quad \mathbf{R}_R(\varphi) = \begin{bmatrix} (R_{P1} + R_{P2}) \cos\varphi \\ (R_{P1} + R_{P2}) \sin\varphi \\ (R_{P1} + R_{P2}) \\ 0 \end{bmatrix} \tag{6.41}$$

Here, both radii of normal curvatures, namely R_{P1} and R_{P2}, are signed values. They are of positive values when the lines of intersection of the part surfaces P_1 and P_2 by a plane through the common perpendicular $\mathbf{n}_{P1}$ are convex, and they are of negative values when the lines of intersection of the part surfaces by a plane through the common perpendicular are concave.

Further, the characteristic curve $\mathbf{Pl}_R(P_1/P_2)$ can be reduced to a corresponding planar characteristic curve. Omitting the intermediate considerations, one may wish to go directly to the "*-relative indicatrix*" at a point of contact of the part surfaces P_1 and P_2.

Fig. 6.3 An example of the "$\mathscr{Pl}_R(P_1/P_2)$*-relative indicatrix*" at a point of contact K of two part surfaces P_1 and P_2 ($R_{1.P1} = 2\,\text{mm}$, $R_{2.P1} = 3\,\text{mm}$, $R_{1.P2} = -2\,\text{mm}$, $R_{2.P2} = -5\,\text{mm}$, $\mu = 45°$), plotted together with the corresponding "$\mathscr{Pl}_R(P_1)$*-indicatrix*" of the part surface P_1 , and the "$\mathscr{Pl}_R(P_2)$*-indicatrix*" of the part surface P_2 constructed at that same contact point K

6.3.2 "$\mathscr{Pl}_R(P_1/P_2)$**-Relative Indicatrix"** *at Point of Contact of Two Part Surfaces* **P**$_1$ *and* **P**$_2$

Aiming for further simplification of the analytical description of the contact geometry of two part surfaces P_1 and P_2, the "*Plücker relative indicatrix*, $\mathscr{Pl}_R(P_1/P_2)$" can be replaced with the planar characteristic curve of a simpler structure. The equation of the 2*D* "$\mathscr{Pl}_R(P_1/P_2)$*-relative indicatrix*" at a point of contact of the part surfaces P_1 and P_2 can be derived from Eq. (6.41):

$$\mathscr{Pl}_R(P_1/P_2) \;\Rightarrow\; \mathbf{R}_{iR}(\varphi) = \begin{bmatrix} (R_{P1} + R_{P2})\cos\varphi \\ (R_{P1} + R_{P2})\sin\varphi \\ 0 \\ 0 \end{bmatrix} \tag{6.42}$$

This planar characteristic curve is referred to as the "$\mathscr{A}n_R(P_1/P_2)$*-relative indicatrix of the first kind.*" The distribution of summa of normal radii of curvature at a point of contact K of the part surfaces P_1 and P_2 is described analytically by the "$\mathscr{A}n_R(P_1/P_2)$*-relative indicatrix of the first kind.*"

In Eq. (6.42), the radii of normal curvature R_{P1} and R_{P2} can be expressed in terms of the corresponding principal radii of curvature $R_{1.P1}$, $R_{2.P1}$, and $R_{1.P2}$, $R_{2.P2}$, and in terms of the angle μ of the part surfaces' P_1 and P_2 local relative orientation at the contact point K.

An example of the "$\mathscr{A}n_R(P_1/P_2)$*-relative indicatrix*" at a point of contact of two part surfaces P_1 and P_2 is shown in Fig. 6.3. Parameters of the characteristic curve $\mathscr{A}n_R(P_1/P_2)$ are calculated at point of contact of the convex elliptic local patch of the part surface P_1 ($R_{1.P1} = 3\,\text{mm}$, and $R_{2.P1} = 15\,\text{mm}$), and the concave elliptic local patch of the part surface P_2 ($R_{1.P2} = -2\,\text{mm}$, and $R_{2.P2} = -5\,\text{mm}$). The part surfaces P_1 and P_2 are turned around the common perpendicular $\mathbf{n}_{P1}$ with respect to one another through the angle of local relative orientation $\mu = 45°$. The corresponding "$\mathscr{A}n_R(P_1)$*-indicatrix*" as well as the "$\mathscr{A}n_R(P_1)$*-indicatrix*" is also plotted in Fig. 6.3. It is of importance to point out here that the direction of the minimum diameter $d_{ind}^{\min}$ and the direction of the maximum diameter $d_{ind}^{\max}$ of the characteristic curve $\mathscr{A}n_R(P_1/P_2)$ do not align either with the principal directions $\mathbf{t}_{1.P1}$ and $\mathbf{t}_{2.P1}$ on the part surface P_1 or with the principal directions $\mathbf{t}_{1.P2}$ and $\mathbf{t}_{2.P2}$ on the part surface P_2. The extremal directions of the "$\mathscr{A}n_R(P_1/P_2)$*-relative indicatrix*" are not orthogonal to one other. In the general case of two part surfaces in contact, they make a certain angle $\vartheta \neq 90°$.

The following statement can be made at this point:

Conclusion 6.1 *In the general case of part surfaces in contact, the directions of the extremal (i.e., of maximum minimum) degree of conformity of two surfaces P_1 and P_2 at the contact point K are not orthogonal to one another. The directions of the extremal degree of conformity of the part surface P_1 and P_2 could be orthogonal to one another only in a particular (degenerated) cases of the surfaces contact.*

The shape and parameters of the "$\mathscr{A}n_R(P_1/P_2)$*-relative indicatrix*" depend upon the algebraic values of the principal radii of curvature $R_{1.P1}$, $R_{2.P1}$ and $R_{1.P2}$, $R_{2.P2}$ at a point of contact of the part surfaces P_1 and P_2, as well as on the actual value of the angle μ of the part surfaces P_1 and P_2 local relative orientation.

The "*Dupin* indicatrix $Dup\,(\mathscr{R})$" at a point of the surface of relative curvature indicates that the directions of the extremum degree of conformity of the part surfaces P_1 and P_2 at the contact point K are always perpendicular to one another. The above consideration reveals that this is not correct and results in errors of calculations.

The characteristic curve $\mathscr{A}n_R(P_1/P_2)$ is of simpler structure rather than the "*Plücker relative indicatrix*, $\mathscr{P}l_R(P_1/P_2)$" itself. The "$\mathscr{A}n_R(P_1/P_2)$*-relative indicatrix*" is always a kind of planar curve, while the "*Plücker relative indicatrix*, $\mathscr{P}l_R(P_1/P_2)$" is always a spatial 3*D* curve. This makes use of the characteristic curve $\mathscr{A}n_R(P_1/P_2)$, preferred rather than the "*Plücker relative indicatrix*, $\mathscr{P}l_R(P_1/P_2)$."

The distribution of the differences between normal curvatures of the part surfaces P_1 and P_2 at the contact point K can be described analytically by a planar characteristic curve of another kind:

Fig. 6.4 Comparison of the *-relative indicatrix* of two part surfaces P_1 and P_2 in contact with the *Dupin* indicatrix $Dup(\mathscr{R})$ of the surface of relative curvature for that same part surfaces P_1 and P_2

$$\mathscr{A}n_k(P_1/P_2) \quad \Rightarrow \quad \mathbf{R}_{ik}(\varphi) = \begin{bmatrix} (k_{P1} - k_{P2})\cos\varphi \\ (k_{P1} - k_{P2})\sin\varphi \\ 0 \\ 1 \end{bmatrix} \tag{6.43}$$

The characteristic curve [see Eq. (6.43)] is referred to as the "$\mathscr{A}n_k(P_1/P_2)$*-relative indicatrix of the second kind*".

Equation (6.43) of the "$\mathscr{A}n_k(P_1/P_2)$*-indicatrix*" can be expressed in terms of radii of principal curvature of the contacting part surfaces P_1 and P_2:

$$\mathscr{A}n_k(P_1/P_2) \quad \Rightarrow \quad \mathbf{R}_{ik}(\varphi) = \begin{bmatrix} [k_{1.P1}\cos\varphi + k_{2.P1}\sin\varphi - k_{1.P2}\cos(\varphi+\mu) - k_{2.P2}\sin(\varphi+\mu)]\cos\varphi \\ [k_{1.P1}\cos\varphi + k_{2.P1}\sin\varphi - k_{1.P2}\cos(\varphi+\mu) - k_{2.P2}\sin(\varphi+\mu)]\sin\varphi \\ 0 \\ 1 \end{bmatrix} \tag{6.44}$$

The difference between the "$\mathscr{I}n_R(P_1/P_2)$-*relative indicatrix of the second kind*" and between the "*Dupin indicatrix*, $Dup(\mathscr{R})$" of the surface of relative curvature is clear illustrated in Fig. 6.4.

The planar characteristic curves $\mathscr{I}n_R(P_1)$ and $\mathscr{I}n_k(P_1)$, as well as the characteristic curves $\mathscr{I}n_R(P_2)$ and $\mathscr{I}n_k(P_2)$ originate from the "*Plücker conoid*." Equations (6.37), (6.38) and (6.42), (6.43) of the corresponding indicatrices, $\mathscr{I}n_R(P_1)$, $\mathscr{I}n_k(P_1)$ and, $\mathscr{I}n_R(P_2)$, $\mathscr{I}n_k(P_2)$ are derived on the premise of Eq. (6.8) of the surface of "*Plücker conoid*" (see [8], and Sect. 4.9, pp. 257–260 in [9]).

It is proven analytically that both planar characteristic curves, say the characteristic curve $\mathscr{I}n_R(P_1/P_2)$, and the "*indicatrix of conformity* $Cnf_R(P_1/P_2)$" at a point of contact of two smooth regular part surfaces P_1 and P_2 specify that same direction $\mathbf{t}_{cnf}^{\max}$ at which the degree of conformity of the part surfaces P_1 and P_2 reaches its maximum value. Both the characteristic curves, $Cnf_R(P_1/P_2)$ and $\mathscr{I}n_R(P_1/P_2)$, are powerful tools in engineering geometry of surfaces. They are extensively used for the analysis of the geometry of contact of two smooth regular part surfaces P_1 and P_2.

Chapter 7

Possible Kinds of Contact of Two Smooth Regular Part Surfaces in the First Order of Tangency

Interaction of two part surfaces in contact is of tremendous importance for plurality of engineering applications. Therefore, analysis and classification of all possible kinds of contact of two smooth regular part surfaces P_1 and P_2 in the first order of tangency is a critical issue in engineering geometry of surfaces. Development of scientific classification of all possible kinds of contact of part surfaces P_1 and P_2 could be considered as the ultimate point in the analysis of the part surfaces P_1 and P_2 contact.

Prior to discussing this important issue, two more particular issues need to be mentioned.

The first issue relates to the possibility of implementation of the indicatrix of conformity for the identification of the actual kind of contact of two part surfaces P_1 and P_2.

The second issue relates to the impact of the accuracy of the computations on the desired parameters of the indicatrix of conformity $Cnf_R(P_1/P_2)$ at a point of contact of the part surfaces P_1 and P_2, that is, onto the directions of extreme degree of their conformity.

7.1 On a Possibility of Implementation of the Indicatrix of Conformity for the Purposes of Identification of the Actual Kind of Contact of Two Smooth Regular Part Surfaces

Two regular part surfaces P_1 and P_2 can make contact either at a point, or along a line, or ultimately over a surface patch. Actually, the kind of contact of two part surfaces results in certain features in the shape and the parameters of the indicatrix of conformity $Cnf_R(P_1/P_2)$ of the contacting part surfaces P_1 and P_2.

As follows from Eqs. (6.34) and (6.35), special features in the shape and the parameters of the indicatrix of conformity $Cnf_R(P_1/P_2)$ are inherited to every pos-

Fig. 7.1 Correspondence between the shape of the indicatrix of conformity $Cnf_R(P_1/P_2)$ and the kind of contact of two part surfaces P_1 and P_2: **a** point contact, **b** line contact, and **c** surface contact

conformity $Cnf_R(P_1/P_2)$ at a point of contact (as well as all other diameters of this characteristic curve) is always of a positive value ($d_{cnf}^{\min} > 0$);

(b) along a curve L_c (Fig. 7.1b), then the minimum diameter $d_{cnf}^{\min}$ of the indicatrix of conformity $Cnf_R(P_1/P_2)$ at a point of contact is always identical to zero ($d_{cnf}^{\min} \equiv 0$), while all other diameters of this characteristic curve are of a positive value ($d_{cnf} > 0$), and finally

(c) over a surface patch (Fig. 7.1c), then the indicatrix of conformity at a point of contact of the part surfaces P_1 and P_2 shrinks to a point, which coincides with the point K of contact of the part surfaces P_1 and P_2.

The above examples are worked out for the cases of the part surfaces P_1 and P_2 contact, when in the local vicinity of the contact point K both of the surfaces P_1 and P_2 are smooth regular surfaces of saddled type (having negative "*Gauss curvature*" $\mathscr{G}_{P1} < 0$, and $\mathscr{G}_{P2} < 0$). A similarity is observed for all other types of local patches of part surfaces P_1 and P_2 as well.

In a case when the part surfaces P_1 and P_2 intersect one another, that is, the interference of the surfaces P_1 and P_2 into each other is observed as illustrated schematically in Fig. 5.6, then the minimum diameter of the indicatrix of conformity $Cnf_R(P_1/P_2)$ at a point of contact of the part surfaces P_1 and P_2 is always of a negative value ($d_{cnf}^{\min} < 0$).

It is of importance to make difference between partial and full interference of the part surfaces P_1 and P_2 in the differential vicinity of the contact point K.

For instance, in the differential vicinity of the point of contact K, a convex elliptical local patch of the part surface P_2 can partially intersect a hyperbolical local patch of the part surface P_1 (Fig. 5.6a). In this case, the minimum diameter $d_{cnf}^{\min}$of the indicatrix of conformity $Cnf_R(P_1/P_2)$ is of a negative value ($d_{cnf}^{\min} < 0$). Owing to this, the indicatrix of conformity $Cnf_R(P_1/P_2)$ not only intersects itself, but intersection of each of its branches also occurs. Varying the angular parameter φ within the interval $0 \leq \varphi \leq \pi$, positive ($d_{cnf} > 0$), as well as negative ($d_{cnf} < 0$) values of the current diameter d_{cnf} of the characteristic curve $Cnf_R(P_1/P_2)$ are observed.

Another example: In the differential vicinity of the contact point K, the local patch of the part surface P_2 interferes into a local patch of the part surface P_1 totally, as shown for two hyperbolic local patches (Fig. 5.6b) and for two parabolic (Fig. 5.6c) local patches of the part surfaces P_1 and P_2. For the cases of total local interference of the part surfaces P_1 and P_2, the minimum diameter $d_{cnf}^{\min}$of the indicatrix of conformity $Cnf_R(P_1/P_2)$ is always of a negative value ($d_{cnf}^{\min} < 0$), as well as all other diameters d_{cnf} of this characteristic curve $Cnf_R(P_1/P_2)$ are also of a negative value, regardless of the actual value of the angular parameter φ.

The examples above show that every type of contact of the part surfaces P_1 and P_2 features important peculiarities in the shape and parameters of the indicatrix of conformity $Cnf_R(P_1/P_2)$ at the point K of contact of the part surfaces P_1 and P_2. The shape and the parameters of the characteristic curve $Cnf_R(P_1/P_2)$ uniquely follow from the actual kind of contact of the part surfaces P_1 and P_2 and are completely predetermined by the actual kind of contact of these surfaces. Here, it is natural to assume that the inverse statement could also be true. The question can be formulated as follows:

Question 7.1 *Are the features in the shape and parameters of the indicatrix of conformity* $Cnf_R(P_1/P_2)$ *at a point of contact of two part surfaces in contact* P_1 *and* P_2 *necessary and sufficient for drawing a conclusion regarding the kind of surfaces'* P_1 *and* P_2 *contact: contact at a point, along a curve* L_c*, or over a surface patch*?

Or, in another words, could the value and sign of the minimum diameter $d_{cnf}^{\min}$of the indicatrix of conformity $Cnf_R(P_1/P_2)$ and the features in its shape be implemented as a criterion for determining uniquely the kind of contact of the part surfaces P_1 and P_2?

The detailed investigation of this particular sub-problem enables one to make the following statement:

Conclusion 7.1 *The actual value and sign of the minimum diameter* $d_{cnf}^{\min}$*of the indicatrix of conformity* $Cnf_R(P_1/P_2)$ *at a point of contact of two part surfaces* P_1 *and* P_2*, as well as features in the shape of this characteristic curve, cannot be implemented as a sufficient criterion for determining uniquely the actual kind of contact of the part surfaces* P_1 *and* P_2.

The positive value of the minimum diameter $d_{cnf}^{\min}$of the indicatrix of conformity $Cnf_R(P_1/P_2)$ (that is, $d_{cnf}^{\min} > 0$) is a sufficient but not a necessary requirement for contact of the part surfaces P_1 and P_2 at a point.

The indicatrix of conformity $Cnf_R(P_1/P_2)$, that is shrunk to the contact point K, is not sufficient to identify the kind of contact of the part surfaces P_1 and P_2 over a surface patch. However, if two part surfaces P_1 and P_2 are congruent to each other within a certain surface patch, then the indicatrix of conformity shrinks to a point, which coincides with the point of contact K. The inverse statement is not correct. In the event of the indicatrix of conformity $Cnf_R(P_1/P_2)$ shrinking to a point, then the part surfaces P_1 and P_2 can be congruent to one another only "*locally.*" Thus, if the indicatrix of conformity $Cnf_R(P_1/P_2)$ shrinks to the contact point K, this indicates only a necessary but not a sufficient condition for the part surfaces P_1 and P_2 contact over a certain surface patch. In the case under consideration, the part surfaces P_1 and P_2 can make contact along a characteristic curve L_c and/or at a point K as well.

If the minimum diameter $d_{cnf}^{\min}$of the indicatrix of conformity $Cnf_R(P_1/P_2)$ at a point of contact of the part surfaces P_1 and P_2 is equal to zero, this does not necessarily mean that the part surfaces P_1 and P_2 make contact along a curve L_c. This requirement is only a necessary but not a sufficient condition for the line contact of two smooth regular part surfaces. In the event $d_{cnf}^{\min} = 0$, the part surfaces P_1 and P_2 can make contact at a point.

As follows from the above discussion, in the event, the part surfaces P_1 and P_2 make contact along a line L_c, then the direction along the minimum diameter $d_{cnf}^{\min}$of the indicatrix of conformity $Cnf_R(P_1/P_2)$ at a point of contact of the part surfaces P_1 and P_2 is aligned with the tangent line to the curve L_c at the contact point K. This issue is of importance for engineering geometry of surfaces because it follows directly from the statement made above. According to this statement, in the differential vicinity of the point of contact K, the direction, along which minimum diameter $d_{cnf}^{\min}$ can be measured, is aligned with the direction, along which the degree of conformity at a point of contact of the part surfaces P_1 and P_2 reaches a maximal value. Therefore, at the contact point K, the direction along the minimum diameter $d_{cnf}^{\min}$ and the direction that is tangent to the line of contact L_c align to one another. Hence, contact point K is a point of tangency of:

(a) the straight line that aligns with the direction in which the minimum diameter $d_{cnf}^{\min}$ of the indicatrix of conformity $Cnf_R(P_1/P_2)$ is measured, and
(b) the line of contact L_c of the part surfaces P_1 and P_2.

The statements above are also true for the inverse indicatrix of conformity $Cnf_k(P_1/P_2)$ at a point of contact of the part surfaces P_1 and P_2 in the first order of tangency.

It is of critical importance to stress here that some of the conclusions similar to those listed above could be made based on other known approaches. This proves indirectly that the proposed novel approach for analytical description of the geometry of contact of two smooth regular part surfaces in the first order of tangency is in perfect agreement with the earlier developed approaches in the field. In a case when the contacting part surfaces are of a simple geometry (that is, planes, spheres, cylinders of revolution), implementation of the discussed approach, as well as implementation of known approaches for analytical description of contact geometry of two part surfaces returns identical results. If the contacting part surfaces are of a complex geometry, then implementation only of the indicatrix of conformity (of both kinds), or of the relative indicatrix (of both kinds), and not of any other characteristic curve, enable correct results of computation of parameters of the geometry of contact of two surfaces.

7.1.1 Impact of Accuracy of Computation on the Parameters of the Indicatrices of Conformity $Cnf_R(P_1/P_2)$

All the calculations, whether performed manually or by computer, are subject to errors of the computation. No calculations of any kind are performed with zero error. Errors of the calculation are unavoidable for many reasons.

The accuracy of calculation affects the desired parameters of the indicatrix of conformity $Cnf_R(P_1/P_2)$ at a point of contact of the part surfaces P_1 and P_2. For a predetermined error of the calculation, the optimal parameters of the characteristic curve $Cnf_R(P_1/P_2)$ can be computed. As is known, the characteristic curve $Cnf_R(P_1/P_2)$ is a function of the design parameters of two part surfaces P_1 and P_2 and of their relative orientation. Commonly, the design parameters of the given part

Implementation of the discussed results allows for:

(a) representation of the gear tooth flank, $\mathscr{G}$, and the pinion tooth flank, $\mathscr{P}$, of the form cutting tool, as well as their relative motion in a common coordinate system, and
(b) consideration meshing of the gear tooth flank, $\mathscr{G}$, in any desired coordinate systems that is a component of the chain and/or the closed loop of consequent coordinate system transformations.

Transition from one coordinate system to another coordinate system can be performed in both of two feasible directions, say in direct as well as in inverse directions.

B.5 Impact of the Coordinate Systems Transformations on Fundamental Forms of the Surface

Every coordinate system transformation results in a corresponding change to equation of the gear tooth flank, $\mathscr{G}$, and/or pinion tooth flank, $\mathscr{P}$. Because of this, it is often necessary to re-calculate coefficients of the first $\Phi_{1.g}$ and of the second $\Phi_{2.g}$ fundamental forms of the gear tooth flank, $\mathscr{G}$ (as many times as the coordinate system transformation is performed). This routing and time-consuming operation can be eliminated if the operators of coordinate system transformations are used directly to the fundamental forms $\Phi_{1.g}$ and $\Phi_{2.g}$.

After been calculated in an initial reference system, the fundamental magnitudes E_g, F_g, and G_g of the first, $\Phi_{1.g}$, and the fundamental magnitudes L_g, M_g, and N_g of the second, $\Phi_{2.g}$, fundamental forms can be determined in any new coordinate system using for this purpose, the operators of translation, of rotation, and of resultant coordinate system transformation [106]. Transformation of such kind of the fundamental magnitudes, $\Phi_{1.g}$ and $\Phi_{2.g}$, becomes possible due to implementation of a formula, that can be found out immediately below.

Let us consider a gear tooth flank, $\mathscr{G}$, that is given by equation $\mathbf{r}_g = \mathbf{r}_g(U_g, V_g)$, where $(U_g, V_g) \in G$.

For the analysis below, it is convenient to use the equation of the first fundamental form, $\Phi_{1.g}$, of the gear tooth flank, $\mathscr{G}$, represented in matrix form:

$$\left[\Phi_{1.g}\right] = \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right] \cdot \begin{bmatrix} E_g & F_g & 0 & 0 \\ F_g & G_g & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} dU_g \\ dV_g \\ 0 \\ 0 \end{bmatrix} \tag{B.65}$$

Similarly, equation of the second fundamental form $\Phi_{2.g}$ of the gear tooth flank, $\mathcal{G}$, can be given by:

$$\left[\Phi_{2.g}\right] = \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right] \cdot \begin{bmatrix} L_g & M_g & 0 & 0 \\ M_g & N_g & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} dU_g \\ dV_g \\ 0 \\ 0 \end{bmatrix} \tag{B.66}$$

The coordinate system transformation that is performed by the operator of linear transformation $\mathbf{Rs}(1 \to 2)$ transfers the equation $\mathbf{r}_g = \mathbf{r}_g(U_g, V_g)$ of the gear tooth flank, $\mathcal{G}$, initially given in $X_1Y_1Z_1$, to the equation $\mathbf{r}_g^* = \mathbf{r}_g^*(U_g^*, V_g^*)$ of that same gear tooth flank, $\mathcal{G}$, in a new coordinate system $X_2Y_2Z_2$. It is clear that $\mathbf{r}_g \neq \mathbf{r}_g^*$.

In the new coordinate system, the gear tooth flank, $\mathcal{G}$, is analytically described by the following expression:

$$\mathbf{r}_g^*(U_g^*, V_g^*) = \mathbf{Rs}(1 \to 2) \cdot \mathbf{r}_g(U_g, V_g) \tag{B.67}$$

The operator of the resultant coordinate system transformation $\mathbf{Rs}(1 \to 2)$ casts the column matrices of variables in Eqs. (B.65) and (B.66) to the form:

$$\left[\, dU_g^* \quad dV_g^* \quad 0 \quad 0 \,\right]^T = \mathbf{Rs}(1 \to 2) \cdot \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right]^T. \tag{B.68}$$

Substitution of Eq. (B.68) into Eq. (B.65) and Eq. (B.66) makes it possible the expressions for the fundamental forms, $\Phi_{1.g}^*$ and $\Phi_{2.g}^*$, in the new coordinate system:

$$\begin{aligned} \left[\Phi_{1.g}^*\right] = {} & \left[\mathbf{Rs}(1 \to 2) \cdot \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right]^T\right]^T \cdot \left[\Phi_{1.g}\right] \cdot \\ & \mathbf{Rs}(1 \to 2) \cdot \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right]^T \end{aligned} \tag{B.69}$$

$$\begin{aligned} \left[\Phi_{2.g}^*\right] = {} & \left[\mathbf{Rs}(1 \to 2) \cdot \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right]^T\right]^T \cdot \left[\Phi_{2.g}\right] \cdot \\ & \mathbf{Rs}(1 \to 2) \cdot \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right]^T \end{aligned} \tag{B.70}$$

The following equation is valid for multiplication:

$$\left[\mathbf{Rs}(1 \to 2) \cdot \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right]^T\right]^T = \mathbf{Rs}^T(1 \to 2) \cdot \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right] \tag{B.71}$$

Therefore,

$$\begin{aligned} \left[\Phi_{1.g}^*\right] = {} & \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right]^T \cdot \left\{\mathbf{Rs}^T(1 \to 2) \cdot \left[\Phi_{1.g}\right] \cdot \mathbf{Rs}(1 \to 2)\right\} \\ & \cdot \left[\, dU_g \quad dV_g \quad 0 \quad 0 \,\right] \end{aligned} \tag{B.72}$$

$$\left[\Phi^{*}_{2.g}\right] = \left[dU_g \quad dV_g \quad 0 \quad 0\right]^{T} \cdot \left\{\mathbf{Rs}^{T}(1 \to 2) \cdot \left[\Phi_{2.g}\right] \cdot \mathbf{Rs}(1 \to 2)\right\} \cdot \left[dU_g \quad dV_g \quad 0 \quad 0\right] \tag{B.73}$$

It can be easily shown that the matrices $\left[\Phi^{*}_{1.g}\right]$ and $\left[\Phi^{*}_{2.g}\right]$ in Eq. (B.72) and Eq. (B.73) represent quadratic forms with respect to dU_g and dV_g.

The operator of transformation $\mathbf{Rs}(1 \to 2)$ of the gear tooth flank, $\mathscr{G}$, having the first, $\Phi_{1.g}$, and the second, $\Phi_{2.g}$, fundamental forms from the initial coordinate system $X_1Y_1Z_1$ to the new coordinate system, $X_2Y_2Z_2$, results in that in the new coordinate system the corresponding fundamental forms are expressed in the form:

$$\left[\Phi^{*}_{1.g}\right] = \mathbf{Rs}^{T}(1 \to 2) \cdot \left[\Phi_{1.g}\right] \cdot \mathbf{Rs}(1 \to 2) \tag{B.74}$$

$$\left[\Phi^{*}_{2.g}\right] = \mathbf{Rs}^{T}(1 \to 2) \cdot \left[\Phi_{2.g}\right] \cdot \mathbf{Rs}(1 \to 2) \tag{B.75}$$

Equations (B.74) and (B.75) reveal that after the coordinate system transformation is completed, the first $\Phi^{*}_{1.g}$ and the second $\Phi^{*}_{2.g}$ fundamental forms of the gear tooth flank, $\mathscr{G}$, in the coordinate system $X_2Y_2Z_2$ are expressed in terms of the first, $\Phi_{1.g}$, and the second, $\Phi_{2.g}$, fundamental forms initially represented in the coordinate system $X_1Y_1Z_1$. In order to do that, the corresponding fundamental form (either the form, $\Phi_{1.g}$, or the form, $\Phi_{2.g}$) must be pre-multiplied by $\mathbf{Rs}(1 \to 2)$ and after that, it been post-multiplied by $\mathbf{Rs}^{T}(1 \to 2)$.

Implementation of Eqs. (B.74) and (B.75) significantly simplifies formulae transformations.

Equations similar to those above Eqs. (B.74) and (B.75) are valid with respect to pinion tooth flank, $\mathscr{P}$.

In case of use of the third, $\Phi_{3.g}$, and of the fourth, $\Phi_{4.g}$, fundamental forms, their coefficients can be expressed in terms of the fundamental magnitudes of the first and of the second order.

3 Planar Linkage Mechanisms

In this chapter, we discuss aspects of the movements of linkage mechanisms embedded in the plane, permitting links to pass through one another, without obstacles. Our goal is to explain Kempe's universality theorem 3.2.1.

3.1 STRAIGHT-LINE LINKAGES

In preparation for presenting this universality result, we discuss the fascinating history of the design of linkages to draw straight lines, which led directly to Kempe's work.

3.1.1 Degrees of Freedom

Linkages that have a point that follows a particular curve have 1 degree of freedom, that is, the configuration space is one-dimensional. We consider two types of joints: pinned and unpinned or free. Both are universal joints, but a pinned joint is fixed to a particular point on the plane. Let a linkage have j free joints and r rods (or links). Pinned joints add no freedom, a free joint adds 2 degrees of freedom, and a rod removes 1 degree of freedom if it is not redundant (Graver 2001, p. 135). Thus, if all rods are "nonredundant" (a common situation), a linkage has $2j - r$ degrees of freedom. Thus, to follow a curve, a linkage should have $r = 2j - 1$ rods; in particular, it must have an odd number of rods.

3.1.2 Watt Parallel Motion

It was a question of considerable practical importance to design a linkage so that one point moves along a straight line, a motion needed in many machines, for example, to drive the piston rod of a steam engine. James Watt invented a simple linkage in 1784 that nearly, but not quite, achieves this.[1] Watt's "parallel motion" linkage (something of a misnomer that has stuck) is illustrated in Figure 3.1. Two pinned joints x and y are centers of equal-radii circles traced by joints a and b respectively. Here $j = 2$ and $r = 3$, so it has $2j - r = 1$ degree of freedom. The midpoint c of ab moves approximately on a vertical straight line. Joint a is pulled leftward and b rightward on their circles, with

---

[1] We rely here primarily on Kempe (1877).

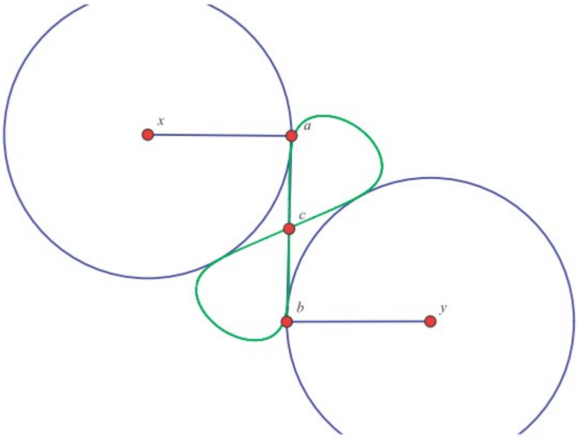

Figure 3.1. A Watt linkage. Joints x and y are pinned; joints a and b are free. The locus of point c is the figure-8 curve. [Construction from Cinderella.]

c staying approximately balanced between. Point c actually follows a "lemniscate," a figure-8 shape with one long, nearly straight section. Variations on this theme are now called "Watt linkages." Watt wrote, "I am more proud of the parallel motion than of any other mechanical invention I have ever made."[2]

3.1.3 Peaucellier Linkage

It was 80 more years before exact straight-line motion was achieved in 1864, by Charles-Nicolas Peaucellier, a captain in the French army. He received a prize, the Prix Montyon, from the Institute of France for his discovery.[3] His remarkable linkage is illustrated in Figure 3.2. Joints x and y are pinned, and rods xa and xb keep joints a and b on circle C_x and rod yc keeps joint c on circle C_y, which also includes x. There are $j = 4$ free joints and $r = 7$ rods, so the linkage has $2j - r = 1$ degree of freedom. The rhombus $abcd$ expands and narrows symmetrically about the diagonal ab. As the cell $abcd$ is rotated clockwise, the gap between the circles C_x and C_y narrows, squeezing the cell, remarkably just enough so that joint d stays on a vertical line L. It is clear that x and the tips c and d of the rhombus are collinear. It can be shown that the product of the distances from x to c and to d is a constant, and that this implies that d follows a straight line.

When Lord Kelvin worked a model of the device, he is reputed to have remarked that "it was the most beautiful thing he had ever seen" (Fergusson 1962).

Peaucellier's linkage was discussed by J. J. Sylvester in a lecture in 1874, and soon improved by Hart to a linkage of only five links, as we will describe in Section 3.3. It was

---

[2] Hunt (1978, p. 134), quoting Reuleaux from 1875.

[3] The history is tangled. A student of Chebyshev, Lippman Lipkin, independently discovered the same mechanism in 1871 (contra: Coxeter and Greitzer 1967, p. 109), as Peaucellier acknowledged in 1873 (Cabillon 1999). Peaucellier's result was first published in 1864 (Peaucellier 1864). See also Koetsier (1999) and Kempe (1877, p. 12).

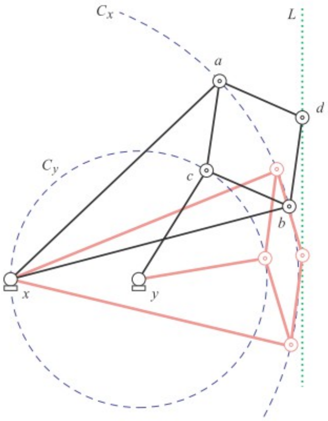

Figure 3.2. Peaucellier linkage. The dark lines show it in one position, the light lines in another.

this lecture that initiated Alfred Bray Kempe[4] to the intricacies of linkages and inspired his work toward his universality theorem.[5]

3.2 KEMPE'S UNIVERSALITY THEOREM

An attractive version of Kempe's result was formulated by Thurston in the 1970s (King 1999, Cor. 2.1):

> There is a linkage that signs your name.

As mentioned, Kempe's proof of Theorem 3.2.1 was flawed, and the subsequent history rather complex. We will not detail this history (see King 1999 or Connelly and Demaine 2004), but content ourselves by mentioning that the first complete, detailed proof is generally acknowledged to be by Kapovich and Millson (2002). In King (1999), the universality theorem is credited to Thurston and Kapovich-Millson. Because Kempe is acknowledged by all to be the source of the main ideas, we will continue to call it "Kempe's universality theorem":

Theorem 3.2.1 (Kempe 1876). *Let $\mathcal{C}$ be a bounded portion of an algebraic curve in the plane, that is, the intersection of zero-set of a real-coefficients polynomial $\phi(x, y) = 0$ with a closed disk. Then there exists a planar linkage such that the orbit of one joint is precisely $\mathcal{C}$.*

We now describe Kempe's proof, tracking his own presentation (Kempe 1876), followed by a discussion of the flaw and one route to repair.

---

[4] Kempe was a barrister by profession, but an excellent amateur mathematician. He is best known for his false proof of the four-color theorem in 1879, which stood for 11 years before Heawood found a flaw. Several ideas in his "proof" were, however, valid, and survive in the form of "Kempe chains" in the computer-aided proof of Appel and Haken a century later (Appel and Haken 1977). The story with linkages is similar: His proof was flawed, but the overall conception was brilliant.

[5] There has since been an extension to 3D (Zindler 1931).

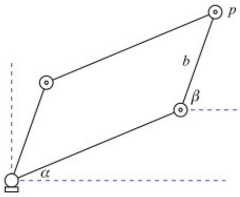

Figure 3.3. Linkage parallelogram.

3.2.1 Kempe's Proof

Let $\phi(x, y) = 0$ be the algebraic curve to be followed by some joint p. The construction begins by placing p at the apex of a parallelogram as shown in Figure 3.3. This parallelogram constrains the range of p's motion, but if we choose a and b equal and large, p is free to move anywhere within distance $2a$ of the pinned vertex O. The feature of this construction is that, if we view O as the origin $(0, 0)$, then the coordinates of $p = (x, y)$ may be expressed in terms of cosines of angles α and β:

$$x = a\cos\alpha + b\cos\beta,$$
$$y = a\cos(\alpha - \pi/2) + b\cos(\beta - \pi/2).$$

(This linkage has $j = 3$ and $r = 4$ and so $2j - r = 2$ degrees of freedom.) Substituting into $\phi(x, y)$ and repeatedly applying the trigonometric product-to-sum identity

$$\cos A \cos B = \frac{1}{2}\cos(A + B) + \frac{1}{2}\cos(A - B) \tag{3.1}$$

converts powers and products of x and y into cosines of sums of angles, resulting in the following general form for the polynomial $\phi(x, y)$:

$$\phi(x, y) = c + \sum_i c_i \cos(r_i\alpha + s_i\beta + \delta_i), \tag{3.2}$$

where c and c_i are constants, r_i and s_i are integers, and $\delta_i \in \{0, \pm\pi/2\}$. For example, the term xy^2 expands and reduces to

$$\frac{1}{4}\big[a^3\cos\alpha + 2ab^2\cos\alpha - a^3\cos(3\alpha) + ab^2\cos(\alpha - 2\beta) + a^2b\cos(2\alpha - \beta)$$
$$+ 2a^2b\cos\beta + b^3\cos\beta - b^3\cos(3\beta) - 3a^2b\cos(2\alpha + \beta) - 3ab^2\cos(\alpha + 2\beta)\big].$$

Each term of the sum in Equation (3.2) is achieved by a link of length c_i, at a suitable angle, with the whole shifted by c. Thus the problem reduces to constructing an angle of the form $r_i\alpha + s_i\beta + \delta_i$ from α and β.

Kempe shows that such a construction can be accomplished with three "gadgets": a "translator" for translating a motion, an "additor" for adding any two angles, and a "multiplicator" for multiplying an angle by a positive integer. The essence of the translator is the action of a pantograph, touched on earlier in Section 1.2.2. Note that while a multiplicator could naturally be implemented using a collection of additors (adding an angle repeatedly to itself), in fact the additor construction uses a multiplicator, and thus both are necessary. Hence, we describe these gadgets in reverse order.

Multiplicator. First, a *contraparallelogram* is a four-bar linkage formed by flipping two adjacent sides of a parallelogram across the diagonal they determine (see Figure 3.4).

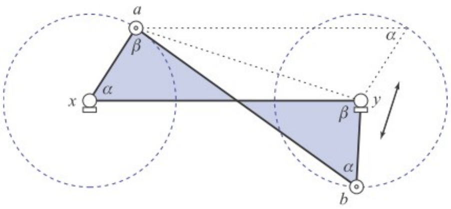

Figure 3.4. A contraparallelogram. $|xa| = |yb|$ and $|xy| = |ab|$. (Note: There is no joint at the point at which the two rods xy and ab cross.)

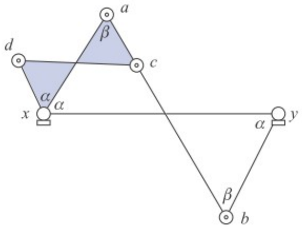

Figure 3.5. Kempe's "multiplicator": two nested, similar contraparallelograms.

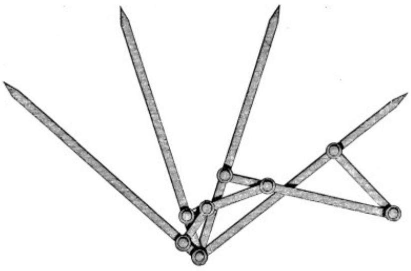

Figure 3.6. Kempe's angle trisector (Kempe 1877, p. 42).

(This structure plays a key role in Hart's linkage, as we will see in Section 3.3.) The opposite angles α and β are equal as in a parallelogram; the two shaded triangles are congruent. The linkage has 1 degree of freedom with x and y pinned[6] and so fixing either one of α or β determines the other. Kempe cleverly joined two similar contraparallelograms as shown in Figure 3.5 so that the angle β at joint a is shared. The two have their lengths in proportion: $|xy|/|xa| = |xa|/|xd|$. Because fixing β determines α in a contraparallelogram, and because of their similarity, the angle α is duplicated at x in the smaller, shaded contraparallelogram, effectively multiplying the angle α by 2. This is why Kempe called this linkage a "multiplicator." Its dynamic action is quite pleasing.[7]

This same process may be repeated, as illustrated in Figure 3.6 for $r_i = 3$, to multiply an angle by a positive integer r_i. Kempe notes that this linkage of eight bars exactly

---

[6] In this case, the xy rod is redundant. So $j = 2$ and $r = 3$, and $2j - r = 1$.

[7] See http://www.gfalop.org/I.

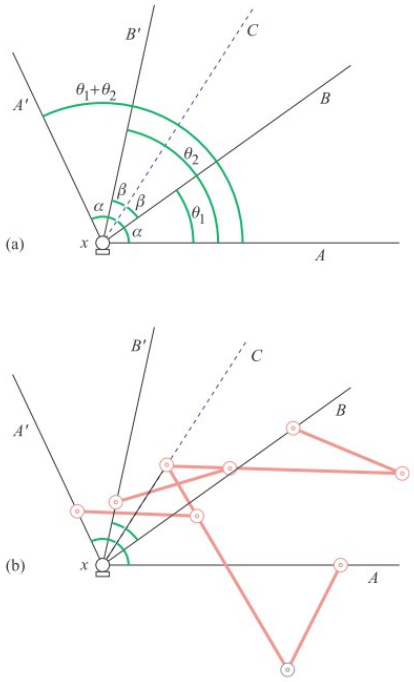

Figure 3.7. (a) A reflects to A' about C, as does B to B'; (b) the construction with superimposed reversors.

trisects an angle, a construction not possible by straight edge and compass. We will return to this point in Part II, Chapter 19 (p. 285).

Additor. Kempe's "additor" adds two angles together. This relies on the multiplicator, but only in its times-2 version in Figure 3.5, which he also called a "reversor" because it can be viewed as reflecting the angle α about the line xa. The construction for adding two angles θ_1 and θ_2 is illustrated in Figure 3.7. It consists of five links, all joined at x, as illustrated in Figure 3.7(a). A makes an angle α with C and reflects across C to A'. Similarly, B makes an angle β with C and reflects across C to B'. If these reflections are maintained, then A and A' are placed symmetrically α around C and B and B' are placed symmetrically β around C. Then the angle $\theta_1 = \alpha - \beta$ and $\theta_2 = \alpha + \beta$ so that $\theta_1 + \theta_2 = 2\alpha$, which is the angle between A and A'. Thus, with A the "base" link, we can "input" the angle θ_1 with link B and θ_2 with link B', and then A' reads off the "output" $\theta_1 + \theta_2$.

The reflections about C can be maintained by Kempe's "reversor" in Figure 3.5. This requires erecting an appropriate contraparallelogram that maintains the reflected angle between A and C, and another to maintain the reflection of B about C. These extra links and joints are shown shaded in Figure 3.7(b).

Translator. Kempe's simplest gadget is the translator, whose purpose is to copy a link at its same orientation elsewhere. His design is shown in Figure 3.8(a). Link A, making an angle α with the horizontal, is displaced to the parallel link C. It makes sense to choose $|D| = |E|$ so that C is free to be placed anywhere within a disk centered on x,

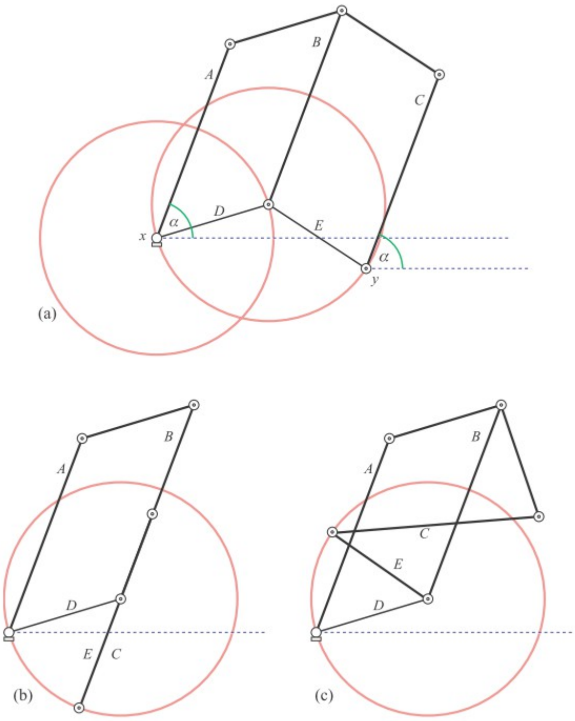

Figure 3.8. (a) Kempe's translator; (b) alignment of C with B; (c) second parallelogram flips to a contraparallelogram. [See also Figure 2.3.2 in Hopcroft et al. 1984.]

that is, the annulus of reachability for the point y (according to Theorem 5.1.2) is a disk. There is, however, a flaw in this design, to which we will return below.

Overall design. Returning to Equation (3.2), the "multiplicator" permits multiplying any angle by an integer r_i. The "additor" permits adding angles, and the "translator" permits connecting together the terms of the sum. Combining these gadgets in an appropriate arrangement yields a joint p' that stays at a horizontal distance $\phi(x, y) - c$ from the y-axis. Using a Peaucellier linkage to force p' to stay on the vertical line $x + c = 0$ in turn forces p to stay on the curve $\phi(x, y) = 0$. Thus, this complex linkage of 1 degree of freedom has the joint p follow the equation $\phi(x, y) = 0$ within the range of x values provided by the parallelogram linkage in Figure 3.3 (see Figure 3.9).

3.2.2 The Flaw and Repairs

Concerning the translator in Figure 3.8, Kempe (1876, p. 214) says: "it is clear that the link [C] is equal and parallel to [A], but is otherwise free to assume any position." What he missed is that when link C aligns with B ((b) of the figure), the second parallelogram is free to flip to a contraparallelogram, as in (c), in which case C is no longer parallel to

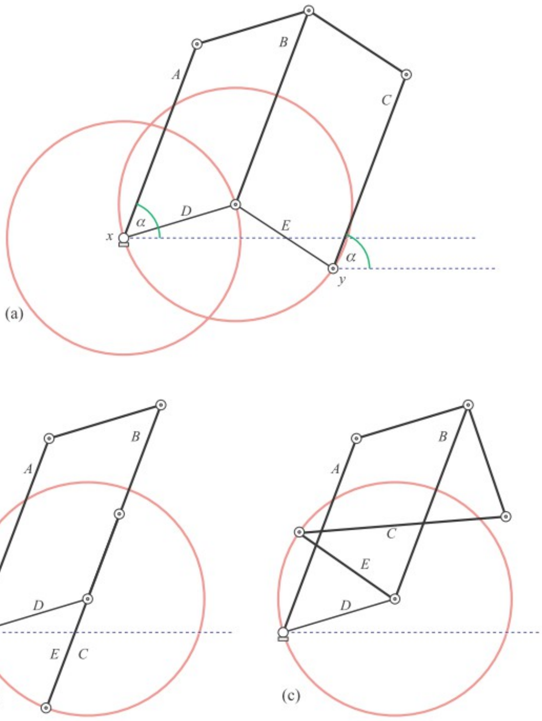

Figure 3.8. (a) Kempe's translator; (b) alignment of C with B; (c) second parallelogram flips to a contraparallelogram. [See also Figure 2.3.2 in Hopcroft et al. 1984.]

that is, the annulus of reachability for the point y (according to Theorem 5.1.2) is a disk. There is, however, a flaw in this design, to which we will return below.

Overall design. Returning to Equation (3.2), the "multiplicator" permits multiplying any angle by an integer r_i. The "additor" permits adding angles, and the "translator" permits connecting together the terms of the sum. Combining these gadgets in an appropriate arrangement yields a joint p' that stays at a horizontal distance $\phi(x, y) - c$ from the y-axis. Using a Peaucellier linkage to force p' to stay on the vertical line $x + c = 0$ in turn forces p to stay on the curve $\phi(x, y) = 0$. Thus, this complex linkage of 1 degree of freedom has the joint p follow the equation $\phi(x, y) = 0$ within the range of x values provided by the parallelogram linkage in Figure 3.3 (see Figure 3.9).

3.2.2 The Flaw and Repairs

Concerning the translator in Figure 3.8, Kempe (1876, p. 214) says: "it is clear that the link [C] is equal and parallel to [A], but is otherwise free to assume any position." What he missed is that when link C aligns with B ((b) of the figure), the second parallelogram is free to flip to a contraparallelogram, as in (c), in which case C is no longer parallel to

Figure 3.9. A schematic of the overall structure of Kempe's construction. Each term of Equation (3.2) is simulated by a link whose projection on the horizontal axis is that term. The point p' is constrained to follow a particular vertical line by a Peaucellier linkage. The joints labeled O are the same joints.

A! This unwanted passage through a degeneracy to another part of the configuration space is a generic problem throughout Kempe's construction, noted by Thurston, and in Hopcroft et al. (1984), and perhaps by others. This is how the problem is phrased by Kapovich and Millson (2002):

> The main problem with Kempe's proof is that it works well only for a certain subset of the moduli space,[8] however, near certain "degenerate" configurations the moduli

---

[8] Another term for the configuration space of the linkage.

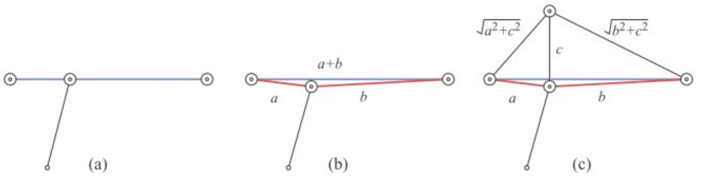

Figure 3.10. Simulating a joint in the interior of a link.

space splits into several components and the linkage fails to describe the desired polynomial function. We use the "rigidified parallelograms" to resolve this problem and get rid of undesirable configurations (p. 3).

To repair Kempe's proof, we need to "brace" both the parallelogram and the contraparallelogram to prevent flipping from one to the other. For the first bracing, we follow King's presentation (King 1999), of Kapovich and Millson's resolution. The latter authors did not need to brace the contraparallelogram, as their proof deviates from Kempe's and does not employ that mechanism. For the second bracing, we follow a recent idea of Abbott and Barton (2004).

3.2.2.1 Bracing the Parallelogram

It is convenient to be able to locate a joint in the interior of a rigid bar. One could either permit this as part of the definition of a linkage or retain the restriction that joints are only at endpoints of bars and simulate an interior joint as follows. Refer to Figure 3.10. The joint in the interior of edge *e* in (a) of the figure can be simulated with links whose length sums the length of *e*, as shown in (b). This linkage is not "infinitesimally rigid" (as defined in Section 4.4, p. 49), so one might want to add the "stiffening truss" shown in (c).

Now we show how to "rigidify" parallelograms. Consider a rhombus linkage (see Figure 3.11). With its two bottom vertices a and b pinned, it has the natural circular motion shown in (a). However, as Kapovich and Millson pointed out, it also has the degenerate motions shown in (b) and (c). So the configuration space of this linkage is three circles, each pair intersecting in a single point. Blocking of the degenerate motions is accomplished by adding a bar between the midpoints of opposite sides, as in (d). These extra links are needed at many points throughout Kempe's construction, for example, in the parallelogram that is part of the Peaucellier linkage (Figure 3.2) employed in Kempe's construction.

3.2.2.2 Bracing the Contraparallelogram

Bracing the contraparallelogram is a bit more complicated. Here we describe a bracing due to Abbott and Barton (2004).

Let the contraparallelogram be $abcd$, and let p, q, r, and s be the midpoints of its links. The linkage is braced by four extra bars to a common point x on the perpendicular bisector of the line containing those midpoints (see Figure 3.12(a)). As long as these four extra bars are chosen long enough, the contraparallelogram is prevented from flipping to the parallelogram configuration. The reason why is hinted at in Figure 3.12(b). When $abcd$ is a parallelogram, so is $pqrs$. Now, returning to (a) of the figure, we know that x is on the perpendicular bisector of sq and on the perpendicular bisector of pr. This

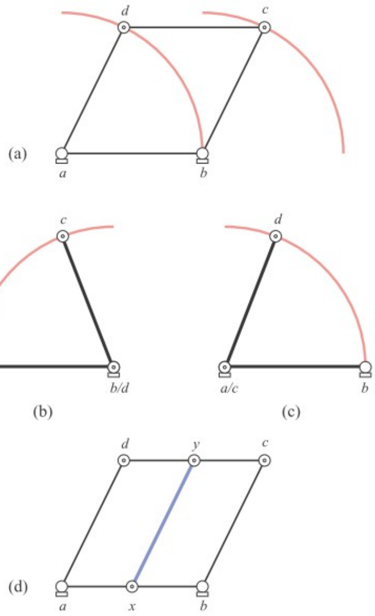

Figure 3.11. (a–c) Three circular motions of a rhombus; (d) rhombus rigidified.

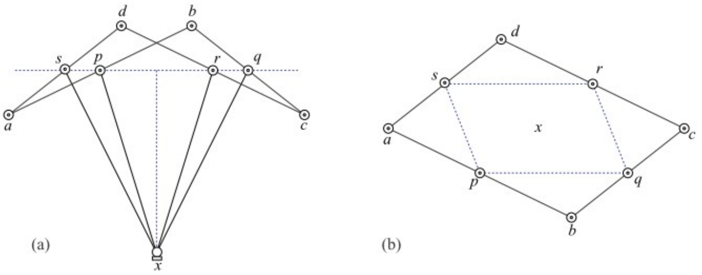

Figure 3.12. (a) Braced contraparallelogram; (b) flipping to the corresponding parallelogram is not possible.

would place x at the center of the parallelogram $pqrs$. But if the extra bars are chosen long enough, this is impossible. See Box 3.1 for details.

3.2.3 Recap

We have chosen to present Kempe's original proof with repairs, but as mentioned, the first full proof is due to Kapovich and Millson. They follow Kempe's construction in spirit but not detail. Their proof employs modified versions of many of his linkages, but avoids

Box 3.1: Braced Contraparallelogram

Let $r_1 = |xp| = |xr|$ and $r_2 = |xs| = |xq|$ be the two lengths of the bracing bars. These lengths are chosen so that $r_2^2 - r_1^2 = \frac{1}{4}(|ab|^2 - |ad|^2)$. A few facts:

1. p, q, r, and s are collinear.
2. $|sp| = |rq|$.
3. x is on the perpendicular bisector of sq and on the perpendicular bisector of pr.
4. $|sp| \cdot |sr| = \frac{1}{4}(|ab|^2 - |ad|^2)$.

This last claim is not obvious, but we defer a proof to the discussion of Hart's inversor (Box 3.2). Let L be the linkage composed of just the closed 4-chain $abcd$, and let L_b be the braced version. Using the facts above, Abbott and Barton (2004) prove that any degenerate (flat) or contraparallelogram configuration of L can be extended to a configuration of L_b, and, conversely, the bracing of L_b restricts the configurations of $L \subset L_b$ to be just the degenerate and contraparallelogram configurations.

his multiplicator in favor of a more complex multiplier mechanism (incorporating three translators, a pantograph, three inversors (modified Peaucellier linkages), and an adder) whose properties are more easily controlled. The collection of elementary linkages allow a nearly straightforward composition of a linkage for complex polynomial maps, $f : \mathbb{C}^n \to \mathbb{C}$, without recourse to the trigonometric expansions employed by Kempe. This complex linkage is then modified further to obtain a linkage realizing a real polynomial map $f : \mathbb{R}^n \to \mathbb{R}$, achieving a version of the universality theorem (Theorem 2.2.3): for any compact real algebraic set X (e.g., a bounded portion of a curve), there is a linkage L such that the map is an "analytically trivial covering"[9] of X. Thus, the formidable full proof finally firmly establishes that, indeed, there is a linkage that signs your name, even if (as King 1999, notes) your signature includes cusps and multiple strokes! And, as previously noted, this beautiful generalization of the task of creating straight-line mechanisms has led to a thorough understanding of the rich topology of the configuration space of linkages.

It is natural to ask how many links are required to trace a curve defined by a polynomial of degree n. This was first addressed in Gao et al. (2002), where an $O(n^4)$ bound was obtained on the number of links. This was subsequently improved by Abbott and Barton (2004) to $O(n^2)$, and extended to arbitrary dimension d to $O(n^d)$ bars. They also offer strong evidence that these bounds are optimal.

Two interesting open questions were recently posed on this topic:

Open Problem 3.1: Continuous Kempe Motion.[a] Given a (connected) curve C in the plane, is there is a linkage that traces exactly that curve via a continuous motion/reconfiguration?

[a] Abbott and Barton (2004).

---

[9] The map is an *analytic isomorphism*, with both f and f^{-1} restrictions of analytic maps (i.e., locally, power series).

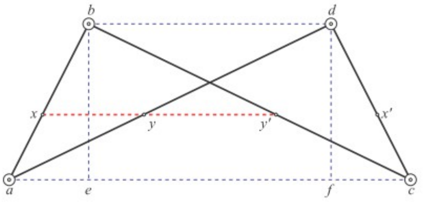

Figure 3.13. Hart's inversor. $|ab| = |cd|$ and $|bc| = |da|$, so that $abcd$ is a contraparallelogram.

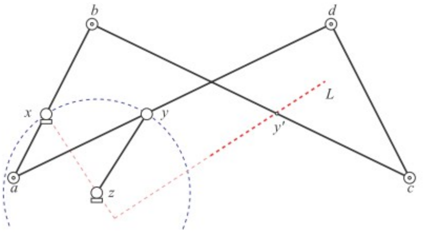

Figure 3.14. Hart's mechanism to convert circular motion of y to linear motion of y'. Joint x is pinned and the center of inversion. L is perpendicular to the line containing xz.

The point here is that although the proofs construct a linkage such that the positions of one joint are exactly C, it is possible that the whole of C cannot be traced by a continuous reconfiguration of the linkage. Perhaps it is necessary to jump to a different configuration to trace different sections of C.

The next open problem ties into linkages forbidden from self-intersection, a topic discussed at great length later on in Part I:

Open Problem 3.2: Noncrossing Linkage to Sign Your Name.[a] Is there a linkage that traces any given algebraic curve, and moves without any self-intersection throughout the tracing? If not, what is the class of curves that can be traced by a noncrossing linkage?

---

[a] Don Shimamoto, April 2004.

3.3 HART'S INVERSOR

We complete the story of linear-motion linkages by sketching Hart's 1875 5-link mechanism,[10] which "improves" upon Peaucellier's 7-link arrangement at the cost of a loss of some symmetry and the use of one more complex joint.

Start with a contraparallelogram $abcd$ as in Figure 3.13. The symmetry of the contraparallelogram guarantees that ac and bd remain parallel during movement. Hart takes four points x, y, y', x' dividing the four links in the same proportion. It is then not hard to see that these four points are collinear, and remain collinear and parallel to ac and bd throughout the free motion of the linkage. The key property – not at all obvious – is

---

[10] Hart (1875), as described in Kempe (1877, p. 18ff). See also Hunt (1978, p. 15) and http://poncelet.math.nthu.edu.tw/disk3/cabrijava/hart2.html.

21 Introduction and Overview

21.1 OVERVIEW

In 1525 the painter and printmaker Albrecht Dürer[1] published a book, *Underweysung der Messung* (later translated as "The Painter's Manual"), in which he explained the methods of perspective, which he had just learned himself on a trip to Italy[2] (see Figure 21.1).

Dürer's book includes a description of many polyhedra, which he presented as surface unfoldings, are now called "nets." For example, Figure 21.2 shows his net for a cuboctahedron. Even when he drew a more complex net, such as that for a truncated icosahedron (the shape of a soccer ball; Figure 21.3), he always chose an unfolding that avoided self-overlap. Although there is no evidence that Dürer distilled this property into a precise question, it is at least implicit in the practice of subsequent generations that every convex polyhedron may be so unfolded.[3] More precisely, define an *edge unfolding* as a development of the surface of a polyhedron to a plane, such that the surface becomes a flat polygon bounded by segments that derive from edges of the polyhedron. One may view such an unfolding as obtained by slicing the surface along a collection of edges. We would like an unfolding to possess three characteristics, enjoyed by all Dürer's drawings:

1. The unfolding is a single, simply connected piece.
2. The boundary of the unfolding is composed of (whole) edges of the polyhedron, that is, the unfolding is a union of polyhedron faces.
3. The unfolding does not self-overlap, that is, it is a "simple polygon."

We call a simple polygon that satisfies these conditions a *net* for the polyhedron.[4] This leads to the following open problem:

---

[1] 1471–1528, Nürnberg, Germany.

[2] Here we rely on George Hart's history at http://www.georgehart.com/virtual-polyhedra/durer.html.

[3] This point was first made to us by Branko Grünbaum (personal communication, 1987).

[4] Here we follow Shephard's (1975) and Grünbaum's usage (2001) in insisting that a net is derived from an edge unfolding. We will also explore polygons that fold to a polyhedron but are not a union of polyhedron faces. (Alexandrov (2005, p. 61) uses what is translated to English as "net" for another concept. What is translated to German as "das Netz" in Alexandrov (1958) is translated to English as "development" in Alexandrov (2005).) Dolbilin calls a net a "regular edgewise development" (Dolbilin 1998).

Open Problem 21.1: Edge-Unfolding Convex Polyhedra.[a] Does every convex polyhedron have an edge unfolding to a simple, nonoverlapping polygon, i.e., does every convex polyhedron have a net?

---

[a] Dürer (1525).

This has remained unsolved over the 475 years since Dürer's drawings. (The first explicit statement of the problem of which we are aware was formulated by Shephard in 1975 (Shephard 1975): "Does every 3-polytope possess a net?") This problem can be viewed as a central motivation for the third part of this book.

21.2 CURVATURE

The concept of "curvature" will play an important role in this part of the book. Although we will employ it primarily for polyhedra, its origins lie in the differential geometry of smooth curves and surfaces. After describing curvature in these contexts, the definition for polyhedral surfaces will be motivated.

21.2.1 Smooth Curves

Let $c(t)$ be a smooth[5] curve in the plane, having a unit-speed parametrization by t. The curvature of $c(t)$ at a point p measures how sharply the curve turns at p by the magnitude of the acceleration $|\ddot{c}|$ felt at p by a particle (or a car) traveling at unit speed along $c(t)$. This acceleration is the same[6] as the reciprocal of the radius of the *osculating circle* at p: the unique circle that matches at p both the velocity vector (the tangent) and the acceleration vector (which is normal to the curve), in both magnitude and direction (see Figure 21.4). If $c(t)$ is straight at p, the circle radius is effectively infinite and the curvature is zero.

---

[5] For our purposes, *smooth* means C^{∞}: possessing a continuous kth derivative for all $k = 1, 2, 3, \ldots$, although usually the assumption of C^2 suffices.

[6] The same under the assumption that $|\ddot{c}| = 1$.

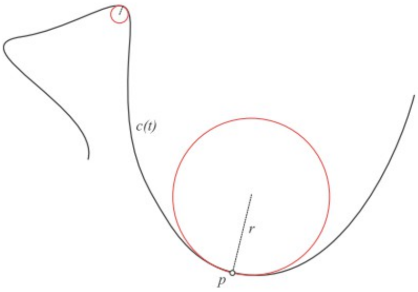

Figure 21.4. The curvature at a point is $1/r$, where r is the radius of the osculating circle.

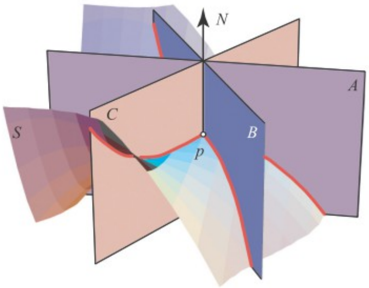

Figure 21.5. Spinning a plane about N through $p \in S$ yields the principal curvatures at p. The curvature of the curves for plane A and B are positive at p, but negative for plane C.

21.2.2 Smooth Surfaces

The curvature of a surface $S \subset \mathbb{R}^3$ at a point p cannot be captured by the osculating sphere, for this sphere does not distinguish between a spherical surface and a cylindrical surface, which intuitively have different curvatures (e.g., they have different flattening properties). Two numbers are needed at each point rather than one.

Principal curvatures. These two numbers are known as the *principal curvatures* and may be defined as follows (Lee 1997, p. 5). Let N be the unit normal vector to an oriented surface S at p, and P a plane through p containing N. Then $P \cap S$ is a one-dimensional curve whose curvature at p is defined as described above. It can be given a sign according to whether the osculating circle is locally inside S (+) or outside (−), with "outside" defined by the direction in which N points. Now imagine spinning P about N. The principal curvatures κ_1 and κ_2 at p are the minimum and maximum signed curvatures over all intersection curves obtained (see Figure 21.5). Notice that the principal curvatures do distinguish between a sphere and a cylinder: $\kappa_1 = \kappa_2 = 1/r$ for a sphere of radius r, but $\kappa_1 = 0$ and $\kappa_2 = 1/r$ for a cylinder of the same radius. There remains a flaw of sorts, however: the principal curvatures are not "intrinsic" properties of the surface, invariant under isometric embeddings. A flat piece of paper and the same paper rolled to a cylinder have the same intrinsic properties (to, say, flatlanders living in the surface), but have different principal curvatures.

Gaussian curvature. Gauss discovered in 1827 that the product $K = \kappa_1\kappa_2$ is intrinsic. He called this result the "*Theorema Egregium*" – roughly, the distinguished, extraordinary theorem – and said that it "ought to be counted among the most elegant in the theory of curved surfaces" (Spivak 1979, II: p. 114). K, known as the *Gaussian Curvature*, will be used frequently in the sequel. Note that both the flat paper and the cylinder have the same Gaussian curvature K: for the cylinder, $\kappa_1\kappa_2 = 0 \cdot 1 = 0$.

Curvature and normals. A useful extrinsic view of the Gaussian curvature is that "K measures the total spread of normal directions per unit surface area": it is "the ratio between the solid angle subtended by the normals on a small patch divided by the area" (Koenderink 1989, p. 215). Positive K spreads the normals, and negative K reverses the orientation of the spherical image of the normals.

Curvature and perimeter and area. Another equivalent – but this time intrinsic – definition of the Gaussian curvature at $p \in S$ is in terms of the perimeter or area of a small disk around p. Define a *geodesic disk* centered on p of radius r to be the locus of points of S at distance r of p, where distance to a point x is measured by the shortest path on S from p to x. (We will discuss shortest paths and geodesics in Chapter 24.) Such a disk is sometimes said to have "intrinsic radius" r. Let the circumference of the disk be $C(r)$. Bertrand and Puiseux proved in 1848 (Berger 2003, p. 110; Spivak 1979, II: p. 130) that

$$K = \lim_{r\to 0} \frac{3(2\pi r - C(r))}{\pi r^3}. \tag{21.1}$$

From this equation, we can see that points of positive curvature have a perimeter deficit with respect to the flat $2\pi r$ and those of negative curvature have a perimeter excess. Points of positive curvature are called *elliptic* and those of negative curvature *hyperbolic*.

Integrating around the perimeter of a geodesic disk leads to a similar equation for K in terms of the area deficit, discovered by Diquet:

$$K = \lim_{r\to 0} \frac{12(\pi r^2 - A(r))}{\pi r^4}, \tag{21.2}$$

where $A(p)$ is the area of the disk. Again we have the same classification: area deficit corresponds to positive curvature, and area excess to negative curvature.

21.2.3 Polyhedral Surfaces: Angle Deficit

The area-deficit viewpoint of Gaussian curvature makes the definition of Gaussian curvature on a polyhedral surface S natural, or at least plausible: the *Gaussian curvature* (or simply "the curvature") of a point p on a polyhedral surface S is the *angle deficit*[7] at p: 2π minus the total face angle incident to p. Thus, a point in the interior of a face of S has curvature zero. Less obvious is that a point on the relative interior of a polyhedron edge e also has curvature zero, for it has π face angle incident from either side of e. All the curvature of a (closed) polyhedron is concentrated at the vertices: A vertex v has curvature 2π minus the sum of the face angles (the *total angle*) incident to v.

For example, each vertex of a cube has curvature $\pi/2 = 90^\circ = 360^\circ - 3(90^\circ)$; and each vertex of a dodecahedron has curvature $\pi/5 = 36^\circ = 360^\circ - 3(108^\circ)$

---

[7] Sometimes called the "angle defect" or "jump angle." This notion of angle deficit was introduced by Descartes in his "Treatise on Polyhedra," which he wrote in the mid-1600s, a century prior to Gauss.

If the surface is cut open and flattened in the neighborhood of v, there will be an angle gap equal to the curvature at v. It is this notation of curvature that will be used in the sequel.

21.3 GAUSS–BONNET THEOREM

If a person walks around the boundary of a simple polygon, by the time they revisit their starting point, they have turned or twisted in total (with negative turnings canceling positive turnings) exactly 2π. This is an easy consequence of the fact that the sum of the internal angles of a polygon of n vertices is $(n-2)\pi$. The sum of the complete angles at the n vertices is $n(2\pi)$, and so the sum of the exterior angles is $(n+2)\pi$. The turn at each vertex is the excess of the exterior angle there over π (e.g., no turn at all corresponds to an exterior angle of π). So the total turn is $(n+2)\pi - n\pi = 2\pi$. The same holds true for any Jordan curve in the plane, with the discrete sum of angles replaced by an integral of the angle turn at each point of the curve. Call this total angle turn around a curve or polygon τ. This turn τ is sometimes called the *geodesic curvature* of the curve, as it measures the deviation from a straight geodesic.

On an arbitrary (nonflat) surface, one can define a notion of the turn of a curve on the surface, which intuitively is the turn experienced by a person walking along the curve while vertically aligned with the surface normal. Under this notion of surface angle turn, a closed curve does not in general have an angle turn of 2π. For example, consider a spherical triangle on a sphere, with a corner on the equator, a corner at the north pole, and, after a 90° turn there, a third corner on the equator. The total turn of this triangle is $\tau = 3\pi/2$. The reason τ is less than 2π on the sphere is that each curve encloses some positive curvature. There is a tradeoff between turn and enclosed curvature, which is captured precisely in the *Gauss – Bonnet formula*, one of the jewels of differential geometry[8]:

$$\tau + \gamma = 2\pi, \tag{21.3}$$

where τ is the total turn around the boundary of the curve and γ is the integral of the Gaussian curvature enclosed in the "polygon" P:

$$\int_P K dA. \tag{21.4}$$

On the plane, $\gamma = 0$, so $\tau = 2\pi$. On positively curved surfaces, polygons turn less than 2π, and on negatively curved surfaces, they turn more than 2π.

Because the equator of (or any great circle on) a sphere is a geodesic, it has $\tau = 0$. A west–east walk around the equator implies via Equation (21.3) that the northern hemisphere must contain 2π of curvature, as must the southern hemisphere via an east–west walk. Thus the total curvature of a sphere is 4π. This result generalizes to any surface homeomorphic to a sphere (i.e., of genus zero), by partitioning it into regions and applying Equation (21.3) to each region:

Theorem 21.3.1. *The total sum of the Gaussian curvature over all points of a surface homeomorphic to a sphere is* 4π.

---

[8] See, e.g., Lee (1997, Ch. 9) and Morgan (1991, Ch. 8).

Several examples:

1. *Sphere.* The curvature at each point of a sphere of radius $r = 2$ is $1/r^2 = 1/4$, and the integral over the entire surface area of $4\pi r^2 = 16\pi$ is 4π.
2. *Cube and dodecahedron.* The curvature sum for a cube is $8(\pi/2) = 4\pi$, and for a dodecahedron is $20(\pi/5) = 4\pi$.
3. *Cylinder.* Curvature is concentrated at the points on the top and bottom rim of a cylinder. If it has radius $r = 1$, each rim point has curvature 1, which, integrated over the $2\pi r = 2\pi$ length of the top and bottom rims, is 4π.

The reach of this theorem is breathtaking, as it holds for any surface, convex or nonconvex, smooth or polyhedral,[9] and connects the intrinsic, local curvature to a global constant. Intuitively it says that a dent in a surface at one location must be compensated by an equal bump at another. The theorem generalizes to surface of genus g with a sum of $2\pi(2 - 2g)$; the number $\chi = 2 - 2g = V - E + F$ is known as the *Euler characteristic* of the manifold.

One immediate consequence that we will exploit in Section 24.4 is the generalization of our observation about the great circles on the sphere: a closed geodesic (which does not turn, and so has $\tau = 0$) must enclose $\gamma = 2\pi$ of curvature.

---

[9] This result for convex polyhedra was proved by Descartes, and is sometimes known as Descartes' theorem (Phillips 1999).

19.2 Huzita's Axioms and Hatori's Addition

Box 19.1: Abe's trisection

Important: three parallel lines

Estudar!!! com Pappus ✡

Fig. 19.4 Abe's trisection analyzed.

Jandaia

Box 19.1: Abe's trisection

Let a, b, and c be three points at the left ends of the bottom three parallel lines: the bottom side of the square and the first two fold lines (see Figure 19.4). Point b is the midpoint of ac by construction. Now reflection through the A6 crease line L maps the three points to a', b', and c', with again b' the midpoint of $a'c'$. Because a' lies on the horizontal line through b and because b is the midpoint of the vertical line segment ac, length $a'c$ equals length $a'a$, so $\triangle aa'c$ is isosceles. Therefore its reflection through crease line L, $\triangle aa'c'$, is also isosceles. Thus, $\angle a'ac'$ is cleverly split in half: $\angle a'ab' = \angle b'ac' = \alpha$. Because $\triangle aa'c'$ is isosceles, its base angle $\angle aa'c' = 90^\circ - \alpha$. Because a' is a reflection of the corner of the square, it is a right angle, leaving $\angle xa'a = \alpha$, and therefore by reflection $\angle xaa' = \alpha$. Thus the angle θ at a is trisected into $\alpha + \alpha + \alpha$.

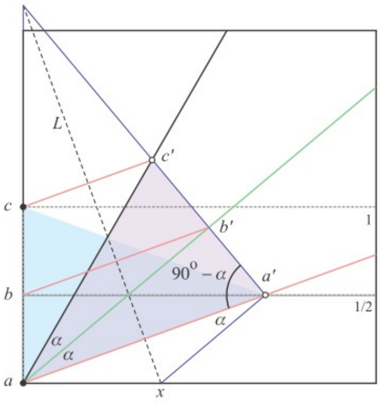

Figure 19.4. Abe's trisection analyzed.

constructions can construct rational numbers, the roots of quadratic equations with constructible coefficients, and nothing more. The key word here is "quadratic," not surprising because circles are quadratics. Axioms A1–A5 have been shown to be equivalent to straight edge and compass constructions (Alperin 2000; Geretschläger 1995; Justin 1989b). However, A6 cannot be accomplished (in general) using straight edge and compass; it adds the power to solve certain cubic equations. To see this, let us revisit A5, in Figure 19.5(a). A5 maps a point to a line over a crease. Because the point reflects across the crease, its distance to the crease is the same as the distance from the crease to the reflected point. This shows that the crease is tangent to the parabola whose focus is the point and whose directrix is the line, for a parabola is the locus of points equidistant from the focus and the directrix.

Now it should be clear that the crease in A6 is tangent to two parabolas, as shown in Figure 19.5(b). Finding a common tangent between two parabolas can be phrased as solving a cubic equation (Emert et al. 1994).[3]

---

[3] Alperin (2004) describes another geometric view of this axiom and its connections to "petals of conics."

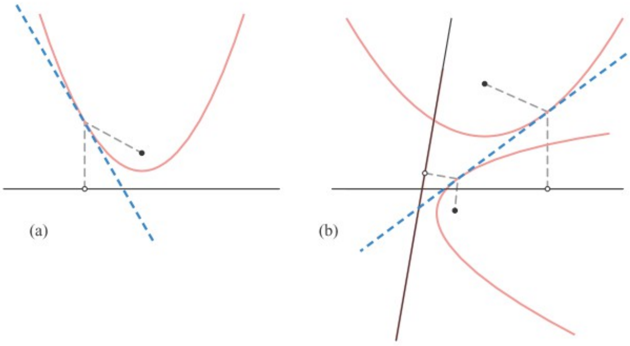

Figure 19.5. Huzita's axioms A5 and A6.

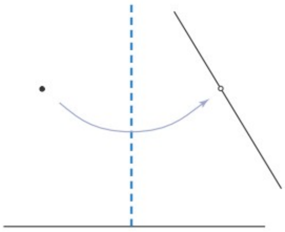

Figure 19.6. Hatori's axiom A7.

19.2.1 Hatori's Seventh Axiom

Recently Hatori suggested a seventh axiom (Hatori 2004; Hull 2003b):

A7. Given one point and two lines, one can fold a crease perpendicular to one line so that the point maps to the other line.

See Figure 19.6.

This axiom is again fundamentally quadratic, but not equivalent to any one of the others. Lang proved that these seven axioms together are complete in the sense that "these are all of the operations that define a single fold by alignment of combinations of points and finite line segments" (Lang 2004, p. 234).

19.3 CONSTRUCTIBLE NUMBERS

We mentioned that origami, as specified by the Huzita–Hatori axioms, can go beyond the quadratic limitation of straight edge and compass constructions, in having at least some cubic capabilities, leading to the ability to trisect an angle. It is then natural to ask if origami can do more than trisect. There is a characterization of what is achievable with a straight edge, compass, and a tool that only trisects a given angle: one can then

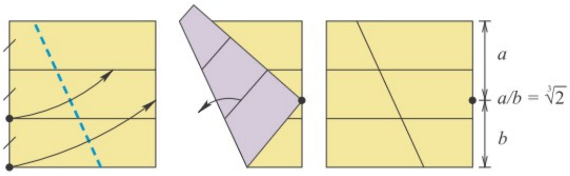

Figure 19.7. Messer's method for doubling a cube using origami.

solve a real cubic equation with constructible coefficients if and only if all its roots are real (Gleason 1988). In particular, because $z^3 - 2 = 0$ has only one real root, one cannot "double a cube," that is, construct $\sqrt[3]{2}$, using such tools.[4]

However, Messer (1986) showed in 1985 that you can double a cube using origami (see Figure 19.7).

Justin (1989b), Geretschläger (1995), and Alperin (2000) independently showed that all cubic equations with constructible coefficients can be solved with origami. Unknown to these authors, a proof of this result was published already in 1936 by Margherita Piazzolla Beloch (1936) (see also Huzita 1994). Because quartic equations can be solved with cubics, the consequence of this result is that all quartic equations can be solved with origami.

It remained an open problem for several years (Hull 1996; Murakami 1987) to determine whether origami can go beyond solving quartics. The answer is NO. This was first established by Huzita and Scimemi (1989), and independently by Alperin (2000). Here we rely on a connection to other work first noted by Demaine and Demaine (2000).

The basic origami fold that the axioms use is a "book fold," which amounts to a reflection through a line. A related geometric-construction tool with this property is a semireflective mirror allowing you to simultaneously see a reflection and see through the mirror. Originally, such a mirror was made by coating plate glass with a thin layer of evaporated metal. Today, one can use a hard thin piece of dark-colored transparent plastic with a smooth finish. Such a device is commonly referred to by the trade name Mira.[5]

Many papers have considered the geometric power of the Mira, starting in 1963 when Hochstein (1963) showed how to trisect an angle with a semireflective mirror (before the term "Mira" was coined). In 1994, Emert et al. (1994) were the first to give a full axiomatic characterization of the Mira. And it turns out that the operations are in fact equivalent to the origami axioms. Emert et al. provided a complete characterization of Mira-constructible (and hence origami-constructible) numbers; they proved that every constructible number is the root of a quadratic or cubic equation with constructible coefficients. Thus, origami can solve all quartic equations but no more.

19.4 FOLDING REGULAR POLYGONS

A classic motivation for determining the power of a particular geometric device is to characterize the constructible regular polygons. For example, it is well known that straight edge and compass can construct a regular n-gon exactly when n is of the form $2^r p_1 \cdots p_k$, where the p_i's are distinct Fermat primes (i.e., prime numbers of the form $2^u + 1$). Origami has a similar characterization, essentially by adding "3" in addition to "2," because origami can solve cubic equations in addition to quadratic equations. More precisely, origami can construct a regular n-gon exactly when n is of the form $2^r 3^s p_1 \cdots p_k$, where the p_i's are distinct primes of the form $2^u 3^v + 1$ (Emert et al. 1994). Curiously, these are precisely the same regular polygons that are constructible with straight edge, compass, and a tool that just trisects (Gleason 1988). In other words, the ability to solve general cubic equations, instead of just those with all real roots, does not help to construct any new regular polygons.

---

[4] This is one of the three classical Euclidean construction questions: given the side of a cube, construct the side of a cube that has twice the volume. If the given side has length 1, the goal is to construct $\sqrt[3]{2}$.

[5] Registered trademark of the Mira-Math Company in Willowdale, Ontario, Canada.

In comparison to straight edge and compass, origami can construct many more regular polygons. Below we list the first several unconstructible polygons for each. In particular, $n = 11$ is the smallest unconstructible regular polygon by paper folding.

Straight edge and compass: 7, 9, 11, 13, 14, 18, 19, 21, 22, 23, 25, 26, 27, 28, 29, 31, 33, 35, 36, 37, 38, 39, 41, 42, 43, 44, 45, 46, 47, 49, 50, 52, 53, 54, 55, 56, 57, 58, 59, . . .

Origami: 11, 22, 23, 25, 29, 31, 33, 41, 43, 44, 46, 47, 49, 50, 53, 55, 58, 59, 61, 62, 66, 67, 69, 71, 75, 77, 79, 82, 83, 86, 87, 88, 89, 92, 93, 94, 98, 99, 100, 101, 103, 106, 107, . . .

19.5 GENERALIZING THE AXIOMS TO SOLVE ALL POLYNOMIALS?

The results on the power of paper folding rely on the restricted set of Huzita–Hatori axioms, which only permit simple folds. It is conceivable that more powerful axioms would permit solving polynomial equations of arbitrary degree via origami. Here we give the germ of an idea from Demaine and Demaine (2000) that might lead to this result. The plan is to exploit the universality theorems from linkages (Part I, Section 3.2, p. 31) that say that any polynomial curve can be traced out by a linkage. We sketch the method first and then discuss what additional axioms might be needed.

The first step is to use the methods described in Chapter 15 to fold the paper into a shape with several *rulers*, as shown in Figure 19.8(a), making n long rulers available for manipulation, plus the shaded *construction area*. The edges of this silhouette are horizontal and vertical and have integral length, and so are easily constructible.

The second step is to "draw" (crease) in the construction area the bars (line segments) of a linkage, conceptually connected by hinges at their endpoints. The example in Figure 19.8(b) shows a 4-bar linkage, but in fact the linkage will have to follow the complete Kempe or Kapovich–Millson universality proofs. We suppose that the linkage has n bars, the same as the number of rulers we construct.

The third step is to fold each ruler into position, atop a corresponding bar in the linkage, as in Figure 19.8(c)–(d). In general, a ruler can be folded into position by first folding it vertically upward, then horizontally left (for bars with negative slope), and then at an appropriate angle to match the bar. By first folding a ruler upward, we never fold a ruler on top of a lower ruler. Thus, we can assign each ruler a "layer" that it occupies, and these layers of paper do not interfere, so the rulers can be folded flexibly and independently.

The fourth step is to reconfigure the rulers so as to simulate the linkage. Each ruler can be marked (by creasing) with the length of the corresponding bar. The resulting

CHAPTER X

Two-Variable Iwasawa Theory of Elliptic Curves

Our study of the p-ordinary part of the Selmer group for E is almost at an end. However there is one last twist in the tale. Up to this point, the ground field $\mathbf{F}$ we have been working over has remained fixed, but this assumption can now be relaxed. In particular, allowing the number field $\mathbf{F}_n$ to vary in a cyclotomic $\mathbb{Z}_p$-extension adjoins an extra variable, Y say, to the ambient deformation ring.

Why is this cyclotomic variable Y important, and what net benefits are gained? The principal motivation has its origins in the Iwasawa theory of elliptic curves admitting complex multiplication. Specifically, if E has CM by an order in $\mathcal{O}_{\mathbb{Q}(\sqrt{-D})}$ then $\mathrm{Gal}\Big(\mathbb{Q}(E[p^\infty])/\mathbb{Q}(E[p])\Big) \cong \mathbb{Z}_p \times \mathbb{Z}_p$. In terms of completed group algebras

$$\mathbb{Z}_p[[G]] \;\cong\; \mathbb{Z}_p[[\Gamma^{\mathrm{wt}} \times \Gamma^{\mathrm{cy}}]][\Delta] \;\cong\; \bigoplus_{\delta\in\Delta} \mathbb{Z}_p[[X,Y]].\delta$$

where $G = \mathrm{Gal}\Big(\mathbb{Q}(E[p^\infty])/\mathbb{Q}(\sqrt{-D})\Big)$, and Δ is finite with order coprime to p. Therefore in the CM case, combining the cyclotomic deformation with the weight deformation is *equivalent* to studying the arithmetic of E over the field of definition of its p-power division points.

If E does not admit complex multiplication, then $\mathrm{Gal}\big(\mathbb{Q}(E[p^\infty])/\mathbb{Q}\big)$ is an open subgroup of $\mathrm{GL}_2(\mathbb{Z}_p)$, and its underlying Iwasawa algebra is a non-commutative power series ring in four variables. In this scenario $\mathbb{Z}_p\big[[\Gamma^{\mathrm{wt}} \times \Gamma^{\mathrm{cy}}]\big]$ represents the completed group ring of its maximal torus, i.e. the cyclotomic-weight deformation encodes the abelianisation of GL_2-Iwasawa theory.

A major goal of this chapter is to formulate three new **Main Conjectures**: the first corresponding to the vertical line $s = 1$, another for the line of symmetry $s = k/2$, and the last for the whole (s, k)-plane. These are fundamental statements reconciling the 'algebraic world' with the 'analytic world' (as a useful mnemonic). More precisely, there should be a one-to-one correspondence

$$\Big\{\text{characteristic ideals of Selmer}\Big\} \quad \xleftrightarrow{\text{Main Conj.}} \quad \Big\{p\text{-adic } L\text{-functions}\Big\}.$$

Warning: Before we forget it entirely, let's first remember to compute the leading term of the algebraic L-series $\text{Ш}_{\mathbf{F}}\Big(\mathbb{T}^{-1/2}_{\infty,E}\Big)$. Indeed this p-adic L-value is a vital constituent of the Euler characteristic over the two-variable deformation of $E[p^\infty]$. As many of the details are akin to the vertical calculation (in the previous chapter), we shall attempt to keep the exposition relatively brief.

10.1 The half-twisted Euler characteristic formula

Throughout one takes $\mathbf{F}$ to be an abelian number field, and the prime number $p \geq 3$. For simplicity assume $\rho_{\infty,E}$ is residually irreducible, and $\mathcal{R}_E$ is a Gorenstein ring. The fundamental work of Flach and Nekovář [Fl,Ne3] guarantees the existence of a (nearly) self-dual, symplectic form

$$\big\langle -,- \big\rangle^{\mathrm{Nek}}_{\mathbf{F},p,\mathbb{T}^{-1/2}_{\infty,E}} \;:\; \widetilde{H}^1_f\left(\mathbf{F}_\Sigma/\mathbf{F},\ \mathbb{T}^{-1/2}_{\infty,E}\right) \;\times\; \widetilde{H}^1_f\left(\mathbf{F}_\Sigma/\mathbf{F},\ \mathbb{T}^{-1/2}_{\infty,E}\right) \;\longrightarrow\; \mathcal{R};$$

its manifestation at weight two, yields a $\mathbb{Z}_p$-bilinear pairing

$$\big\langle -,- \big\rangle^{-1/2}_{\mathbf{F},p} : H^1_f\big(\mathbf{F}_\Sigma/\mathbf{F},\ V_pE\big)^{\mathrm{gen}} \;\times\; H^1_f\big(\mathbf{F}_\Sigma/\mathbf{F},\ V_pE\big)^{\mathrm{gen}} \;\longrightarrow\; \mathbb{Q}_p$$

on the 'generic part' of the vector-space H^1_f.

Notation: Let us denote by $\widetilde{\lambda}^{-1/2}_{\infty,E}$ the direct sum of the restriction maps

$$H^1\Big(\mathbf{F}_\Sigma/\mathbf{F},\ A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big) \longrightarrow \bigoplus_{\nu\in\Sigma-S_{\mathbf{F},p}} \left(\frac{H^1\Big(\mathbf{F}_\nu, A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big)}{H^1_{\mathrm{nr}}\Big(\mathbf{F}_\nu, A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big)}\right) \oplus \bigoplus_{\nu\in S_{\mathbf{F},p}} \left(\frac{H^1\Big(\mathbf{F}_\nu, A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big)}{H^1_+\big(\mathbf{F}_\nu\big)^{\perp}}\right).$$

The next result is effectively the half-twisted analogue of Theorem 9.18.

Theorem 10.1. *Suppose the following four conditions hold:*

(i) $\#\text{Ш}_{\mathbf{F}}(E)[p^\infty]$ *is finite;*

(ii) $\big\langle -,- \big\rangle^{-1/2}_{\mathbf{F},p}$ *is non-degenerate;*

(iii) the homomorphism $\widetilde{\lambda}^{-1/2}_{\infty,E}$ *is surjective;*

(iv) E does **not** *attain split multiplicative reduction at any place above p.*

Then $\mathrm{order}_{w=2}\text{Ш}_{\mathbf{F}}\left(\mathbb{T}^{-1/2}_{\infty,E}, w\right) \;=\; \mathrm{rank}_{\mathbb{Z}}E(\mathbf{F}) - \mathrm{corank}_{\Lambda^{\mathrm{wt}}}\mathrm{Sel}_{\mathbf{F}}\big(\mathbb{T}^{-1/2}_{\infty,E}\big) \;=\; r^{\dagger}_{\mathbf{F}}$ *say, and its leading term is given by*

$$\left.\frac{\text{Ш}_{\mathbf{F}}\big(\mathbb{T}^{-1/2}_{\infty,E}, w\big)}{(w-2)^{r^{\dagger}_{\mathbf{F}}}}\right|_{w=2} \times \prod_{\nu} \mathrm{Tam}^{(2)}_{\mathbf{F}_\nu}\left(\mathbb{T}^{-1/2}_{\infty,E}\right) \;\times\; \mathrm{covol}^{(2)}_{\mathbb{T}^{-1/2}_{\infty,E}}\big(\mathbf{F}\otimes\mathbb{Z}_p\big) \;\times\; \mathfrak{D}_{\mathbf{F},p}\big(\rho_{\infty,E}\big)$$

$$= \prod_{\mathfrak{p}\in S^{\mathrm{good}}_{\mathbf{F},p}} \#\widetilde{E}\left(\mathbb{F}_{q_{\mathfrak{p}}}\right)^2 \times \frac{\#\text{Ш}_{\mathbf{F}}(E)\prod_\nu\big[E(\mathbf{F}_\nu):E_0(\mathbf{F}_\nu)\big]}{\#E\big(\mathbf{F}\big)^2_{\mathrm{tors}}} \times \det\big\langle -,- \big\rangle^{-1/2}_{\mathbf{F},p}\Big|_{E(\mathbf{F})\times E(\mathbf{F})}$$

modulo $\mathbb{Z}_p^\times$*, where* $S^{\mathrm{good}}_{\mathbf{F},p} \;=\; S_{\mathbf{F},p} \,\cap\, \big\{\mathfrak{p}\nmid N_E\big\}$.

N.B. The quantity $\prod_{\mathfrak{p}\in S^{\mathrm{good}}_{\mathbf{F},p}}\left(\#\widetilde{E}\left(\mathbb{F}_{q_{\mathfrak{p}}}\right)\right)^2$ is trivial when $p\big|N_E$ as the set $S^{\mathrm{good}}_{\mathbf{F},p} = \emptyset$. Alternatively, if $p\nmid N_E$ then the subset $S^{\mathrm{good}}_{\mathbf{F},p}$ is the whole of $S_{\mathbf{F},p}$, and the product is therefore non-empty.

Proof: The main ingredients are identical to the demonstration of Theorem 9.18. Firstly condition (iv) implies the set of split multiplicative primes $S^{\mathrm{mult}}_{\mathbf{F},p}$ is void, in which case Conjecture 7.11 holds. As a nice consequence, the natural mapping $\mathrm{Sel}_{\mathbf{F}}\left(\mathcal{C}^{\min}\right)[p^\infty] \overset{\alpha^{-1/2}_{\infty,E}}{\longrightarrow} \mathrm{Sel}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}\otimes\Psi^{-1/2}\Big)^{\Gamma^{\mathrm{wt}}}$ will then be a quasi-isomorphism of cofinitely-generated groups over $\mathbb{Z}_p$.

Fortunately, condition (iii) ensures we have the short exact sequence

$$0 \longrightarrow \mathrm{Sel}_{\mathbf{F}}\Big(\mathbb{T}^{-1/2}_{\infty,E}\Big) \longrightarrow H^1\Big(\mathbf{F}_\Sigma/\mathbf{F},\ A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big) \overset{\widetilde{\lambda}^{-1/2}_{\infty,E}}{\longrightarrow} \bigoplus_{\nu\in\Sigma} \frac{H^1\big(\mathbf{F}_\nu, A^{-1/2}_{\mathbb{T}_{\infty,E}}\big)}{H^1_{\star,+}\big(\mathbf{F}_\nu, \mathbb{T}^{-1/2}_{\infty,E}\big)^{\perp}} \longrightarrow 0.$$

Taking its Γ^{wt}-cohomology, produces a commutative diagram with exact columns:

$$\begin{tikzcd}
0 \arrow[d] & 0 \arrow[d] \\
\mathrm{Sel}_{\mathbf{F}}\left(\mathcal{C}^{\min}\right)[p^\infty] \arrow[d] \arrow[r, "\alpha^{-1/2}_{\infty,E}"] & \mathrm{Sel}_{\mathbf{F}}\Big(\mathbb{T}^{-1/2}_{\infty,E}\Big)^{\Gamma^{\mathrm{wt}}} \arrow[d] \\
H^1\Big(\mathbf{F}_\Sigma/\mathbf{F},\ \mathcal{C}^{\min}[p^\infty]\Big) \arrow[d, "\lambda^{-1/2}_{\mathcal{C}^{\min}}"] \arrow[r, "\beta^{-1/2}_{\infty,E}"] & H^1\Big(\mathbf{F}_\Sigma/\mathbf{F},\ A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big)^{\Gamma^{\mathrm{wt}}} \arrow[d, "\lambda^{-1/2}_{\infty,E}"] \\
\begin{array}{c} \displaystyle\bigoplus_{\nu\in\Sigma-S_{\mathbf{F},p}} \frac{H^1\big(\mathbf{F}_\nu,\mathcal{C}^{\min}[p^\infty]\big)}{H^1_{\mathrm{nr}}\big(\mathbf{F}_\nu,\mathcal{C}^{\min}[p^\infty]\big)} \\ \displaystyle\oplus \bigoplus_{\nu\in S_{\mathbf{F},p}} \frac{H^1\big(\mathbf{F}_\nu,\mathcal{C}^{\min}[p^\infty]\big)}{\mathcal{W}_{\mathcal{C}^{\min},+}\big(\mathbf{F}_\nu\big)^{\perp}} \end{array} \arrow[d] \arrow[r, "\oplus\delta^{-1/2}_{\infty,E,\nu}"] & \begin{array}{c} \displaystyle\bigoplus_{\nu\in\Sigma-S_{\mathbf{F},p}} \left(\frac{H^1\Big(\mathbf{F}_\nu, A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big)}{H^1_{\mathrm{nr}}\Big(\mathbf{F}_\nu, A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big)}\right)^{\Gamma^{\mathrm{wt}}} \\ \displaystyle\oplus \bigoplus_{\nu\in S_{\mathbf{F},p}} \left(\frac{H^1\Big(\mathbf{F}_\nu, A^{-1/2}_{\mathbb{T}_{\infty,E}}\Big)}{H^1_{+}\big(\mathbf{F}_\nu\big)^{\perp}}\right)^{\Gamma^{\mathrm{wt}}} \end{array} \arrow[d] \\
H^1_f\Big(\mathbf{F},\mathrm{Ta}_p\big(\mathcal{C}^{\min}\big)\Big)^{\vee} & \mathrm{Sel}_{\mathbf{F}}\Big(\mathbb{T}^{-1/2}_{\infty,E}\Big)_{\Gamma^{\mathrm{wt}}} \arrow[l, dashed, "\widehat{\theta}^{-1/2}_{\infty,E}"']
\end{tikzcd}$$

Figure 10.1

Under the conditions (i) and (ii), the order of vanishing of $\text{Ш}_{\mathbf{F}}\left(\mathbb{T}^{-1/2}_{\infty,E},\ w\right)$ at $w=2$ is precisely equal to the dimension of $\mathbb{Q}_p\otimes H^0\left(\Gamma^{\mathrm{wt}},\ \left(\mathrm{Sel}_{\mathbf{F}}\left(\mathbb{T}^{-1/2}_{\infty,E}\right)_{/\Lambda^{\mathrm{wt}}\text{-div}}\right)^{\vee}\right)$. In fact, the half-twisted pairing $\big\langle -,-\big\rangle^{-1/2}_{\mathbf{F},p}$ factorises through the dual map $\theta^{-1/2}_{\infty,E}$. Its discriminant is therefore intertwined with that of

$$H^0\left(\Gamma^{\mathrm{wt}}, \mathrm{Tors}_{\Lambda^{\mathrm{wt}}}\left(\mathrm{Sel}_{\mathbf{F}}\left(\mathbb{T}^{-1/2}_{\infty,E}\right)^{\vee}\right)\right) \overset{\mathrm{nat}}{\longrightarrow} H^1\left(\Gamma^{\mathrm{wt}}, \mathrm{Tors}_{\Lambda^{\mathrm{wt}}}\left(\mathrm{Sel}_{\mathbf{F}}\left(\mathbb{T}^{-1/2}_{\infty,E}\right)^{\vee}\right)\right)$$

which can now be computed via Figure 10.1.

Remarks: (a) Every horizontal arrow in the above diagram is a quasi-isomorphism.

(b) If the map $\xi_{\mathrm{div}}^{-1/2} : \mathcal{S}^{\Gamma^{\mathrm{wt}}} \longrightarrow \mathcal{S}_{\Gamma^{\mathrm{wt}}}$ where $\mathcal{S} = \mathrm{Sel}_{\mathbf{F}}\left(\mathbb{T}_{\infty,E}^{-1/2}\right)_{/\Lambda^{\mathrm{wt}}\text{-div}}$, then

$$\log_p(u_0)^{-r_{\mathbf{F}}^{\dagger}} \times \mathrm{disc}\left(\langle -,- \rangle_{\mathbf{F},p}^{-1/2}\right) \;=\; \mathcal{H}\Big(\xi_{\mathrm{div}}^{-1/2}\Big)^{-1} \times \mathcal{H}\Big(\oplus\, \delta_{\infty,E,\nu}^{-1/2}\Big) \times \mathcal{H}\Big(\beta_{\infty,E}^{-1/2}\Big)^{-1}.$$

(c) The Herbrand quotient of $\beta_{\infty,E}^{-1/2}$ was calculated in Lemma 7.12(a).

(d) The Herbrand quotient of $\delta_{\infty,E,\nu}^{-1/2}$ was calculated in Proposition 8.7(ii) if $\nu \nmid p$, and in Proposition 8.13 when $\nu \big| p$.

Combining (a)-(b)-(c)-(d) together, one obtains a formula relating the half-twisted arithmetic invariants of $\mathcal{C}^{\min}$ to the reciprocal Herbrand quotient $\mathcal{H}\Big(\xi_{\mathrm{div}}^{-1/2}\Big)^{-1}$. However the latter quantity is the leading term of $\text{Ш}_{\mathbf{F}}\left(\mathbb{T}_{\infty,E}^{-1/2}\right)$ at $X = 0$.

Finally, one may exchange the optimal curve $\mathcal{C}^{\min}$ with the strong Weil curve E using Cassels' Isogeny Theorem 1.19, which explains why the defect term $\mathfrak{D}_{\mathbf{F},p}$ rears its ugly head once more.

□

Example 10.2. Let's consider the modular curve $E = X_0(11)$ over the field $\mathbf{F} = \mathbb{Q}$. Since the analytic rank is zero, the half-twisted regulators must therefore be trivial. If $7 \leq p \leq 97$ and $p \neq 11, 19, 29$ then the elliptic curve E has good ordinary reduction at p, and our theorem implies that $\text{Ш}_{\mathbb{Q}}\left(\mathbb{T}_{\infty,E}^{-1/2},\, 2\right)$ will be a p-adic unit. It follows at all good ordinary primes $p < 100$ excluding 5, the μ-invariant over $\mathbb{Q}$ associated to the half-twisted deformation of $\mathrm{Ta}_p\big(X_0(11)\big)$ vanishes (c.f. Ex. 9.19).

The reader will notice that we have studiously avoided the prime $p = 11$ in the above example, because Theorem 10.1 does not cover split multiplicative reduction. Nevertheless in the semistable case, one has a shrewd idea what to expect.

Conjecture 10.3. *Assume that the prime number p divides N_E. Then*

$$\mathrm{order}_{w=2}\text{Ш}_{\mathbf{F}}\left(\mathbb{T}_{\infty,E}^{-1/2}, w\right) \;=\; \mathrm{rank}_{\mathbb{Z}}E(\mathbf{F}) \;+\; \#S_{\mathbf{F},p}^{\mathrm{split}} \;-\; \mathrm{corank}_{\Lambda^{\mathrm{wt}}}\mathrm{Sel}_{\mathbf{F}}\big(\mathbb{T}_{\infty,E}^{-1/2}\big);$$

moreover, the leading term of $\text{Ш}_{\mathbf{F}}^{-1/2}$ satisfies

$$\left.\frac{\text{Ш}_{\mathbf{F}}\big(\mathbb{T}_{\infty,E}^{-1/2}, w\big)}{(w-2)^{r_{\mathbf{F}}^{\dagger} + \#S_{\mathbf{F},p}^{\mathrm{split}}}}\right|_{w=2} \times \prod_{\nu} \mathrm{Tam}_{\mathbf{F}_\nu}^{(2)}\left(\mathbb{T}_{\infty,E}^{-1/2}\right) \;\times\; \mathrm{covol}_{\mathbb{T}_{\infty,E}^{-1/2}}^{(2)}\big(\mathbf{F} \otimes \mathbb{Z}_p\big) \;\times\; \mathfrak{D}_{\mathbf{F},p}$$
$$= \quad \prod_{\nu \in S_{\mathbf{F},p}^{\mathrm{split}}} \frac{\log_p\left(\mathbf{q}_{E_{/\mathbf{F}_\nu}}\right)}{\mathrm{ord}_\nu\left(\mathbf{q}_{E_{/\mathbf{F}_\nu}}\right)} \;\times\; \frac{\#\text{Ш}_{\mathbf{F}}(E)\prod_\nu \big[E(\mathbf{F}_\nu) : E_0(\mathbf{F}_\nu)\big]}{\#E(\mathbf{F})_{\mathrm{tors}}^{\,2}} \;\times\; \det\langle -,- \rangle_{\mathbf{F},p}^{-1/2}$$

again up to p-adic units.

N.B. Over the rationals, the $\mathcal{L}$-invariant $\frac{\log_p(\mathbf{q}_E)}{\mathrm{ord}_p(\mathbf{q}_E)} \neq 0$ courtesy of the result in [StÉ]. For a general number field $\mathbf{K} \neq \mathbb{Q}$ the non-vanishing is still an open problem.

Question. *When is the global-to-local map* $\widetilde{\lambda}_{\infty,E}^{-1/2}$ *surjective?*

In general, the answer to this question lies fairly deep.

If the representation $\rho_{\infty,E} : G_{\mathbb{Q}} \longrightarrow \mathrm{GL}_2\big(\mathbb{Z}_{p,\mathbb{U}_E}\langle\langle w\rangle\rangle\big)$ is of CM-type by $\mathcal{O}_{\mathbb{Q}(\sqrt{-D})}$, this reduces to the existence or otherwise of non-trivial pseudo-null submodules in the (Pontrjagin dual of) the two-variable Selmer group over $\mathbf{F}\Big(\sqrt{-D},\ E[p^\infty]\Big)$. Alternatively, if we demand that the p-adic L-function is suitably well-behaved along the line $s = k/2$, one can still make some progress:

Proposition 10.4. *Assume Greenberg's conjecture holds for the family* $\{\mathbf{f}_k\}_{k\in\mathbb{U}_E\cap\mathbb{N}}$ *with its generic rank* $r_{\mathrm{gen}}(\mathbf{F}) = 0$*, and in addition that* $\mathcal{R}_E$ *is a regular local ring. Then the homomorphism* $\widetilde{\lambda}_{\infty,E}^{-1/2}$ *is always surjective.*

Proof: Let $\mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big)$ denote the compact Selmer group associated to the half-twisted deformation of $\rho_{E,p}$. Its Pontrjagin dual sits inside the Poitou-Tate sequence

$$\begin{aligned} 0 \ \longrightarrow\ \mathrm{Sel}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big) \ &\longrightarrow\ H^1\Big(\mathbf{F}_\Sigma/\mathbf{F},\ A_{\mathbb{T}_{\infty,E}}^{-1/2}\Big) \\ \xrightarrow{\widetilde{\lambda}_{\infty,E}^{-1/2}}\ \bigoplus_{\nu\in\Sigma} \frac{H^1\big(\mathbf{F}_\nu, A_{\mathbb{T}_{\infty,E}}^{-1/2}\big)}{H^1_{\star,+}\big(\mathbf{F}_\nu, \mathbb{T}_{\infty,E}^{-1/2}\big)^{\perp}} \ &\longrightarrow\ \mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big)^{\vee} \ \longrightarrow\ \ldots . \end{aligned}$$

To establish the surjectivity of $\widetilde{\lambda}_{\infty,E}^{-1/2}$, clearly it is enough to show $\mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big) = 0$. There are two stages:

(A) Prove that $\mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big)$ is Λ^{wt}-torsion, and has universally p-bounded order;

(B) Prove that all proper subgroups of $H^1\Big(\mathbf{F}_\Sigma/\mathbf{F},\ \mathbb{T}_{\infty,E}^{-1/2}\Big)\big[p^\infty\big]$ are zero.

Since (A) implies the compact Selmer group lies in the $\mathbb{Z}_p$-torsion submodule of $H^1\Big(\mathbf{F}_\Sigma/\mathbf{F},\ \mathbb{T}_{\infty,E}^{-1/2}\Big)$, any finite subgroup of $\mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big)$ must then be zero by (B). As a corollary, the whole Selmer group was trivial to begin with.

Remark: One can identify the p^∞-torsion submodule of $H^1\Big(\mathbf{F}_\Sigma/\mathbf{F},\ \mathbb{T}_{\infty,E}^{-1/2}\Big)$ with the 0^{th}-cohomology group

$$H^0\Big(\mathbf{F}_\Sigma/\mathbf{F},\ \mathbb{T}_{\infty,E}^{-1/2}\otimes\mathbb{Q}_p/\mathbb{Z}_p\Big) \quad\subset\quad \left(\Psi_{\mathcal{R}}^{-1/2}\otimes\mathbf{e}_{\mathcal{R}}.\varinjlim_{\pi_1^*}{}^{\mathbf{t}}\mathcal{J}_r^{\mathrm{ord}}\big[p^\infty\big]^{\vee}\otimes_{\mathbb{Z}_p}\mu_{p^\infty}\right)(\mathbf{F}).$$

The right-hand side has no finite p-subgroups, which can be seen by using the same argument to Step 3 of Theorem 9.2 (N.B. as an $\mathcal{R}_E$-module $\mathbf{e}_{\mathcal{R}}.\varinjlim_{\pi_1^*}{}^{\mathbf{t}}\mathcal{J}_r^{\mathrm{ord}}\big[p^\infty\big]^{\vee}$ is identical to $\Psi_{\mathcal{R}}^{-1/2}\otimes\mathbf{e}_{\mathcal{R}}.\varinjlim_{\pi_1^*}{}^{\mathbf{t}}\mathcal{J}_r^{\mathrm{ord}}\big[p^\infty\big]^{\vee}$, therefore the transition maps π_1^*, $\pi_{p\,*}$ must again act nilpotently on the p-torsion). It immediately follows (B) is true.

This leaves us with the task of establishing (A).

Key Claim: For almost all arithmetic weights $k \in \mathbb{U}_E \cap \mathbb{N}_{\geq 2}$, the natural map

$$\mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big) \otimes_{\Lambda^{\mathrm{wt}},\mathfrak{g}_k} \mathbb{Z}_p \quad \overset{\mathrm{nat}}{\longrightarrow} \quad H^1_{f,\mathrm{Spec}\mathcal{O}_{\mathbf{F}}}\Big(\mathbf{F}_\Sigma/\mathbf{F},\ \mathbb{T}_{\infty,E}^{-1/2} \otimes_{\Lambda^{\mathrm{wt}},\mathfrak{g}_k} \mathbb{Z}_p\Big)$$

has finite kernel and cokernel, bounded independently of k.

When $\mathbf{F} = \mathbb{Q}$ and $\mathcal{R}_E = \Lambda^{\mathrm{wt}}$ this statement is shown in the article [NP, Sect.4]. However the proof generalises seamlessly to Noetherian regular local rings, as all their height one prime ideals are principal. Similarly, the argument for abelian number fields $\mathbf{F}$ reduces to the analogous result over $\mathbb{Q}$, since one may decompose the Selmer group into its $X_{\mathbf{F}}$-eigencomponents.

Remark: If $k \equiv 2 \mod 2(p-1)$ then $\mathbb{T}_{\infty,E}^{-1/2} \otimes_{\Lambda^{\mathrm{wt}},\mathfrak{g}_k} \mathbb{Z}_p$ is a lattice inside $V_{\mathbf{f}_k}\big(k/2\big)$. Provided that the L-value $L\big(\mathbf{f}_k/\mathbf{F}, k/2\big)$ is non-zero, Kato has shown [Ka1, 14.2(2)] the vector-space Selmer group

$$H^1_{f,\mathrm{Spec}\mathcal{O}_{\mathbf{F}}}\Big(\mathbf{F}_\Sigma/\mathbf{F},\ V_{\mathbf{f}_k}\big(k/2\big)\Big) \ = \ 0.$$

In particular, the above specialisation $H^1_{f,\mathrm{Spec}\mathcal{O}_{\mathbf{F}}}\Big(\mathbf{F}_\Sigma/\mathbf{F},\ \mathbb{T}_{\infty,E}^{-1/2} \otimes_{\Lambda^{\mathrm{wt}},\mathfrak{g}_k} \mathbb{Z}_p\Big)$ must therefore be a finite abelian p-group.

Because we assumed that the generic rank $r_{\mathrm{gen}}(\mathbf{F}) = 0$, the L-value at $s = k/2$ is non-zero at all bar finitely many exceptional weights k. Moreover the 'Key Claim' together with Kato's result implies $\#\left(\mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big) \otimes_{\Lambda^{\mathrm{wt}},\mathfrak{g}_k} \mathbb{Z}_p\right) < \infty$ for such k, in which case the compact Selmer group over $\mathbf{F}$ is Λ^{wt}-torsion.

Lastly, an identical argument to Theorem 9.2 (Step 2) establishes that its order is bounded above by $p^{\nu_1^\dagger + \nu_2^\dagger}$; here $p^{\nu_1^\dagger}$ is chosen large enough to kill off the kernel of

$$\mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big) \otimes_{\Lambda^{\mathrm{wt}},\mathfrak{g}_k} \mathbb{Z}_p \overset{\mathrm{nat}}{\to} H^1_{f,\mathrm{Spec}\mathcal{O}_{\mathbf{F}}} \hookrightarrow \Big(\big(\mathbb{T}_{\infty,E}^{-1/2} \otimes_{\Lambda^{\mathrm{wt}},\mathfrak{g}_k} \mathbb{Z}_p\big) \otimes \mathbb{Q}/\mathbb{Z}\Big)^{G_{\mathbf{F}}}$$

and likewise $\nu_2^\dagger = \max_{\tau,\psi}\left\{\nu_{2,\tau,\psi}^\dagger\right\}$, where each integer $\nu_{2,\tau,\psi}^\dagger$ is set equal to

$$\max_{1 \leq j \leq n(\tau,\psi)} \left\{\mathrm{ord}_p\Big(1 - \psi(l)a_l(\mathbf{f}_k)l^{1-k/2} + \psi(l)^2 l^{2-k/2} < l >^{k-2}\Big) \,\Big|\, k \in D_j^{\tau,\psi},\, k \equiv \tau\right\}$$

N.B. the above notation is the same as was employed in the proof of Theorem 9.2.

The surjectivity of the homomorphism $\widetilde{\lambda}_{\infty,E}^{-1/2}$ follows immediately.

□

If $r_{\mathrm{gen}}(\mathbf{F}) > 0$ then it is unclear whether or not the global-to-local map surjects. One possibility is to mimic the approach of §6.5, and construct an embedding

$$\mathfrak{S}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big) \quad \overset{?}{\hookrightarrow} \quad \mathrm{Hom}_{\Lambda^{\mathrm{wt}}}\left(\mathrm{Sel}_{\mathbf{F}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big)^{\vee},\ \mathbb{Z}_p\langle\!\langle w\rangle\!\rangle\right)^{\square}.$$

The right-hand side is a free $\mathbb{Z}_p[\![\Gamma^{\mathrm{wt}}]\!]$-module of finite-type; one could then compute Λ^{wt}-ranks along the Poitou-Tate sequence, to deduce triviality of $\mathrm{Coker}\Big(\widetilde{\lambda}_{\infty,E}^{-1/2}\Big)$.

10.2 The p-adic height over a double deformation

It is fair to say we now possess a pretty good understanding of the arithmetic of E along the vertical line $s = 1$, and also along the line of symmetry $s = k/2$ (subject to Greenberg's Conjecture 7.5, of course). The very last piece of the jigsaw is to allow the number field $\mathbf{F}$ to vary in a cyclotomic $\mathbb{Z}_p$-extension of the ground field. The finite sub-layers in this $\mathbb{Z}_p$-extension '$\mathbf{F}^{\mathrm{cy}}$' are still abelian extensions of $\mathbb{Q}$, however they are no longer unramified at the prime p.

We'll begin by recalling the structure theory for modules over a two-variable deformation ring. Let R be a normal integral domain, finite and flat over $\mathbb{Z}_p[\![X]\!]$. An $R[\![Y]\!]$-module is called *pseudo-null* if its localisations at all height one primes in Spec $R[\![Y]\!]$ are trivial. Further, a homomorphism $\phi : M \longrightarrow N$ of $R[\![Y]\!]$-modules is said to be a *pseudo-isomorphism* if Kerϕ and Cokerϕ are both pseudo-null.

Notation: $M \overset{\mathrm{ps}\sim}{\longrightarrow} N$.

Assume that M denotes some compact, finitely-generated, torsion $R[\![Y]\!]$-module. The structure theory informs us there exists a pseudo-isomorphism

$$M \quad \overset{\mathrm{ps}\sim}{\longrightarrow} \quad \bigoplus_{i=1}^{t} \frac{R[\![Y]\!]}{\mathcal{P}_i^{e_i}}$$

where the $\mathcal{P}_i$'s are height one prime ideals of $R[\![Y]\!]$, and the e_i's are positive integers. The product $\prod_{i=1}^{t} \mathcal{P}_i^{e_i}$ is the characteristic ideal of M (it need not be principal).

Hypothesis. *The integral domain R is regular.*

As an immediate consequence, the two-variable ring $R[\![Y]\!]$ must also be regular. This condition guarantees that the ideal $\mathrm{char}_{R[\![Y]\!]}\big(M\big)$ has a principal generator. We also observe that all regular CNL rings are automatically Gorenstein.

Lemma 10.5. *Let $\mathfrak{C}_M(Y)$ denote the characteristic power series of M. Then*

$$r \;=\; \mathrm{order}_{Y=0}\Big(\mathfrak{C}_M(Y)\Big) \;\geq\; \mathrm{rank}_R\Big(M/Y.M\Big)$$

with equality iff $\alpha : M[\times Y] \longrightarrow M/Y.M$ has an R-torsion kernel and cokernel; assuming this does occur, one has the leading-term formula

$$\left.\frac{\mathfrak{C}_M(Y)}{Y^r}\right|_{Y=0} \;=\; \frac{\mathrm{char}_R\big(\mathrm{Coker}(\alpha)\big)}{\mathrm{char}_R\big(\mathrm{Ker}(\alpha)\big)} \qquad \text{modulo } R^{\times}.$$

The proof is fairly standard, and can be found in any decent algebra textbook.

Remark: In the next section we shall take $R = \mathcal{R}_E$, the universal p-ordinary deformation ring for $\rho_{E,p} : G_{\mathbb{Q}} \to \mathrm{GL}_2(\mathbb{Z}_p)$. The $R[\![Y]\!]$-module M will then either be the dual of $\mathrm{Sel}_{\mathbf{F}^{\mathrm{cy}}}\Big(\mathbb{T}_{\infty,E}\Big)$, or in the half-twisted case the dual of $\mathrm{Sel}_{\mathbf{F}^{\mathrm{cy}}}\Big(\mathbb{T}_{\infty,E}^{-1/2}\Big)$.

II. For points between BCD, and ABC, ACD, ADC produced,

$$\frac{s}{l} \text{ is negative, } \frac{s}{m},\ \frac{s}{n},\ \frac{s}{r} \text{ between 1 and } \infty.$$

III. For points within the solid angle formed by BCA, CDA, DBA produced,

$$\frac{s}{l} \text{ is between 0 and 1, } \frac{s}{m},\ \frac{s}{n},\ \frac{s}{r} \text{ negative.}$$

IV. For points between ACD, BCD, BAC, ABD produced,

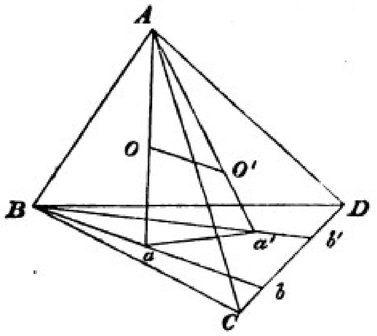
$$\frac{s}{m} \text{ and } \frac{s}{l} \text{ are negative, } \frac{s}{n} \text{ and } \frac{s}{r} \text{ are positive.}$$

And similarly for the nine other compartments.

103. The results of the preceding article may be obtained, if we assume a knowledge of Tetrahedral Co-ordinates, by observing that the tetrahedral co-ordinates of the point are

$$\frac{l}{s},\ \frac{m}{s},\ \frac{n}{s},\ \frac{r}{s}. \qquad \text{(Art. 97).}$$

104. *To find the distance between two points whose equations are given.*



Let the equations of the two points O, O' be

$$l\alpha + m\beta + n\gamma + r\delta = 0,$$
$$l'\alpha + m'\beta + n'\gamma + r'\delta = 0,$$

and let $l + m + n + r = s$, $l' + m' + n' + r' = s'$.

Digitized by Google

Then, if AO, AO' meet BCD in a, a', and Ba, Ba' meet CD in b, b', we have from the triangles OAO', aAa',

$$\frac{AO^2+AO'^2-OO'^2}{2AO.AO'}=\cos OAO'=\frac{Aa^2+Aa'^2-aa'^2}{2Aa.Aa'}.$$

But $\dfrac{Oa}{l}=\dfrac{Aa}{s}=\dfrac{AO}{s-l}$, and $\dfrac{O'a'}{l'}=\dfrac{Aa'}{s'}=\dfrac{AO'}{s'-l'}$;

$$\therefore\ OO'^2=\left(1-\frac{l}{s}\right)^2 Aa^2+\left(1-\frac{l'}{s'}\right)^2 Aa'^2$$

$$-\left(1-\frac{l}{s}\right)\left(1-\frac{l'}{s'}\right)(Aa^2+Aa'^2-aa'^2)$$

$$=\left(1-\frac{l}{s}\right)\left(\frac{l'}{s'}-\frac{l}{s}\right)Aa^2$$

$$+\left(1-\frac{l'}{s'}\right)\left(\frac{l}{s}-\frac{l'}{s'}\right)Aa'^2+\left(1-\frac{l}{s}\right)\left(1-\frac{l'}{s'}\right)aa'^2.$$

From which form it is manifest that the final result will be an expression in terms of the squares of the edges, and we shall obtain the result by investigating the coefficient of AB^2, and deducing the rest by symmetry.

Now the only terms which can involve AB^2 are contained in Aa^2 and Aa'^2, and, as before,

$$\frac{AB^2+Ba^2-Aa^2}{2AB.Ba}=\cos ABa=\frac{AB^2+Bb^2-Ab^2}{2AB.Bb},$$

also $$\frac{ab}{m}=\frac{Bb}{s-l}=\frac{Ba}{s-l-m};$$

$$\therefore\ Aa^2=AB^2-\left(1-\frac{m}{s-l}\right)AB^2+\ldots\ldots$$

$$=\frac{m}{s-l}AB^2+\ldots\ldots$$

writing down only the terms in which AB^2 appears.

Similarly, $Aa'^2=\dfrac{m'}{s'-l'}AB^2+\ldots\ldots$

$$\therefore\ OO'^2 = \frac{m}{s}\left(\frac{l'}{s'} - \frac{l}{s}\right) AB^2 + \frac{m'}{s'}\left(\frac{l}{s} - \frac{l'}{s'}\right) AB^2 + \ldots\ldots$$
$$= \left(\frac{l'}{s'} - \frac{l}{s}\right)\left(\frac{m}{s} - \frac{m'}{s'}\right) AB^2 + \ldots\ldots$$

which gives the distance required.

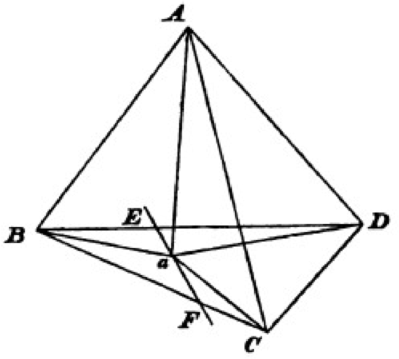
105. If $\alpha, \beta, \gamma, \delta$ and $\alpha', \beta', \gamma', \delta'$ be tetrahedral co-ordinates of the points O, O' we deduce the expression for the square of the distance,

$$OO'^2 = (\alpha' - \alpha)(\beta - \beta') AB^2 + \ldots\ldots$$

which gives the distance between two points, when their tetrahedral co-ordinates are given.

106. *To find the relation between the co-ordinates of a plane.*

Let $\alpha, \beta, \gamma, \delta$ be the co-ordinates of a plane, λ, μ, ν, ρ the cosines of the angles between the direction in which the co-ordinates are measured, and the perpendiculars from A, B, C, D on the opposite faces, and let Aa be the perpendicular on BCD, ϖ_b, ϖ_c, ϖ_d those from B, C, D on the plane drawn through a parallel to the given plane, EF the trace of this plane on BCD.



Project Aa on the normal to the given plane;

$$\left.\begin{aligned} \therefore\ p_1\lambda &= \alpha - \beta + \varpi_b \\ &= \alpha - \gamma + \varpi_c \\ &= \alpha - \delta + \varpi_d \end{aligned}\right\}. \qquad (1)$$

Digitized by Google

Now since ϖ_b, ϖ_c, ϖ_d are proportional to the perpendiculars on EF, from B, C, D,

$$\varpi_b \,.\, aCD + \varpi_c \,.\, aDB + \varpi_d \,.\, aBC = 0\,;^*$$

$$\text{and } aCD + aDB + aBC = BCD\,;$$

$\therefore$ by (1), $p_1\lambda \,.\, BCD = \alpha \,.\, BCD - \beta \,.\, aCD - \gamma \,.\, aDB - \delta \,.\, aBC$;

also, $p_1 \,.\, BCD = p_2 \,.\, ACD = p_3 \,.\, ADB = p_4 \,.\, ABC$;

$$\therefore\ \lambda = \frac{\alpha}{p_1} - \frac{\beta}{p_2}\cos(CD) - \frac{\gamma}{p_3}\cos(DB) - \frac{\delta}{p_4}\cos(BC),$$

denoting by (CD) the angle between the faces which meet in CD, and similarly for the rest.

Similar values may be obtained in the same way for μ, ν, and ρ.

If P be the foot of the perpendicular from A on the given plane, the perpendiculars from P on the faces of the tetrahedron will be

$$a\lambda - p_1,\ a\mu,\ a\nu,\ a\rho,$$

$$\therefore\ \alpha\frac{a\lambda - p_1}{p_1} + \beta\frac{a\mu}{p_2} + \gamma\frac{a\nu}{p_3} + \delta \,.\, \frac{a\rho}{p_4} = 0\,; \qquad \text{Art. (81)}$$

$$\therefore\ \frac{\alpha}{p_1}\lambda + \frac{\beta}{p_2}\mu + \frac{\gamma}{p_3}\nu + \frac{\delta}{p_4}\rho = 1,$$

$$\text{or, } \frac{\alpha^2}{p_1^{\,2}} + \frac{\beta^2}{p_2^{\,2}} + \frac{\gamma^2}{p_3^{\,2}} + \frac{\delta^2}{p_4^{\,2}}$$
$$- \frac{2\alpha\beta}{p_1p_2}\cos(CD) - \frac{2\alpha\gamma}{p_1p_3}\cos(DB) - \frac{2\alpha\delta}{p_1p_4}\cos(BC)$$
$$- \frac{2\gamma\delta}{p_3p_4}\cos(AB) - \frac{2\delta\beta}{p_4p_2}\cos(AC) - \frac{2\beta\gamma}{p_2p_3}\cos(AD) = 1,$$

which is the relation required.

---

[*] The equation of a straight line, referred to trilinear co-ordinates, is

$$\alpha\frac{\varpi_1}{p_1} + \beta\frac{\varpi_2}{p_2} + \gamma\frac{\varpi_3}{p_3} = 0,$$

where ϖ_1, ϖ_2, ϖ_3 are the perpendiculars, estimated in the same direction, from the angular points of the fundamental triangle upon the straight line, and p_1, p_2, p_3 those upon the sides. Now, taking EF for the straight line, and BCD for the fundamental triangle, for a, a point in that line, $\frac{\alpha}{p_1} : \frac{\beta}{p_2} : \frac{\gamma}{p_3} :: aCD : aDB : aBC$,

$$\therefore\ \varpi_1 \,.\, aCD + \varpi_2 \,.\, aDB + \varpi_3 \,.\, aBC = 0,$$

whence the equation in the text.

Here (αβγ) are the trilinear point coor. of the point a

Digitized by Google

107. *To find the relations between the co-ordinates of a plane at an infinite distance.*

If the plane be at an infinite distance, the difference between any two of its co-ordinates will vanish compared with either of them; whence, if α, β, γ, δ be the co-ordinates of the plane, we must have

$$\alpha = \beta = \gamma = \delta,$$

the relations required.

108. Since each of the co-ordinates is of infinite magnitude, the expression for λ in the last article will give us

$$0 = \frac{1}{p_1} - \frac{1}{p_2}\cos(CD) - \frac{1}{p_3}\cos(DB) - \frac{1}{p_4}\cos(BC),$$

which is the equation arising from the projection of the faces meeting in A upon BCD.

From this and the three similar equations, we may eliminate p_1, p_2, p_3, and p_4, and obtain the relation which subsists between the cosines of the inclinations of the faces.

109. *To find the perpendicular from a given point upon a given plane, referred to Tetrahedral Co-ordinates.*

Let $(\alpha', \beta', \gamma', \delta')$ be the co-ordinates of the point,

$$l\alpha + m\beta + n\gamma + r\delta = 0,$$

the equation of the plane.

If α_1, β_1, γ_1, δ_1 be the point-co-ordinates of the plane, the equation of the plane may be written

$$\alpha\alpha_1 + \beta\beta_1 + \gamma\gamma_1 + \delta\delta_1 = 0, \qquad \text{Art. (81)},$$

and the perpendicular required is equal to

$$\alpha'\alpha_1 + \beta'\beta_1 + \gamma'\gamma_1 + \delta'\delta_1. \qquad \text{Art. (94)}.$$

Now $\dfrac{\alpha_1}{l} = \dfrac{\beta_1}{m} = \dfrac{\gamma_1}{n} = \dfrac{\delta_1}{r} = \dfrac{\pm\sqrt{\left\{\dfrac{\alpha_1^2}{p_1^2} + \ldots\ldots - \dfrac{2\alpha_1\beta_1}{p_1p_2}\cos(CD) - \ldots\ldots\right\}}}{\sqrt{\left\{\dfrac{l^2}{p_1^2} + \ldots\ldots - \dfrac{2lm}{p_1p_2}\cos(CD) - \ldots\ldots\right\}}}$,

therefore the perpendicular required is

$$\frac{l\alpha' + m\beta' + n\gamma' + r\delta'}{\pm\sqrt{\left\{\dfrac{l^2}{p_1^2} + \ldots\ldots - \dfrac{2lm}{p_1p_2}\cos(CD) - \ldots\ldots\right\}}}.$$

Digitized by Google

It may be shewn, without much difficulty, that the denominator of this expression cannot vanish for real values of $l : m : n : r$, except when $l = m = n = r$, in which case, since $\alpha_1 = \beta_1 = \gamma_1 = \delta_1$, the plane is at an infinite distance.

110. *To find the cosines of the angles which a plane, whose co-ordinates are given, makes with the faces of the tetrahedron.*

If λ, μ, ν, ρ be these cosines, α, β, γ, δ the co-ordinates of the given plane, we have deduced in the previous article

$$\lambda = \frac{\alpha}{p_1} - \frac{\beta}{p_2}\cos(CD) - \frac{\gamma}{p_3}\cos(DB) = \frac{\delta}{p_4}\cos(BC),$$

and similarly for μ, ν, ρ.

The relation between λ, μ, ν and ρ is formed immediately from the consideration that the equation

$$\frac{\lambda\alpha}{p_1} + \frac{\mu\beta}{p_2} + \frac{\nu\gamma}{p_3} + \frac{\rho\delta}{p_4} = 1,$$

when the plane moves parallel to itself to an infinite distance, becomes

$$\frac{\lambda}{p_1} + \frac{\mu}{p_2} + \frac{\nu}{p_3} + \frac{\rho}{p_4} = 0.$$

If the plane be the face BCD,

$$\lambda = 1, \quad \mu = -\cos CD, \quad \nu = -\cos DB, \text{ and } \rho = -\cos BC;$$

$$\therefore\ \frac{1}{p_1} - \frac{1}{p_2}\cos CD - \frac{1}{p_3}\cos DB - \frac{1}{p_4}\cos BC = 0,$$

as before, Art. (108).

111. *To find the condition that two planes whose co-ordinates are given may be parallel.*

If $(\alpha, \beta, \gamma, \delta)$ $(\alpha_1', \beta_1', \gamma_1', \delta')$ be the two planes,

$$\alpha - \alpha' = \beta - \beta' = \gamma - \gamma' = \delta - \delta',$$

since the perpendicular distance between the planes is constant.

112. *To find the equation of a line.*

Let the equations of two points in the line be

$$u = l\alpha + m\beta + n\gamma + \nu\delta = 0,$$
$$v = l'\alpha + m'\beta + n'\gamma + \nu'\delta = 0,$$

1.1 Newton's Laws

The foundational equation of our subject

> For in those days I was in the prime of my age for invention and minded Mathematicks & Philosophy more than at any time since.
>
> —Newton describing his youth in his memoirs

Let us start with one of Newton's laws, which curiously enough is spoken as $F = ma$ but written as $ma = F$. For a point particle moving in D-dimensional space with position given by $\vec{x}(t) = (x^1(t), x^2(t), \cdots, x^D(t))$, Mr. Newton taught us that

$$m\frac{d^2x^i}{dt^2} = F^i \tag{1}$$

with the index* $i = 1, \cdots, D$. For $D \leq 3$ the coordinates have traditional "names": for example, for $D = 3$, x^1, x^2, x^3 are often called, with some affection, x, y, z, respectively.

Bad notation alert! In teaching physics, I sometimes feel, with only slight exaggeration, that students are confused by bad notation almost as much as by the concepts. I am using the standard notation of x and t here, but the letter x does double duty, as the position of the particle, which more strictly should be denoted by $x^i(t)$ or $\vec{x}(t)$, and as the space coordinates x^i, which are variables ranging from $-\infty$ to ∞ and which certainly are independent of t.

The different status between x and t in say (1) is particularly glaring if $N > 1$ particles are involved, in which case we write $m\frac{d^2{x^i}_a}{dt^2} = {F^i}_a$ or $m\frac{d^2\vec{x}_a}{dt^2} = \vec{F}_a$ with ${x^i}_a(t)$ for $a = 1, 2, \cdots, N$. But certainly t_a is a meaningless concept in Newtonian physics. In the Newtonian universe, t is the time ticked off by a universal clock, while $\vec{x}_a(t)$ is each particle's private business. We will have plenty more to say about this point. Here ${x^i}_a(t)$ are $3N$ functions of t, but there are still only 3 x^i.

---

* See appendix 2.

Some readers may feel that I am overly pedantic here, but in fact this fundamental inequality of status between x and t will come to a head when we get to the special theory of relativity. (I now drop the arrow on $\vec{x}$.) Perhaps Einstein as a student was bothered by this bad notation. One way to remedy the situation is to use q (or q_a) to denote the position of particles, as in more advanced treatments. But here I bow to tradition and continue to use x.

Have differential equation, will solve

After Newton's great insight, we "merely" have to solve some second order differential equations.

To understand Newton's fabulous equation, it's best to work through a few examples. (I need hardly say that if you do not already know Newtonian mechanics, you are unlikely to be able to learn it here.)

A priori, the force F^i could depend on any number of things, but from experience we know that in many simple cases, it depends only on x and not on t or $\frac{dx}{dt}$. As physicists unravel the mysteries of Nature, it becomes increasingly clear that fundamental forces are derived from an underlying quantum field theory and that they have simple forms. Complicated forces often merely result from some approximations we make in particular situations.

Example A

A particle in 1-dimensional space tied to a spring oscillates back and forth.

The force F is a function of space. Newton's equation

$$m\frac{d^2x}{dt^2} = -kx \tag{2}$$

is easily solved in terms of two integration constants: $x(t) = a\cos\omega t + b\sin\omega t$, with $\omega = \sqrt{\frac{k}{m}}$. The two constants a and b are determined by the initial position and initial velocity, or alternatively* by the initial position at $t = 0$ and by the final position at some time $t = T$. Energy, but not momentum, is conserved.

Example B

We kick a particle in 1-dimensional space at $t = 0$.

The force F is a function of time. This example allows me to introduce the highly useful Dirac[1] delta function, or simply delta function.[2] By the word "kick" we mean that the time scale τ during which the force acts is much less than the other time scales we are

---

* See part II.

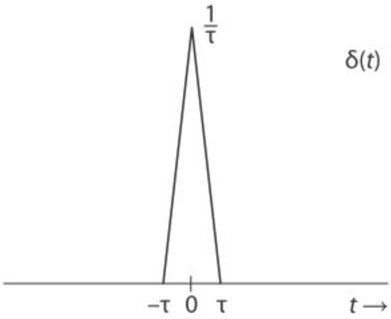

Figure 1 The delta function, which could be thought of as an infinitely sharp spike, is strictly speaking not a function, but the limit of a sequence of functions.

interested in. Thus, take $F(t) = w\delta(t)$, where the function $\delta(t)$ rises sharply just before $t = 0$, rapidly reaches its maximum at $t = 0$, and then sharply drops to 0. Because we included a multiplicative constant w, we could always normalize $\delta(t)$ by

$$\int dt\ \delta(t) = 1 \tag{3}$$

As we will see presently, the precise form of $\delta(t)$ does not matter. For example, we could take $\delta(t)$ to rise linearly from 0 at $t = -\tau$, reach a peak value of $1/\tau$ at $t = 0$, and then fall linearly to 0 at $t = \tau$. For $t < -\tau$ and for $t > \tau$, the function $\delta(t)$ is defined to be zero. Take the limit $\tau \to 0$, in which this function is known as the delta function. In other words the delta function is an infinitely sharp spike. See figure 1.

The δ function is somehow treated as an advanced topic in mathematical physics, but in fact, as you will see, it is an extremely useful function that I will use extensively in this book, for example in chapters II.1 and III.6. More properties of the δ function will be introduced as needed.

Integrating

$$\frac{d^2x}{dt^2} = \frac{w}{m}\delta(t) \tag{4}$$

from some time $t_- < 0$ to some time $t_+ > 0$, we obtain the change in velocity $v \equiv \frac{dx}{dt}$:

$$v(t_+) - v(t_-) = \frac{w}{m} \tag{5}$$

Note that in this example, neither energy nor momentum is conserved. The lack of conservation is easy to understand: (4) does not include the agent administering the kick. In general, a time-dependent force indicates that the description is not dynamically complete.

Example C

A planet approximately described as a point particle of mass m goes around its sun of mass $M \gg m$.

This is of course the celebrated problem Newton solved to unify celestial and terrestrial mechanics, previously thought to be two different areas of physics. His equation now reads

$$m\frac{d^2\vec{r}}{dt^2} = -GMm\frac{\vec{r}}{r^3} \tag{6}$$

where we use the notation $\vec{r} = (x, y, z)$ and $r = \sqrt{\vec{x} \cdot \vec{x}} = \sqrt{x^2 + y^2 + z^2}$.

John Wheeler has emphasized the interesting point that while Newton's law (1) tells us how a particle moves in space as a function of time, we tend to think of the trajectory of a particle as a curve fixed in space. For example, when we think of the motion of a planet around the sun, we think of an ellipse rather than a spiral around the time axis. Even in Newtonian mechanics, it is often illuminating to think in terms of a spacetime picture rather than a picture in space.[3]

Newton and his two distinct masses

> By thinking on it continually.
> —Newton (reply given when
> asked how he discovered
> the law of gravity)

Conceptually, in (6), m represents two distinct physical notions of mass. On the left hand side, the inertial mass measures the reluctance of the object to move. On the right hand side, the gravitational mass measures how strongly the object responds to a gravitational field. The equality of the inertial and the gravitational mass was what Galileo tried to verify in his famous apocryphal experiment dropping different objects from the Leaning Tower of Pisa. Newton himself experimented with a pendulum consisting of a hollow wooden box, which he proceeded to fill with different substances, such as sand and water. In our own times, this equality has been experimentally verified[4,5] to incredible accuracy.

That the same m appears on both sides of the equation turns out to be one of the greatest mysteries in physics before Einstein came along. His great insight was that this unexplained fact provided the clue to a deeper understanding of gravity. At this point, all we care about this mysterious equality is that m cancels out of (6), so that $\ddot{\vec{r}} = -\kappa\frac{\vec{r}}{r^3}$, with $\kappa \equiv GM$.

Celestial mechanics solved

Since the force is "central," namely it points in the direction of $\vec{r}$, a simple symmetry argument shows that the motion is confined to a plane, which we take to be the $(x\text{-}y)$ plane. Set $z = 0$ and we are left with

$$\ddot{x} = -\kappa x/r^3 \quad \text{and} \quad \ddot{y} = -\kappa y/r^3 \tag{7}$$

I have already, without warning, switched from Leibniz's notation to Newton's dot notation

$$\dot{x} \equiv \frac{dx}{dt} \quad \text{and} \quad \ddot{x} \equiv \frac{d^2x}{dt^2} \tag{8}$$

Since this is one of the most beautiful problems[6] in theoretical physics, I cannot resist solving it here in all its glory. Think of this as a warm-up before we do the heavy lifting of learning Einstein gravity. Also, later, we can compare the solution here with Einstein's solution.

Evidently, we should change from Cartesian coordinates (x, y) to polar coordinates (r, θ). We will do it by brute force to show, in contrast, the elegance of the formalism we will develop later. Differentiate

$$x = r\cos\theta \quad \text{and} \quad y = r\sin\theta \tag{9}$$

twice to obtain first

$$\dot{x} = \dot{r}\cos\theta - r\sin\theta\,\dot{\theta} \quad \text{and} \quad \dot{y} = \dot{r}\sin\theta + r\cos\theta\,\dot{\theta} \tag{10}$$

and then

$$\begin{aligned} &\ddot{x} = \ddot{r}\cos\theta - 2\dot{r}\sin\theta\,\dot{\theta} - r\cos\theta\,\dot{\theta}^2 - r\sin\theta\,\ddot{\theta} \\ \text{and}\quad &\ddot{y} = \ddot{r}\sin\theta + 2\dot{r}\cos\theta\,\dot{\theta} - r\sin\theta\,\dot{\theta}^2 + r\cos\theta\,\ddot{\theta} \end{aligned} \tag{11}$$

(Note that in each pair of these equations, the second could be obtained from the first by the substitution $\theta \to \theta - \frac{\pi}{2}$, so that $\cos\theta \to \sin\theta$, and $\sin\theta \to -\cos\theta$.)

Multiplying the first equation in (7) by $\cos\theta$ and the second by $\sin\theta$ and adding, we obtain, using (11),

$$\ddot{r} - r\dot{\theta}^2 = -\frac{\kappa}{r^2} \tag{12}$$

On the other hand, multiplying the first equation in (7) by $\sin\theta$ and the second by $\cos\theta$ and subtracting, we have

$$2\dot{r}\dot{\theta} + r\ddot{\theta} = 0 \tag{13}$$

I remind the reader again that we are doing all this in a clumsy brute force way to show the power of the formalism we are going to develop later.

After staring at (13) we recognize that it is equivalent to

$$\frac{d}{dt}(r^2\dot{\theta}) = 0 \tag{14}$$

which implies that

$$\dot{\theta} = \frac{l}{r^2} \tag{15}$$

for some constant l. Inserting this into (12), we have

$$\ddot{r} = \frac{l^2}{r^3} - \frac{\kappa}{r^2} = -\frac{dv(r)}{dr} \tag{16}$$

where we have defined

$$v(r) = \frac{l^2}{2r^2} - \frac{\kappa}{r} \tag{17}$$

Multiplying (16) by $\dot{r}$ and integrating over t, we have

$$\int dt\, \frac{1}{2}\frac{d}{dt}\dot{r}^2 = \int dt\, \dot{r}\ddot{r} = -\int dt \frac{dr}{dt}\frac{dv(r)}{dr} = -\int dr \frac{dv(r)}{dr}$$

so that finally

$$\frac{1}{2}\dot{r}^2 + v(r) = \epsilon \tag{18}$$

with ϵ an integration constant.

This describes a unit mass particle moving in the potential $v(r)$ with energy ϵ. Plot $v(r)$. Clearly, if ϵ is equal to the minimum of the potential $v_{\text{min}} = -\frac{\kappa^2}{2l^2}$, then $\dot{r} = 0$ and r stays constant. The planet follows a circular orbit of radius l^2/κ. If $\epsilon > v_{\text{min}}$ the orbit is elliptical, with r varying between r_{min} (perihelion) and r_{max} (aphelion) defined by the solutions to $\epsilon = v(r)$. For $\epsilon > 0$ the planet is not bound and should not even be called a planet.

We have stumbled across two conserved quantities, the angular momentum l and the energy ϵ per unit mass, seemingly by accident. They emerged as integration constants, but surely there should be a more fundamental and satisfying way of understanding conservation laws. We will see in chapter II.4 that there is.

Orbit closes

One fascinating apparent mystery is that the orbit closes. In other words, as the particle goes from r_{min} to r_{max} and then back to r_{min}, θ changes by precisely 2π. To verify that this is so, solve (18) for $\dot{r}$ and divide by (15) to obtain $\frac{dr}{d\theta} = \pm(r^2/l)\sqrt{2(\epsilon - v(r))}$. Changing variable from r to $u = 1/r$, we see, using (17), that $2(\epsilon - v(r))$ becomes the quadratic polynomial $2\epsilon - l^2u^2 + 2\kappa u$, which we can write in terms of its two roots as $l^2(u_{\text{max}} - u)(u - u_{\text{min}})$. Since u varies between u_{min} and u_{max}, we are led to make another change of variable from $u = u_{\text{min}} + (u_{\text{max}} - u_{\text{min}})\sin^2\zeta$ to ζ, so that ζ ranges from 0 to $\frac{\pi}{2}$. Thus, as the particle completes one round trip excursion in r, the polar angle changes by (note that $u_{\text{min}} = 1/r_{\text{max}}$ and $u_{\text{max}} = 1/r_{\text{min}}$)

$$\begin{aligned}\Delta\theta &= 2\int_{r_{\text{min}}}^{r_{\text{max}}} \frac{l\,dr}{r^2\sqrt{2(\epsilon - v(r))}} = 2\int_{u_{\text{min}}}^{u_{\text{max}}} \frac{l\,du}{\sqrt{2\epsilon - l^2u^2 + 2\kappa u}} \\ &= 2\int_{u_{\text{min}}}^{u_{\text{max}}} \frac{du}{\sqrt{(u_{\text{max}} - u)(u - u_{\text{min}})}} = 4\int_0^{\frac{\pi}{2}} d\zeta = 2\pi\end{aligned} \tag{19}$$

That this integral turns out to be exactly 2π is at this stage nothing less than an apparent miracle. Surely, there is something deeper going on, which we will reveal in chapter I.4. Note also that the inverse square law is crucial here. Incidentally, the change of variable here indicates how the Newtonian orbit* (and also the Einsteinian orbit, as we will see in part VI) could be determined. See exercise 2.

Bad notation alert! In (1), the force on the right hand side should be written as $F^i(x(t))$ (in many cases). In C, the gravitational force exists everywhere, namely $F(x)$ exists as a function, and what appears in Newton's equation is just $F(x)$ evaluated at the position of the particle $x(t)$. In contrast, in A, with a mass pulled by a spring, $F(x)$ does not make sense, only $F(x(t))$ does. The force exerted by the spring does not pervade all of space, and hence is defined only at the position of the particle $x(t)$, not at any old x. I can practically hear the reader chuckling, wondering what kind of person I could be addressing here, but believe me, I have encountered plenty of students who confuse these two basic concepts: spatial coordinates and the location of particles. I may sound awfully pedantic, but when we get to curved spacetime, it is often important to be clear that certain quantities are defined only on so-called geodesic curves, while others are defined everywhere in spacetime.

A historical digression on the so-called Newton's constant

> Wouldn't we be better off with the two eyes we now have plus a third that would tell us what is sneaking up behind? . . . With six eyes, we could have precise stereoscopic vision in all directions at once, including straight up. A six-eyed Newton might have dodged that apple and bequeathed us some levity rather than gravity.
>
> —George C. Williams[7]

Physics textbooks by necessity cannot do justice to physics history. As you probably know, in the *Principia,* Newton (1642–1727) converted his calculus-based calculations to geometric arguments,[8] which most modern readers find rather difficult to follow. Here I want to mention another curious point: Newton never did specifically define what we call his constant G. What he did with $ma = GMm/r^2$ was to compare the moon's acceleration with the apple's acceleration: $a_{\text{moon}} R^2_{\text{lunar orbit}} = GM_{\text{earth}} = a_{\text{apple}} R^2_{\text{radius of earth}}$. But to write $GM_{\text{earth}} = a_{\text{apple}} R^2_{\text{radius of earth}}$, he had to prove what is sometimes referred to as the first of Newton's two "superb theorems," namely that with the inverse square law the gravitational force exerted by a spherical mass distribution acts as if the entire mass were concentrated in a point at the center of the distribution. (See exercise 4.) Even with his abilities, Newton had to struggle for almost 20 years, the length of which contributed to the bitter priority fight he had with Hooke on the inverse square law, with Newton claiming that he had the law a long time before publication. You should be able to do it faster by a factor of $\sim 10^4$ as an exercise.

---

* On the old one pound note, a portrait of Newton together with his orbits appears on the back. Amusingly, the artist felt compelled to put the sun at the center, rather than one of the foci, of the ellipse.

Knowing the moon's period and $R_{\text{lunar orbit}}$, Newton could calculate a_{moon}. Since $R_{\text{radius of earth}}$ had been known since antiquity, he was thus able to calculate a_{apple} and obtained agreement* with Galileo's measurement of a_{apple}. This of course represents one of the most magnificent advances in physics history, with Newton unifying[9] the previously disparate subjects of celestial and terrestrial mechanics in one stroke. I don't have space to dwell on this here, but I do want to call your attention to the fact that Newton did not need to know G and M_{earth} to perform his feat.

Indeed, G was not measured until 1798 by Henry Cavendish (1731–1810) using equipment built and designed by his friend John Michell (1724–1793), now of black hole fame, who died before he could carry out the experiment.

Needless to say, what I have presented here should only be regarded as a comic book version of history.

Appendix 1: Where is hell?

You will find it in this appendix, sort of.

Curiously, contrary to what some textbooks and popular books stated, Cavendish's goal was not to measure G, but M_{earth} and hence the earth's density. Why this was of more interest to physicists of the time than G is in itself another interesting tidbit in physics history.

I mentioned that Newton had two superb theorems and that the first triggered his feud with Hooke. His second superb theorem states that there is no gravitational force inside a spherical shell.[10] Are you curious why Newton would even attack such a problem? An erroneous calculation had convinced him that the earth was much less dense than the moon, which led his friend Edmond Halley (1656–1742), who by the way published the *Principia* at his expense, to propose the hollow earth theory.[11] Witness the popularity of the idea in science fiction, notably Jules Verne's *Journey to the Center of the Earth* (1864). The idea may seem absurd to us, but at that time, a location for hell had to be found, and leading physicists gave serious thought to this pressing problem. Every epoch in physics has its own top ten problems.

So now we understand Cavendish's interest in M_{earth} and hence in the density of the earth rather than in G. Some textbooks give the impression that people easily obtained M_{earth} by multiplying the density of rock and the volume of the earth. Not so easy if you think that the earth might be hollow! We learn from Newton's second theorem that there is no gravitational force in hell, so the usual portrayal of the leaping flames can't be right!

Appendix 2: Fear of indices

Occasionally, a student or two would profess, unaccountably, a "fear of indices." In fact, there is nothing to fear.[12] At this stage, just stand back and admire how clever the invention of indices is. Instead of giving names to each coordinate axis, such as x, y, and z, we could pass fluidly between different dimensions by writing x^i, with $i = 1, 2, \cdots, D$. The length of the alphabet we use does not limit us, and we could easily go beyond 26 dimensions.

When we get to Einstein's theory, there will be a flood of indices, and we will have to distinguish between upper and lower indices. In Newtonian mechanics, there is no significance to whether we write the index as a superscript or a subscript. Have no fear: we will discuss each of these features of indices when the need arises. At this point, we merely note that a quantity can carry more than one index. In the text, we wrote ${x^i}_a$, with $i = 1, 2, \cdots, D$ labeling the different spatial directions, and $a = 1, 2, \cdots, N$ labeling the different particles. We will encounter more examples as we go along.

---

* Newton's first try did not lead to excellent agreement, because the value for the earth's equatorial radius was off. Just a reminder that physics never progresses as smoothly as textbooks say.

With only slight exaggeration, we could say that the invention of indices represents one of the really clever ideas[13] in the history of physics and mathematics, almost a "magic trick" that enables us to deal with as many particles in as many spatial dimensions as we like with the mere addition of some subscripts and superscripts.

Exercises

1 Show that for some suitably smooth function $f(x)$, the integral $\int_{-\infty}^{\infty} dx\delta(x)f(x) = f(0)$. Then show that $\delta(ax) = \delta(x)/|a|$ by evaluating the integral $\int_{-\infty}^{\infty} dx\delta(ax)f(x)$ for some smooth function $f(x)$.

2 Determine the orbit $r(\theta)$ by changing variable from r to $u = 1/r$. We will need the result of this exercise later.

3 Newton thought that light consists of "corpuscles." Calculate the deflection of light by the sun, applying what you learned in the text to the case $\epsilon > 0$. Note that the mass of these minute "particles of light" drops out in Newtonian theory anyway. We will need this result to compare with Einstein's theory later in chapter VI.3.

4 Prove Newton's first superb theorem: the gravitational force exerted by a spherical mass distribution acts as if the entire mass were concentrated in a point at the center of the distribution.

5 Prove Newton's second superb theorem.

6 Suppose engineers can build a straight tunnel connecting two cities on earth. Then we could have a free unpowered "gravity express"[14] by simply dropping a railroad car into the tunnel, allowing it to fall from one city to the other. Use Newton's two superb theorems to calculate the transit time.

Notes

1. Also introduced by Cauchy, Poisson, Hermite, Kirchoff, Kelvin, Helmholtz, and Heaviside. See J. D. Jackson, *Am. J. Phys.* 76 (2008), pp. 707–709.
2. Rigorous mathematicians go berserk at physicists' use of the word "function" here; they prefer to call it a distribution, defined as the limit of a function. But working physicists do not give a flying barf about such niceties. In any case, I do not personally know a theoretical physicist suffering any harm by calling $\delta(t)$ a function.
3. Consider a game of tennis. Compare a hard drive down the line and a soft lob high over the net. In both cases, we are to solve Newton's law $\frac{d^2x}{dt^2} = 0$, $\frac{d^2y}{dt^2} = -g$, with the boundary conditions $x(0) = 0$, $x(T) = L$, and $y(0) = y(T) = 0$. (The problem is so elementary that we won't bother to explain the notation, that y denotes the vertical direction, that $y = 0$ is the ground, that T is the time of flight before the ball hits the ground, that L is the length of the tennis court, and so on and so forth. You might want to draw your own figure.) The solution is $x = Lt/T$, $y = \frac{1}{2}g(T - t)t$. Note that the two types of tennis shots are governed by the same equation and the same L. Hence we obtain the same solution, but keep in mind that T is small in the case of the hard drive and that T is large in the case of the soft lob. Now eliminate t to obtain y as a function of x, namely $y(x) = \frac{1}{2}gT^2(1 - \frac{x}{L})\frac{x}{L}$, a parabola in both cases (of course). But compare the curvature of the two parabolas: we have $\frac{d^2y}{dx^2} = -g(T/L)^2$, very small in the case of the hard drive (small T) and very large in the case of the lob (large T). The hard drive down the line barely skimming over the net, and the soft lob climbing lazily high up into the sky, look and feel totally different pictured in space. In contrast, consider y as a function of t. We also have two parabolas (of course), namely $y(t) = \frac{1}{2}g(T - t)t$, as given earlier. Now compare the curvature of the two parabolas: we have $\frac{d^2y}{dt^2} = -g$, the same in both cases. The curvature of the ball's trajectory in spacetime is universal (universal gravity, get it?). But we tend to see in our mind's eye the two parabolas $y(x)$ in space, one for the hard drive and one for the lob, which look quite different, rather than the parabolas $y(t)$ in spacetime, which have the same curvature. I learned this long ago from John Wheeler.
4. Currently to one part in 10^{13}. The modern round of experiments started with Loránd Eötvös in 1885 and continues with the Eöt-Wash experiment led by E. Adelberger in our days.

5. The equality of the gravitational and inertial mass of the neutron has also been verified to good accuracy using neutron interferometry.

ON THE OBSERVABLE PROPERTIES OF COSMIC BACKGROUND RADIATION IN THE UNIVERSE WITH NEGATIVE CURVATURE

V.G.Gurzadyan‡and A.A.Kocharyan#

Abstract.– As was shown before the statistical properties (exponential mixing) of motion of CMB photon beams in Friedmann Universe with negative curvature can have definite observable consequences including the decrease of the CMB anisotropy amplitude after the last scattering, distortion of images on CMB sky maps. Here we consider one more consequence concerning the behaviour of temperature autocorrelation function $C(\theta,\beta)$, where θ is the separation angle, and β the observing beam effective angle. We prove that in the Universe with negative curvature the temperature autocorrelation function should tend to become independent on separation angle regardless the initial form of the spectrum of perturbations at last scattering epoch. It is also predicted that the temperature autocorrelation function should increase while obtained from measurements with small beam sizes within some *mixing beam angle.*

The discovery of anisotropy of the Cosmic Microwave Background radiation (CMB) announced the beginning of far more informative studies on the evolution and the present structure of the Universe [1]. The first and most popular viewpoint of COBE and other available data (though slightly revised by later analysis) concerning in particular the temperature autocorrelation function $C(\theta,\beta)$ was the support of Harrison-Zeldovich scale-invariant spectrum of initial fluctuations and hence of inflationary scenario [2].

Below we consider another possible interpretation of the same data, namely as indication of the negative curvature of the Universe. Our approach is based on the studies on properties of photon beam motion in Friedmann-Robertson-Walker Universe with $k=-1$, which can be reduced to the problem of the behaviour of correlation function of geodesic flow on 3-manifold with negative constant curvature. In particular the study of the exponential decay of correlation functions in the context of CMB problem has led to the prediction of the following observable effects [3,4,5]: a) decrease of CMB anisotropy after the last scattering epoch depending on the value of the density parameter Ω; b) distortion of images of anisotropy structures on CMB maps; c) possibility of measuring of similar properties of CMB photon beams arriving from regions having no causal connection.

The first effect as follows from the calculations [3,4], can lead to a damping of $\delta T/T$ since last scattering epoch, $z=1000$, up to the present time by a rather significant factor depending on Ω (up to $100-1000$ at $\Omega\sim 0.1-0.3$).

The second effect can lead to complex-elongated structures of the constant temperature curves on CMB maps. As a simplified indicator, the degree of elongation, if measured on CMB maps can give the present value of Ω by the formula derived in [5]. The preliminary statistical analysis of COBE-DMR maps [6], 1993) does reveal existence of elongated shapes; if attributed to the described effect the results indicate $\Omega = 0.2 - 0.4$; special pattern-recognition code was developed for that study [7] to distinguish from other map properties [8]. The third effect, equivalent to the fact that *two ink drops are mixing in a cup of water in the same manner without requiring information on each other*, removes the mystery of the horizon problem.

All these three effects occur only in Friedmann Universe with negative curvature (i.e. they disappear if either $k = 0$ or $k = +1$), and therefore can be of particular importance for probing of this principal property of the Universe.

Evidently nothing is happening to any individual photon during free propagation after the last scattering, and these effects are purely statistical and are determined by the principal limitations of obtaining information during measurements, i.e. by the impossibility of reconstruction of the trajectory of given photon while observing within finite smoothing angle due to the overlapping of exponentially deviating geodesics in any cut of phase space. This situation of loss of information can be described via *random sequences* of Kolmogorov [9] and Chaitin [10].

Below we consider another aspect of the problem of exponential decay of correlators of geodesic flow having particular observational consequences concerning the properties of temperature autocorrelation function $C(\theta, \beta)$ [11].

Our present study is essentially determined by recent rigorous results on the correlation functions of geodesic flow on 3-manifold with negative curvature [12]. Geodesic flow on d-dimensional manifolds with negative curvature has been object of intense studies rather long time, since Hadamard (1898), Hedlund, Hopf (30ies) up to fundamental results by Anosov and others. In particular, it was proved that geodesic flow on closed (compact, without boundary) manifold with negative curvature is Anosov system [13], is possessing the strongest chaotic properties (e.g. mixing of all degrees), with positive Kolmogorov-Sinai (KS) entropy. Rather informative characteristics of any dynamical system are the correlation functions, in particular the law of their decay, though the obtaining of rigorous results for each given system usually requires great efforts and in fact for only a few classes of dynamical systems results on correlation functions exist up to date. The new result [12] being of remarkable interest for us reads: the correlation function

$$b_{A_1,A_2}(\lambda) = \int_{SM} A_1 \circ f^{\lambda} \cdot A_2 d\mu - \int_{SM} A_1 d\mu \int_{SM} A_2 d\mu$$

of the geodesic flow $\{f^{\lambda}\}$ on the unit tangent bundle SM of the Riemann 3-manifold M with negative constant curvature decreases by exponential law, namely for all functions $A_1, A_2 \in L^2(SM)$ but a finite-dimensional space in $L^2(SM)$ there exists $c > 0$ such that

$$|b_{A_1,A_2}(\lambda)| \leq c \cdot |b_{A_1,A_2}(0)| \cdot e^{-h\lambda} , \tag{1}$$

where μ is the Liouville measure and $\mu(SM) = 1$, h is the KS-entropy of the geodesic flow $\{f^{\lambda}\}$.

We now take up the question of how one describes the free motion of photons in the $4D$-World (for details see [4]). To make matters more simple we will only consider a Friedmann $4D$-World W, decomposed into a homogeneous $3D$-Universe characterized by some coordinates x, evolving with respect to the cosmic time t. Thus each event in the World can be assigned unique space-time coordinates (x, t). One can then project any trajectory γ from the World W into the Universe U simply by associating to $\gamma(\lambda) = (x(\lambda), t(\lambda))$ the curve $c(\lambda) = x(\lambda)$. It turns out that null geodesics in the World project onto geodesics in the Universe with new affine parameter:

$$\lambda(t) = \int_{t_0}^{t} \frac{ds}{a(s)} .$$

The latter relates to the problem of "internal time" of the K-systems in cosmology considered initially in [14]. As it can be easily shown by means of the formulae in [3,4,15], the degree of smoothing of anisotropy $\delta T/T$ in post-scattering epoch is determined by the KS-entropy h and affine parameter λ which depend on the parameters of the Universe. For the matter-dominated Universe one has

$$e^{h\lambda} = (1+z)^2 \left[\frac{1+\sqrt{1-\Omega}}{\sqrt{1+z\Omega}+\sqrt{1-\Omega}} \right]^4 . \tag{2}$$

For $z \gg \Omega^{-1}$ one may obtain

$$e^{h\lambda} \sim \frac{(1+\sqrt{1-\Omega})^4}{\Omega^2} . \tag{3}$$

Here our aim is to investigate the behaviour of the temperature autocorrelation function $C(\theta, \beta)$ using properties of the correlation function of the geodesic flow $\{f^\lambda\}$.

One may readily see that if

$$A_1(u) = \mathcal{T}(u) - 1 = \frac{T(u)}{\bar{T}} - 1 ,$$

and

$$A_2(u) = \frac{\chi_{\mathcal{K}(v)}(u)}{\mu(\mathcal{K}(v))} - 1 ,$$

where $T(u)$ is the real temperature at decoupling time at $u \in SM$,

$$\bar{T} = \int_{SM} T d\mu ,$$

$\mathcal{K}(v) \subset SM$ is a beam of detected photons at $v \in SM$, and $\chi_{\mathcal{K}(v)}$ is the characteristic function of the set $\mathcal{K}(v)$, then normalized "measured" temperature at point u at λ defines as follows

$$\mathcal{T}_\lambda(u) = \frac{1}{\mu(\mathcal{K}(u))} \int_{\mathcal{K}(u)} \mathcal{T} \circ f^\lambda d\mu = 1 + b_{A_1,A_2}(\lambda) . \tag{4}$$

Therefore one may using Eqs. (1), (2) arrive at the following inequality

$$|\mathcal{T}_\lambda(u) - 1| \leq c \cdot |\mathcal{T}_0(u) - 1| \cdot \frac{1}{(1+z)^2} \cdot \left[\frac{\sqrt{1+z\Omega}+\sqrt{1-\Omega}}{1+\sqrt{1-\Omega}} \right]^4 .$$

Thus we see, that for any u, i.e. at any space point in any sky direction, *the "measured" temperature tends to the constant mean temperature, i.e. the isotropic state is the final state.*

For normalized temperature autocorrelation function

$$C_\lambda(\theta, \beta) = \langle \mathcal{T}_\lambda(u) \mathcal{T}_\lambda(v) \rangle_{g(u,v)=\cos\theta} , \tag{5}$$

the following inequality holds

$$|C_\lambda(\theta, \beta) - 1| \leq c \cdot |C_0(\theta, \beta) - 1| \cdot \frac{1}{(1+z)^2} \cdot \left[\frac{\sqrt{1+z\Omega}+\sqrt{1-\Omega}}{1+\sqrt{1-\Omega}} \right]^4 .$$

The following conclusion immediately follows from this formula :

Temperature autocorrelation function $C(\theta,\beta)$ *is almost constant with respect to* θ *at the present time regardless on the initial perturbations at* $z \sim 1000$.

Numerically the effect determined by Eq. (2) as was mentioned above is large enough for CMB photons [3,4], to reveal it during the evolution of the Universe due to negativity of curvature of the Universe.

Using Eq. (4) and the fact that the geodesic flow is an Anosov system one may show that there exists an angle ϕ such that smoothing factor s of $\delta T/T(\beta)$ is almost constant if either $\beta \gg \phi$ $(s \sim e^{-h\lambda})$ or $\beta \ll \phi$ $(s \sim 1)$, and increases as β is decreased at $\beta \sim \phi$ by the law $s \sim const/\beta \cdot e^{-h\lambda}$.

One can explain this result and the content of the *smoothing angle* ϕ as follows. As we have mentioned above, the smoothing of CMB is a statistical effect due to the loss of information during the measurements.while averaging within some beam size. Therefore, the more narrow is the beam size (pencil-beam), the less information is lost at smoothing in terms of the temperature autocorrelation function. Maximal information, e.g. the anisotropy corresponding exactly the last scattering surface should be obtained while measuring by beams within some mixing angle ϕ; measurements on small angles should not influence the autocorrelation function which should be determined solely by physical conditions of the last scattering surface (its thickness, the Silk effect, etc).

Among the measurements (for review see [1]) there are those with smaller beam size than COBE, such as of MAX, ($\delta T/T \leq 4.2 \cdot 10^{-5}$, beam size 0.5°) and of ARGO ($1.6 \cdot 10^{-5} < \delta T/T < 2.6 \cdot 10^{-5}$, beam size 0.8°(52′)) indicating increase of anisotropy compared with COBE and therefore seem to support the prediction made above. Less supporting is the result of South Pole ACME experiment, $\delta T/T \leq 1.4 \cdot 10^{-5}$, with 1.5° beam size. Evidently more accuracy and statistics is needed to distinguish our prediction from, say Doppler shift and predictions of certain CDM galaxy formation models.

This prediction, therefore indicates a way to obtain the sign of the curvature of the Universe, the real anisotropy at the last scattering epoch as well as the present value of Ω.

To summarize, the effects we are considering are model-independent, i.e. they do not depend on dark matter models, initial fluctuations, etc. The effects should appear if the Universe is Friedmann - homogeneous and isotropic, and has negative curvature. One has a real possibility of getting information directly on the curvature of the Universe, since the effects disappear at $k = 0$ and $k = +1$.

1.3 Metric spaces

To go further we need to add structure to a manifold: a *metric* in tangent space, i.e. an inner product for tangent-space vectors (symmetric, bilinear) associating a function $g(\xi, \epsilon)$ with any pair of vectors (ξ, ϵ). This corresponds to a symmetric $(0, 2)$-type tensor g symmetric in its two covariant components $g_{\mu\nu} = g_{(\mu\nu)}$:

$$\xi \cdot \epsilon \equiv g(\xi, \epsilon) = \xi^\mu \epsilon^\nu g_{\mu\nu}. \tag{1.38}$$

The norm squared of a vector is just the product of the vector with itself, $\xi^2 = \xi \cdot \xi$. The metric will be required to be non-singular, i.e.

$$g \equiv \det(g_{\mu\nu}) \neq 0, \tag{1.39}$$

and locally diagonalizable into $\eta_{\mu\nu} = \mathrm{diag}(+ - \cdots -)$ for physical and conventional reasons. Thus, in d dimensions

$$\mathrm{sign}\; g = \frac{g}{|g|} = (-1)^{d-1}. \tag{1.40}$$

As usual, a metric can be used to establish a correspondence between a vector space and its dual, i.e. between vectors and 1-forms: with each vector ξ^μ we associate a 1-form ω_μ whose action on any other vector η^μ is the product of ξ and η, $\omega(\eta) = \xi^\mu \eta^\nu g_{\mu\nu}$, which means the relation between components $\omega_\nu = \xi^\mu g_{\mu\nu}$. It is customary to denote this 1-form by ξ_μ, and the transformation from vector to 1-form is represented by lowering the index.

The inverse metric can be used as a metric in cotangent space, and its components are those of the inverse matrix and are denoted with upper indices. The operation of raising indices can be similarly defined, and the consistency of all these operations is guaranteed because the dual of the dual is the original vector space. The extension to tensors of higher ranks is straightforward.

The determinant of the metric can also be used to relate tensors and weight w tensor densities, since it transforms as a density of weight $w = 2$ and the product of a tensor and $g^{w/2}$ transforms as a density of weight w.

Furthermore, with a metric we can define the *Ricci scalar* R and the *Einstein tensor* $G_{\mu\nu}$,

$$R = R_\mu{}^\mu, \qquad G_{\mu\nu} = R_{\mu\nu} - \tfrac{1}{2} g_{\mu\nu} R, \tag{1.41}$$

which needs not be symmetric (just like the Ricci tensor).

So far we have two independent fields defined on our manifold: the metric and the affine connection. An L_d spacetime equipped with a metric is sometimes denoted by (L_d, g). The affine connection and the metric are related by the *non-metricity tensor* $Q_{\mu\nu\rho}$,

$$Q_{\mu\nu\rho} \equiv -\nabla_\mu g_{\nu\rho}. \tag{1.42}$$

If we take the combination $\nabla_\mu g_{\rho\sigma} + \nabla_\rho g_{\sigma\mu} - \nabla_\sigma g_{\mu\rho}$ and expand it, we find that the connection can be written as follows:

$$\Gamma_{\mu\nu}{}^\rho = \left\{ {\rho \atop \mu\,\nu} \right\} + K_{\mu\nu}{}^\rho + L_{\mu\nu}{}^\rho, \tag{1.43}$$

where

$$\left\{ {\rho \atop \mu\,\nu} \right\} = \tfrac{1}{2} g^{\rho\sigma} \{ \partial_\mu g_{\nu\sigma} + \partial_\nu g_{\mu\sigma} - \partial_\sigma g_{\mu\nu} \} \tag{1.44}$$

are the *Christoffel symbols*, which are completely determined by the metric, and K is called the *contorsion tensor* and is given in terms of the torsion tensor by

$$\begin{aligned} K_{\mu\nu}{}^{\rho} &= \tfrac{1}{2} g^{\rho\sigma} \{ T_{\mu\sigma\nu} + T_{\nu\sigma\mu} - T_{\mu\nu\sigma} \} \,, \\ K_{[\mu\nu]}{}^{\rho} &= -\tfrac{1}{2} T_{\mu\nu}{}^{\rho}, \qquad K_{\mu\nu\rho} = -K_{\mu\rho\nu}. \end{aligned} \tag{1.45}$$

Finally

$$L_{\mu\nu}{}^{\rho} = \tfrac{1}{2} \{ Q_{\mu\nu}{}^{\rho} + Q_{\nu\mu}{}^{\rho} - Q^{\rho}{}_{\mu\nu} \} \,. \tag{1.46}$$

Observe that the contorsion tensor depends on the metric whereas the torsion tensor does not. Furthermore, observe that, since the contorsion and non-metricity tensors transform as tensors, the piece responsible for the non-homogeneous term in the transformation of the affine connection is the Christoffel symbol.

With a metric it is also possible to define the length of a curve γ, $x^\mu(\xi)$, by the integral

$$s = \int_\gamma d\xi \, \sqrt{g_{\mu\nu}(x) \dot{x}^\mu \dot{x}^\nu}. \tag{1.47}$$

If we consider the above expression as a functional in the space of all curves joining two given points, we can ask which of those curves minimizes it. The answer is given by the Euler–Lagrange equations, which take the simple form

$$\ddot{x}^\mu + \dot{x}^\rho \dot{x}^\sigma \left\{ {\mu \atop \rho\,\sigma} \right\} = 0, \tag{1.48}$$

if we parametrize the curve by its proper length s. This is the *geodesic equation*, and is different from the autoparallel equation (1.23) whenever there is torsion and non-metricity.

In the standard theory of gravity metric and affine connection are not independent variables since we want to describe only the degrees of freedom corresponding to a massless spin-2 particle. To relate these two fields one imposes the *metric postulate*

$$Q_{\mu\rho\sigma} = -\nabla_\mu g_{\rho\sigma} = 0, \tag{1.49}$$

which makes the operations of raising and lowering of indices commute with the covariant derivative. A connection satisfying the above condition is said to be *metric compatible* and a spacetime (L_d, g) with a metric-compatible connection is called a *Riemann–Cartan spacetime* and is denoted by U_d.

Sometimes a weaker condition is required: the vanishing of the trace-free part of the non-metricity tensor $\hat{Q}$

$$\hat{Q}_{\mu\nu\rho} \equiv Q_{\mu\nu\rho} - \tfrac{1}{d} Q_{\mu\sigma}{}^{\sigma} g_{\nu\rho} = 0. \tag{1.50}$$

In this case, the non-metricity must take the form

$$Q_{\mu\nu\rho} = -A_\mu g_{\nu\rho}, \quad \Rightarrow \quad L^{\rho}_{\mu\nu} = A_{(\mu} g_{\nu)}{}^{\rho} - \tfrac{1}{2} g_{\mu\nu} A^{\rho}, \tag{1.51}$$

where $A_\mu = -\frac{1}{d}Q_{\mu\sigma}{}^{\sigma}$ is known as the *Weyl connection* and the corresponding space is a *Cartan–Weyl* space. The presence of a Weyl connection makes the spacetime invariant under conformal rescalings of the metric

$$g'_{\mu\nu} \equiv \Omega^2 g_{\mu\nu}, \qquad \nabla'_\mu g'_{\nu\rho} = \Omega^2 \nabla_\mu g_{\nu\rho}, \tag{1.52}$$

assuming that the Weyl connection transforms as

$$A'_\mu = A_\mu - \partial_\mu \ln \Omega^2, \tag{1.53}$$

that is, as a gauge connection with gauge group $\mathbb{R}$ (see Appendix A).[6]

Still, even if the Weyl connection vanishes, the metric postulate leaves the torsion undetermined. If we want to have a connection completely determined by the metric, left as the only independent field, one has to impose the vanishing of the torsion tensor. The torsionless, metric-compatible connection is called *Levi-Civita connection* and its components are given by the Christoffel symbols.[7] A Riemann–Cartan spacetime U_d with vanishing torsion is a *Riemann spacetime* V_d. If the torsion vanishes but there is a Weyl connection, the spacetime is an *Einstein–Weyl spacetime*.

There is another way of reducing the number of independent fields: by imposing the vanishing of the curvature tensor. In this case (for vanishing Weyl connection), both the metric and the connection are completely determined by the *Vielbein* (to be defined latter). The connection is called *Weitzenböck connection* [1243, 1244] and has torsion (also determined by the Vielbein). A Riemann–Cartan spacetime with Weitzenböck connection is a *Weitzenböck spacetime* A_d; if one includes a Weyl connection, then it is called a *Weitzenböck–Weyl space*.

If both torsion and curvature vanish, the space has to be *Minkowski spacetime* M_d since the *Minkowski metric* $g_{\mu\nu} = \eta_{\mu\nu}$ is the only one that makes the full Riemann tensor vanish in the absence of torsion. Again, adding a Weyl connection, we have a *Minkowski–Weyl space*.

The diagram in Fig. 1.1, a more complete version of those in Refs. [736, 737] taken essentially from Ref. [927], summarizes the different particular structures that we can have on an affinely connected manifold equipped with a metric. We have introduced some changes in the diagram of Ref. [927] to indicate that Weyl spaces have a Weyl connection and not just arbitrary non-metricity.

In the rest of this section we are going to study the particular properties of some of these spacetimes. The Weitzenböck spacetime will be studied after the introduction of Vielbeins in Section 1.4.

1.3.1 Riemann–Cartan spacetime U_d

As has been said, this is an affinely connected metric spacetime with a metric-compatible connection, so the non-metricity tensor vanishes, $Q_{\mu\nu\rho} = 0$. According to the general result,

---

[6] This is, as a matter of fact, how gauge symmetries were introduced in physics (see Ref. [1004] and references therein.)

[7] Sometimes (especially in the supergravity context) the Levi-Civita connection is written $\Gamma(g)$ to stress the fact that it is a function of the metric in order to distinguish it from arbitrary connections that are independent of the metric. We will do so only when necessary.

Fig. 1.1. Particular structures in an affinely connected spacetime equipped with a metric (L_d, g) classified by their vanishing $(-)$ or non-vanishing $(+)$ Weyl connection A, curvature R, and torsion T expressed as the triplet (A, R, T). Only Weyl connections with vanishing trace-free non-metricity $\hat{Q}$ are usually considered and they are called Cartan–Weyl spacetimes. They can have arbitrary Weyl connection, Riemann curvature, and torsion, and they are denoted by $(+\ +\ +)$. A Cartan–Weyl spacetime with vanishing Weyl connection is a Riemann–Cartan spacetime $(-\ +\ +)$. If the curvature vanishes instead, we have a Weitzenböck–Weyl spacetime $(+\ -\ +)$, and, if it is the torsion that vanishes, we have an Einstein–Weyl spacetime $(+\ +\ -)$. The rest of the diagram follows the same pattern.

a metric-compatible connection of a Riemann–Cartan spacetime always has the form

$$\Gamma_{\mu\nu}{}^{\rho} = \left\{ {\rho \atop \mu\,\nu} \right\} + K_{\mu\nu}{}^{\rho}. \tag{1.54}$$

Observe that the symmetric part of the contorsion tension does not vanish, but

$$K_{(\mu\nu)\,\rho} = \tfrac{1}{2}\left(T_{\mu\rho\nu} + T_{\nu\rho\mu}\right) \neq 0. \tag{1.55}$$

This means that the presence of torsion implies not only that the connection has a non-vanishing antisymmetric part, but also that the symmetric part is not fully determined by the metric but

$$\Gamma_{(\mu\nu)}{}^{\rho} = \left\{ {\rho \atop \mu\,\nu} \right\} + K_{(\mu\nu)}{}^{\rho} \neq \left\{ {\rho \atop \mu\,\nu} \right\}. \tag{1.56}$$

The curvature, Ricci, and Einstein tensors of a metric-compatible connection satisfy further identities. On contracting the γ and σ indices in the third Bianchi identity Eqs. (1.30) and using the metric postulate, we find the so-called *contracted Bianchi identity*

$$\nabla_\alpha G_\mu{}^{\alpha} + T_{\mu\alpha\beta}R^{\beta\alpha} - \tfrac{1}{2}T_{\alpha\beta\gamma}R_\mu{}^{\gamma\alpha\beta} = 0. \tag{1.57}$$

Furthermore, by applying the Ricci identity to the metric and using the metric postulate, one can prove a fourth Bianchi identity:

$$R_{\alpha\beta(\gamma\delta)} = 0. \tag{1.58}$$

If we modify the connection according to Eq. (1.31) and Γ is metric-compatible, the Ricci scalar is

$$R(\tilde{\Gamma}) = R(\Gamma) - T_{\mu\nu}{}^{\rho}\tau_\rho{}^{\mu\nu} + 2\nabla_\mu\tau_\nu{}^{\mu\nu} + \tau_\mu{}^{\mu\lambda}\tau_\nu{}^{\nu}{}_{\lambda} + \tau_\nu{}^{\mu\rho}\tau_{\mu\rho}{}^{\nu}. \tag{1.59}$$

If $\tilde{\Gamma}$ is not a metric-compatible connection, then τ contains all the contributions of the non-metricity tensor $\tau_{\mu\nu}{}^{\rho} = L_{\mu\nu}{}^{\rho}$ and the above formula allows us to work in the framework of a Riemann–Cartan spacetime with non-metric-compatible connections. We will use this formula when we deal with Einstein–Weyl spacetimes.

If both $\tilde{\Gamma}$ and Γ are metric-compatible connections and $\tilde{\Gamma}$ has torsion but $\Gamma = \Gamma(g)$, then $\tau = \tilde{K}$, the contorsion tensor of $\tilde{\Gamma}$, and the above formula takes a simpler form:

$$R(\tilde{\Gamma}) = R[\Gamma(g)] + 2\nabla_\mu\tilde{K}_\nu{}^{\mu\nu} + (\tilde{K}_\mu{}^{\mu\lambda})^2 + \tilde{K}_\nu{}^{\mu\rho}\tilde{K}_{\mu\rho}{}^{\nu}. \tag{1.60}$$

Now, this formula allows us to work with torsion in a Riemann spacetime. Particularly interesting is the case in which the contorsion $\tilde{K}_{\mu\nu\rho}$ is a completely antisymmetric tensor (proportional to the Kalb–Ramond field strength $H_{\mu\nu\rho}$, for instance). Then we have, if

$$\tilde{K}_{\mu\nu\rho} = \frac{1}{\sqrt{12}}H_{\mu\nu\rho}, \tag{1.61}$$

$$\int d^dx\sqrt{|g|}\;R(\tilde{\Gamma}) = \int d^dx\sqrt{|g|}\left\{R[\Gamma(g)] + \frac{1}{2\cdot 3!}H_{\mu\nu\rho}H^{\mu\nu\rho}\right\}. \tag{1.62}$$

1.3.2 Einstein–Weyl spacetime EW_d

This is defined by the conditions $\hat{Q} = T = 0$ which determine the connection Γ to be the sum of the Levi-Civita connection and a Weyl connection so it is invariant under GCTs and Weyl transformations. If we compute the commutator of two covariant derivatives on the metric and use the Ricci identity, we find that the curvature tensor is not antisymmetric in the second pair of indices, and instead of Eq. (1.58) we have this Bianchi identity

$$R_{\mu\nu(\rho\sigma)} = -\tfrac{1}{2}F_{\mu\nu}(A)g_{\rho\sigma}, \qquad \text{where} \qquad F_{\mu\nu}(A) = 2\partial_{[\mu}A_{\nu]}. \tag{1.63}$$

Therefore, $R_{\mu\nu(\rho\sigma)} = 0$ if A is *pure gauge* $A_\mu = \partial_\mu \ln \Omega^2$.

The complete curvature and Ricci tensors and the Ricci scalar can be easily computed using Eqs. (1.31), (1.32), (1.36), and (1.59) with $T = 0$ and $\tau_{\mu\nu}{}^{\rho} = L_{\mu\nu}{}^{\rho}$:

$$\begin{aligned} R_{\mu\nu\rho}{}^{\sigma}(\Gamma) = {} & R_{\mu\nu\rho}{}^{\sigma}(g) + \tfrac{1}{2}F_{\mu\nu}(A)g_{\rho}{}^{\sigma} + \nabla_{[\mu|}A_{\rho}g_{|\nu]}{}^{\sigma} - \nabla_{[\mu}A^{\sigma}g_{\nu]\rho} \\ & + \tfrac{1}{2}\left\{A_{[\mu}A^{\sigma}g_{\nu]\rho} - A_{[\mu|}A_{\rho}g_{|\nu]}{}^{\sigma} - \tfrac{1}{2}A^2 g_{[\mu}{}^{\sigma}g_{\nu]\,\rho}\right\}, \end{aligned} \tag{1.64}$$

$$\begin{aligned} R_{\mu\nu}(\Gamma) = {} & R_{\mu\nu}(g) + \tfrac{1}{4}(d-2)F_{\mu\rho}(A) + \tfrac{1}{2}(d-2)\left[\nabla_{(\mu}A_{\rho)} + \frac{1}{(d-2)}\nabla_\lambda A^\lambda g_{\mu\rho}\right] \\ & - \tfrac{1}{4}(d-2)\left[A_\mu A_\rho - A^2 g_{\mu\rho}\right], \end{aligned} \tag{1.65}$$

$$R(\Gamma) = R(g) + (d-1)\nabla_\lambda A^\lambda + \tfrac{1}{4}(d-2)(d-1)A^2. \tag{1.66}$$

For $A_\mu = \partial_\mu \ln \Omega^2$ we recover the relations between the curvature and Ricci tensors of a metric before and after a Weyl rescaling in Appendix M. The Ricci scalar has an overall factor Ω^{-2} because its definition uses an inverse metric.

1.3.3 Riemann spacetime V_d

It is defined by the conditions $Q = T = 0$ which determine the connection to be the Levi-Civita connection $\Gamma(g)$ whose components in a coordinate basis are given by the Christoffel symbols. In a Riemann spacetime one can construct infinitesimal parallelograms, and autoparallel curves are also geodesics (as in flat spacetime). There are also additional interesting properties. To start with, we can write the transformation of tensors under infinitesimal GCTs (Lie derivatives) in terms of covariant derivatives alone (all torsion terms vanish). In particular, for the metric and r-forms we can write

$$\begin{aligned} \delta_\xi g_{\mu\nu} &= -2\nabla_{(\mu}\xi_{\nu)}, \\ \delta_\xi B_{\mu_1\cdots\mu_r} &= -\xi^\lambda \nabla_\lambda B_{\mu_1\cdots\mu_r} - r(\nabla_{[\mu_1|}\xi^\lambda)B_{\lambda|\mu_2\cdots\mu_r]}. \end{aligned} \tag{1.67}$$

Furthermore, we have the usual identity

$$\Gamma_{\rho\mu}{}^{\rho} = \partial_\mu \ln\left(\sqrt{|g|}\right), \tag{1.68}$$

which allows us to write the Laplacian of a scalar function f in this way:

$$\nabla^2 f = \frac{1}{\sqrt{|g|}} \partial_\mu \Big(\sqrt{|g|}\, \partial^\mu f \Big), \tag{1.69}$$

and the divergence of a completely antisymmetric tensor (k-form) in this way:[8]

$$\nabla_{\mu_1} F^{\mu_1 \mu_2 \cdots \mu_k} = \frac{1}{\sqrt{|g|}} \partial_{\mu_1} \Big(\sqrt{|g|}\, F^{\mu_1 \mu_2 \cdots \mu_k} \Big). \tag{1.70}$$

The Bianchi identities take the form

$$R_{(\alpha\beta)\gamma}{}^{\delta} = 0, \qquad R_{[\alpha\beta\gamma]}{}^{\delta} = 0, \qquad \nabla_{[\alpha} R_{\beta\gamma]\rho}{}^{\sigma} = 0, \qquad R_{\alpha\beta(\gamma\delta)} = 0. \tag{1.71}$$

The first and fourth identities imply together

$$R_{\alpha\beta\gamma\delta} = R_{\gamma\delta\alpha\beta}, \tag{1.72}$$

which in turn implies that the Ricci and Einstein tensors are symmetric. The contracted Bianchi identity says now that the Einstein tensor is divergence free:

$$\nabla_\mu G^{\mu\nu} = 0, \tag{1.73}$$

which is a crucial identity in the development of general relativity.

The number of independent components of the curvature in d dimensions after taking into account all these Bianchi identities is $(1/12)\, d^2 (d^2 - 1)$.

The four-dimensional curvature tensor can be split into different pieces which transform irreducibly under the Lorentz group: a scalar piece $D(0,0)$, which is nothing but the Ricci scalar R, a two-index symmetric, a traceless piece $R_{\mu\nu} - \frac{1}{4} g_{\mu\nu} R$ (corresponding to the representation $D(1,1)$), and a four-index tensor with the same symmetries as the Riemann tensor but traceless: the Weyl tensor $C_{\mu\nu\rho}{}^{\sigma}$ with $C_{\mu\sigma\rho}{}^{\sigma} = 0$,

$$R_{\mu\nu}{}^{\rho\sigma} = C_{\mu\nu}{}^{\rho\sigma} + 2\Big(R_{[\mu}{}^{[\rho} - \tfrac{1}{4} R g_{[\mu}{}^{[\rho} \Big) g_{\nu]}{}^{\sigma]} + \tfrac{1}{6} R g_{[\mu}{}^{\rho} g_{\nu]}{}^{\sigma}. \tag{1.74}$$

The Weyl tensor can be decomposed into its self-dual and anti-self-dual parts (with respect to the last two indices). These two complex tensors transform in the $D(2,0)$ and $D(0,2)$ representations, respectively.

In d dimensions the Weyl tensor is defined by

$$C_{\mu\nu}{}^{\rho\sigma} = R_{\mu\nu}{}^{\rho\sigma} - \frac{4}{d-2} R_{[\mu}{}^{[\rho} g_{\nu]}{}^{\sigma]} + \frac{2}{(d-1)(d-2)} R\, g_{[\mu}{}^{[\rho} g_{\nu]}{}^{\sigma]}. \tag{1.75}$$

The main property of the Weyl tensor $C_{\mu\nu\rho}{}^{\sigma}$ with the indices in these positions is that it is left invariant by Weyl rescalings of the metric (see Appendix M). Furthermore, just as the Riemann curvature vanishes only for Minkowski spacetime, the Weyl tensor vanishes only for conformally flat (Minkowski) spacetimes, i.e. spacetimes that are related to Minkowski's by a given conformal transformation.

---

[8] Observe that this implies that the second term on the r.h.s. of Eq. (1.60) times $\sqrt{|g|}$ is a total derivative.

A final property of the Levi-Civita connection that is worth mentioning is the form of its variation under an arbitrary variation of the metric:

$$\delta\Gamma_{\mu\nu}{}^{\rho}(g) = \tfrac{1}{2}g^{\rho\sigma}\{\nabla_\mu\delta g_{\nu\sigma} + \nabla_\nu\delta g_{\mu\sigma} - \nabla_\sigma\delta g_{\mu\nu}\}\,. \tag{1.76}$$

Since $\delta g_{\mu\nu}$ is a tensor, $\delta\Gamma$ is a tensor even though Γ is not.

1.4 Tangent space

So far we have considered, for a given coordinate system, only one basis in tangent space: the coordinate basis. We are now going to consider an arbitrary basis in tangent space. Such a basis is defined by a set of d contravariant vectors labeled by a *tangent-space index* a $\{e_a = e_a{}^\mu\partial_\mu\}$ and is also referred to as a *frame* or, generically, *Vielbein* basis.[9] The coordinate basis is now a particular case in which $e_a{}^\mu = \delta_a{}^\mu$. Now we can express any vector in this basis $\xi = \xi^a e_a$ and its components ξ^a will be related to the coordinate basis components by

$$\xi^\mu = \xi^a e_a{}^\mu. \tag{1.77}$$

We can immediately define the dual basis of 1-forms $\{e^a = e^a{}_\mu dx^\mu\}$ defined by

$$\langle e^a|e_b\rangle = \delta^a{}_b, \tag{1.78}$$

which implies that the matrix of components $e^a{}_\mu$ of the 1-forms in the coordinate basis is the inverse, transposed, of that of the vectors:

$$e^a{}_\mu e_b{}^\mu = \delta^a{}_b, \quad \Rightarrow e_a{}^\mu e^a{}_\nu = \delta^\mu{}_\nu. \tag{1.79}$$

We can now relate frame and world indices of any tensor using these two matrices. In particular, we can use the frame components g_{ab} of the metric,

$$g_{ab} = e_a{}^\mu e_b{}^\nu g_{\mu\nu}, \tag{1.80}$$

that can also be interpreted as the matrix of inner products of the Vielbein basis $g(e_a, e_b) = g_{ab}$. An orthonormal Vielbein basis leads to $g_{ab} = \eta_{ab}$. Frames are usually chosen in such a way as to obtain a particular g_{ab} and orthonormal frames will be particularly important in what follows.

It is easy to see that g_{ab} and its inverse g^{ab} can be consistently used to raise and lower frame indices. In particular,

$$e^a{}_\mu = g_{\mu\nu}e_b{}^\nu g^{ab}, \qquad g_{\mu\nu} = e^a{}_\mu e^b{}_\nu g_{ab}. \tag{1.81}$$

A frame is invariant under GCTs (only the components in the coordinate basis change) and, thus, frame components of any tensor are also invariant. However, we can make a change of basis. Any two Vielbein bases are related by a $\mathrm{GL}(d,\mathbb{R})$ transformation $\Lambda^a{}_b$ in tangent space at a given point of the manifold. This transformation can in fact be different at each point and thus we have to consider local frame transformations $\Lambda^a{}_b(x)$. We write their action on vectors and forms as follows:

---

[9] *Einbein* for $d = 1$, *Zweibein* for $d = 2$, *Dreibein* for $d = 3$, *Vierbein* for $d = 4$, etc. In four dimensions it is also called a *tetrad*.

$$e'_a = e_b\left(\Lambda^{-1}\right)^b{}_a, \qquad e'^{\,a} = \Lambda^a{}_b e^b. \tag{1.82}$$

The *Ricci rotation coefficients* (or *anholonomy coefficients*) $\Omega_{ab}{}^c$ are the Lie brackets

$$[e_a, e_b] = -2\Omega_{ab}{}^c e_c, \qquad \Omega_{ab}{}^c = e_a{}^\mu e_b{}^\nu \partial_{[\mu} e^c{}_{\nu]}. \tag{1.83}$$

A *non-holonomic* frame is one with non-vanishing Ωs. Observe that, given a basis of vectors $\{e_a\}$, we could try to find a new set of coordinates $y^a(x^\mu)$ such that

$$e_a y^b = e_a{}^\mu \partial_\mu y^b = \delta_a{}^b. \tag{1.84}$$

The integrability condition for the system of partial differential equations $[e_c, e_a]y^b = 0$ is precisely the vanishing of the anholonomy coefficients $\Omega_{ab}{}^c$. A holonomic basis of vectors $\{e_a\}$ is one for which these coefficients vanish and then we can trivialize them ($e_a{}^\mu = \delta_a{}^\mu$) by a change of coordinates.

Just as we defined a covariant derivative transforming world tensors into world tensors we are now going to define a derivative that transforms tangent-space tensors into tangent-space tensors transforming well under local $\mathrm{GL}(d, \mathbb{R})$ transformations associated with a connection ω. Its action on scalars, vectors, and forms is[10]

$$\begin{aligned}
\mathcal{D}_a\phi &= \partial_a\phi, & &(= e_a{}^\mu \partial_\mu\phi),\\
\mathcal{D}_a\xi^b &= \partial_a\xi^b + \omega_{ac}{}^b\xi^c, & &(= e_a{}^\mu \mathcal{D}_\mu\xi^b),\\
\mathcal{D}_a\varepsilon_b &= \partial_a\varepsilon_b - \varepsilon_c\,\omega_{ab}{}^c, & &(= e_a{}^\mu \mathcal{D}_\mu\varepsilon_b).
\end{aligned} \tag{1.85}$$

Local $\mathrm{GL}(d, \mathbb{R})$ covariance implies the inhomogeneous transformation law for the connection:

$$\omega'_{ab}{}^c = \left[\Lambda^c{}_d\omega_{ef}{}^d\left(\Lambda^{-1}\right)^f{}_b - \left(\Lambda^{-1}\right)^d{}_b\partial_e\Lambda^c{}_d\right](\Lambda^{-1})^e{}_a. \tag{1.86}$$

The curvature of this connection can be defined through the Ricci identities in the standard fashion (observe that there are no torsion terms here):

$$\begin{aligned}
[\mathcal{D}_\mu, \mathcal{D}_\nu]\phi &= 0,\\
[\mathcal{D}_\mu, \mathcal{D}_\nu]\xi^a &= R_{\mu\nu b}{}^a\xi^b,\\
[\mathcal{D}_\mu, \mathcal{D}_\nu]\varepsilon_a &= -\varepsilon_b\,R_{\mu\nu a}{}^b,
\end{aligned} \tag{1.87}$$

and then the curvature is given by[11]

$$R_{\mu\nu a}{}^b = 2\partial_{[\mu}\,\omega_{\nu]a}{}^b - 2\omega_{[\mu|a}{}^c\,\omega_{|\nu]c}{}^b. \tag{1.89}$$

---

[10] Of course, the formalism we are developing is just that of a $\mathrm{GL}(d, \mathbb{R})$ gauge theory and our notation is basically identical to that of Appendix A. Here we are dealing with vector representations of $\mathrm{GL}(d, \mathbb{R})$. The d^2 generators of its Lie algebra can be labeled by a pair of vector indices ab and they are given, for instance, by $(T_{ab})^c{}_d = -\eta_{ad}\eta_b{}^c$. Thus $A_\mu{}^I\Gamma_{\mathrm{v}}(T_I) = \omega_\mu{}^{ab}(T_{ab})^c{}_d = -\omega_{\mu\,d}{}^c$. The subgroup $\mathrm{SO}(1, d-1, \mathbb{R})$ will be treated in more detail.

[11] Observe that, with all Latin indices, $R_{abc}{}^d = e_a{}^\mu e_b{}^\nu R_{\mu\nu c}{}^d$ and, therefore,

$$R_{abc}{}^d = 2\partial_{[a}\,\omega_{b]c}{}^d - 2\omega_{[a|c}{}^e\,\omega_{|b]e}{}^d + 2\Omega_{ab}{}^e\omega_{ec}{}^d. \tag{1.88}$$

At this point we have introduced a new connection ω that is independent of the metric. In the previous section we managed to relate the connection Γ to the metric via the metric postulate. Here we are going to generalize the metric postulate first to relate the two connections (the first Vielbein postulate) and then to relate them to the metric (the second Vielbein postulate). Before we enunciate these postulates we introduce the *total covariant derivative*, covariant with respect to all the indices of the object it acts on. We denote it by ∇ again, and, for instance, acting on Vielbeins it is

$$\nabla_\mu e_a{}^\nu = \partial_\mu e_a{}^\nu + \Gamma_{\mu\rho}{}^\nu e_a{}^\rho - e_b{}^\nu \omega_{\mu a}{}^b. \tag{1.90}$$

We can motivate the first Vielbein postulate as follows: we would like to be able to convert tangent into world indices and vice versa inside the total covariant derivative, so $e^a{}_\nu \nabla_\mu \xi^\nu = \mathcal{D}_\mu \xi^a$ and $\mathcal{D}$ is just the projection of ∇ onto the Vielbein basis. To have this property we impose the *first Vielbein postulate*,

$$\nabla_\mu e_a{}^\nu = 0. \tag{1.91}$$

It is worth stressing that this does not imply the covariant constancy of the metric $\nabla_\mu g_{\nu\rho} = 0$. The above postulate implies the following relation between the connections:

$$\omega_{\mu a}{}^b = \Gamma_{\mu a}{}^b - e_a{}^\nu \partial_\mu e^b{}_\nu. \tag{1.92}$$

Furthermore, the curvatures of the two connections are now related by

$$R_{\mu\nu\rho}{}^\sigma(\Gamma) = e^a{}_\rho e_b{}^\sigma R_{\mu\nu a}{}^b(\omega). \tag{1.93}$$

The first Vielbein postulate also gives an important relation between the torsion and the Vielbein: on taking the antisymmetric part of $\nabla_\mu e^a{}_\nu = 0$, we obtain

$$2\mathcal{D}_{[\mu} e^a{}_{\nu]} = 2\left(\partial_{[\mu} e^a{}_{\nu]} - \omega_{[\mu}{}^a{}_{\nu]}\right) = -T_{\mu\nu}{}^a. \tag{1.94}$$

The significance of the torsion in this formalism, from the point of view of the gauge theory of GL$(d, \mathbb{R})$, is unclear. We can provide an interpretation in the framework of the gauge theory of the affine group IGL$(d, \mathbb{R})$ but we will do it in the more restricted context of the Lorentz and Poincaré groups in Section 4.5.

The first Vielbein postulate has allowed us to recover the structure of affinely connected spacetime (L_d, g) with only one (independent) connection, generalized to allow the use of an arbitrary basis in tangent space. Furthermore, we can recover the different particular structures that we defined in the previous section, also generalized to allow the use of arbitrary basis in tangent space. First, if Γ is a completely general connection, it is given by Eq. (1.43) and then ω (which is related to Γ by the first Vielbein postulate) is given by

$$\omega_{ab}{}^c = \omega_{ab}{}^c(e) + K_{ab}{}^c + L_{ab}{}^c, \tag{1.95}$$

where $\omega(e)$ is the (*Cartan* or even *Levi-Civita*) connection related to the Levi-Civita connection $\Gamma(g)$ by Eq. (1.92). It is completely determined by the Vielbeins through the anholonomy coefficients defined in Eq. (1.83):

$$\omega_{ab}{}^c(e) = \left\{ {c \atop a\,b} \right\} + \{-\Omega_{ab}{}^c + \Omega_b{}^c{}_a - \Omega^c{}_{ab}\}, \tag{1.96}$$

where

$$\left\{ {c \atop a\,b} \right\} = \tfrac{1}{2} g^{cd} \{ \partial_a g_{bd} + \partial_b g_{ad} - \partial_d g_{ab} \}. \tag{1.97}$$

$K_{ab}{}^{c}$ is nothing but the contorsion tensor expressed in a tangent-space basis, i.e. $K_{ab}{}^{c} = e_a{}^{\mu} e_b{}^{\nu} e^c{}_{\rho} K_{\mu\nu}{}^{\rho}$ and, similarly, $L_{ab}{}^{c} = e_a{}^{\mu} e_b{}^{\nu} e^c{}_{\rho} L_{\mu\nu}{}^{\rho}$.

Observe that

$$\omega_{a(bc)} = \tfrac{1}{2} (Q_{abc} + \partial_a g_{bc}). \tag{1.98}$$

We can impose the metric-compatibility condition Eq. (1.49), which in this context is known as the *second Vielbein postulate*, and we have a Riemann–Cartan spacetime U_d. The result is that Γ is again given by Eqs. (1.54), (1.44), and (1.45), and ω (which is related to Γ by the first Vielbein postulate) is given by

$$\omega_{ab}{}^{c} = \omega_{ab}{}^{c}(e) + K_{ab}{}^{c}. \tag{1.99}$$

If we now impose the vanishing of torsion, we obtain the Levi-Civita and Cartan connections $\Gamma(g)$ and $\omega(e)$ and we recover a Riemann spacetime V_d.

The two most important cases to which we can apply this general formalism are the following.

1. The case in which we use a coordinate basis $e_a{}^{\mu} = \delta_a{}^{\mu}$, so $g_{ab} = g_{\mu\nu}$, $\Omega = 0$, and the connections Γ and ω are identical.
2. The case in which we use an orthonormal basis $g_{ab} = \eta_{ab}$ in which

$$\left\{ {c \atop a\,b} \right\} = 0$$

and

$$\omega_{abc} = \omega_{abc}(e) + K_{abc} + L_{abc}, \qquad \omega_{abc}(e) = -\Omega_{abc} + \Omega_{bca} - \Omega_{cab}. \tag{1.100}$$

In the second case we would like to restrict ourselves to those changes of frame that preserve the form of the metric in tangent-space indices (here usually referred to as *flat indices* because they are raised and lowered with the flat space metric). By definition, these are transformations of the d-dimensional Lorentz group $\mathrm{SO}(1, d-1)$ whose gauge theory we are now led to consider. This gauge theory is developed in Section A.2.3 of Appendix A and the spinorial representations of the Lorentz group are studied in Appendix D. We are simply going to rewrite here the main formulae we have obtained, adapted to the Lorentz subgroup of $\mathrm{GL}(d, \mathbb{R})$.

The main justification for making this step is that the Lorentz group admits spinorial representations, which are necessary in order to describe fermions, whereas the diffeomorphism group of a manifold does not. This is the only known method by which to describe spinors in curved spacetime in arbitrary coordinates and, thus, the only method known to couple fermions to gravity. This formalism was pioneered by Weyl [1252].

First of all, the generators M_I of the Lorentz subgroup of $\mathrm{GL}(d,\mathbb{R})$ are just the antisymmetric combinations of those of $\mathrm{GL}(d,\mathbb{R})$ and can be labeled by two antisymmetric vector indices, i.e. M_{ab}. In this notation every generator appears twice and factors of $\frac{1}{2}$ have to be included in the right places. However, in general, the connection $\omega_\mu{}^{ab}$ is not antisymmetric in the "gauge" indices ab unless it is also metric compatible ($\mathcal{D}\eta_{ab}=0$), according to Eq. (1.98). We are going to consider only metric-compatible connections that are fully antisymmetric in the gauge indices and we will call them *spin connections*.[12]

Using the explicit form of the infinitesimal Lorentz generators in the vector representation $\Gamma_{\mathrm{v}}(M_{bc})^a{}_d$ given in Eq. (A.60) and in the spinorial representation $\Gamma_{\mathrm{s}}(M_{ab})^\alpha{}_\beta$ (we use temporarily the first few Greek letters $\alpha,\beta,\ldots$ as spinorial indices) given in Eq. (D.3), we find the following expressions for the (total) covariant derivatives of contravariant and covariant vectors and spinors:

$$\begin{aligned}
\nabla_\mu\xi^a &= \partial_\mu\xi^a - \tfrac{1}{2}\omega_\mu{}^{bc}\Gamma_{\mathrm{v}}(M_{bc})^a_d\xi^d = \partial_\mu\xi^a + \omega_{\mu b}{}^a\xi^b,\\
\nabla_\mu\varepsilon_a &= \partial_\mu\varepsilon_a + \varepsilon_d\tfrac{1}{2}\omega_\mu{}^{bc}\Gamma_{\mathrm{v}}(M_{bc})^d_a = \partial_\mu\varepsilon_a - \varepsilon_b\,\omega_{\mu a}{}^b,\\
\nabla_\mu\psi^\alpha &= \partial_\mu\psi^\alpha - \tfrac{1}{2}\omega_\mu{}^{ab}\Gamma_{\mathrm{s}}(M_{ab})^\alpha{}_\beta\psi^\beta = \partial_\mu\psi^\alpha - \tfrac{1}{4}\omega_\mu{}^{ab}(\Gamma_{ab})^\alpha{}_\beta\psi^\beta,\\
\nabla_\mu\varphi_\alpha &= \partial_\mu\varphi_\alpha + \varphi_\beta\tfrac{1}{2}\omega_\mu{}^{ab}\Gamma_{\mathrm{s}}(M_{ab})^\beta{}_\alpha = \partial_\mu\varphi_\alpha + \varphi_\beta\tfrac{1}{4}\omega_\mu{}^{ab}(\Gamma_{ab})^\beta{}_\alpha.
\end{aligned}\tag{1.101}$$

These definitions, once we impose the Vielbein postulates, are consistent with the raising and lowering of vector indices with the Minkowski metric and with Dirac conjugation of the spinors. With the postulates, the spin connection is given by Eqs. (1.100).

The Ricci identities can now be written for the total covariant derivative in this form:

$$\begin{aligned}
[\nabla_\mu,\nabla_\nu]\,\phi &= T_{\mu\nu}{}^\rho\nabla_\rho\phi,\\
[\nabla_\mu,\nabla_\nu]\,\xi^a &= R_{\mu\nu b}{}^a(\omega)\xi^b + T_{\mu\nu}{}^\rho\nabla_\rho\xi^a,\\
[\nabla_\mu,\nabla_\nu]\,\varepsilon_a &= -\varepsilon_b R_{\mu\nu a}{}^b(\omega) + T_{\mu\nu}{}^\rho\nabla_\rho\varepsilon_a,\\
[\nabla_\mu,\nabla_\nu]\;\psi &= -\tfrac{1}{4}R_{\mu\nu}{}^{ab}(\omega)\Gamma_{ab}\psi + T_{\mu\nu}{}^\rho\nabla_\rho\psi,\\
[\nabla_\mu,\nabla_\nu]\;\varphi &= +\tfrac{1}{4}\varphi R_{\mu\nu}{}^{ab}(\omega)\Gamma_{ab} + T_{\mu\nu}{}^\rho\nabla_\rho\varphi.
\end{aligned}\tag{1.102}$$

For more general tensors one has to add a curvature (ω) term for each flat index and a curvature (Γ) term for each world index. The curvatures have the same form as in Eqs. (1.27) and (1.89) but now $R_{\mu\nu}{}^{ab}$ is antisymmetric in ab.

The following expression is sometimes used:

$$R_{ab} = -\partial_a\omega_c{}^c{}_b - \partial_c\omega_{ab}{}^c + \omega_{cda}\omega^{dc}{}_b + \omega_{abd}\omega_c{}^{cd}.\tag{1.103}$$

The Vielbein formalism allows us to study the Weitzenböck spacetime defined on p. 11.

1.4.1 Weitzenböck spacetime A_d

This spacetime is defined by a metric-compatible connection that we denote by $W_{\mu\nu}{}^\rho$ and call the *Weitzenböck connection* [1243, 1244] whose Riemann curvature is identically zero,

---

[12] If we wanted to have a non-metric-compatible spin connection, we would have to modify the first Vielbein postulate.

$R_{\mu\nu\rho}{}^{\sigma}(W)=0$. Trying to solve this equation directly for $W\neq 0$ is a very difficult task. However, we can use the Vielbein formalism to find a solution. Let us denote by $W_{\mathrm{s}\,\mu}{}^{ab}$ the tangent-space connection associated with W via the first Vielbein postulate

$$\nabla_{\mu}e^{a}{}_{\nu}=\partial_{\mu}e^{a}{}_{\nu}-W_{\mu\nu}{}^{a}+W_{\mathrm{s}\,\mu\nu}{}^{a}=0. \tag{1.104}$$

The curvature of W_{s} is obviously zero on account of Eq. (1.93). Now, however, we can use the trivial solution to the equation $R_{\mu\nu}{}^{ab}(W_{\mathrm{s}})=0$, namely $W_{\mathrm{s}}=0$, because, according to the above relation, $W_{\mathrm{s}}=0$ does not imply $W=0$ but

$$W_{\mu\nu}{}^{\rho}=e_{a}{}^{\rho}\partial_{\mu}e^{a}{}_{\nu}. \tag{1.105}$$

This is the Weitzenböck connection whose curvature vanishes identically. It cannot be rewritten in terms of the metric: it is necessary to use the Vielbein formalism. Observe that, using this connection, we can write the relation between any two connections Γ and ω satisfying the first Vielbein postulate in the form

$$\Gamma_{\mu\nu}{}^{\rho}=W_{\mu\nu}{}^{\rho}+\omega_{\mu\nu}{}^{\rho}. \tag{1.106}$$

$\omega_{\mu\nu}{}^{\rho}$ is a tensor, but $\Gamma_{\mu\nu}{}^{\rho}$ is not (it is an affine connection), and responsible for this is the Weitzenböck connection $W_{\mu\nu}{}^{\rho}$. We can also write

$$\omega_{\mu}{}^{ab}=\Gamma_{\mu}{}^{ab}-W_{\mu}{}^{ab},\qquad W_{\mu}{}^{ab}=e^{a\nu}\partial_{\mu}e^{b}{}_{\nu}. \tag{1.107}$$

Now $\Gamma_{\mu}{}^{ab}$ is a $\mathrm{GL}(d,\mathbb{R})$ tensor in the upper two indices whereas $\omega_{\mu}{}^{ab}$ is not (because it is a $\mathrm{GL}(d,\mathbb{R})$ connection). Again, the Weitzenböck connection $W_{\mu}{}^{ab}$ is responsible for this.

Even though we have to search explicitly for a metric-compatible connection to find W, it is easy to check that it is indeed metric compatible. Then, it can be decomposed into the sum of the Levi-Civita connection and the contorsion tensor. The torsion tensor is

$$T_{\mu\nu}{}^{\rho}=-2\Omega_{\mu\nu}{}^{\rho}, \tag{1.108}$$

and, therefore, the contorsion tensor is given by

$$K_{\mu\nu\rho}(W)=\Omega_{\mu\nu\rho}-\Omega_{\nu\rho\mu}+\Omega_{\rho\mu\nu}=-\omega_{\mu\nu\rho}(e), \tag{1.109}$$

where $\omega(e)$ is, as usual, the Cartan connection (which is associated via the first Vielbein postulate with the Levi-Civita connection $\Gamma(g)$).

Now, if we use Eqs. (1.31) and (1.32) for $\tilde{\Gamma}=W,\Gamma=\Gamma(g)$, and $\tau=K$, we find an expression for the Riemann curvature tensor of the Levi-Civita connection in terms of the contorsion tensor of the Weitzenböck connection:

$$R_{\mu\nu\rho}{}^{\sigma}[\Gamma(g)]=-2\nabla_{[\mu}K_{\nu]\rho}{}^{\sigma}-2K_{[\mu|\lambda}{}^{\sigma}K_{|\nu]\rho}{}^{\lambda}. \tag{1.110}$$

On contracting indices, and eliminating a total derivative, we find that

$$\int d^{d}x\,\sqrt{|g|}\,R(g)=-\int d^{d}x\,\sqrt{|g|}\,\left\{K_{\mu}{}^{\mu\lambda}K_{\mu}{}^{\mu}{}_{\lambda}+K_{\nu}{}^{\mu\rho}K_{\mu\rho}{}^{\nu}\right\}, \tag{1.111}$$

which can be expressed entirely in terms of the anholonomy coefficients $\Omega_{\mu\nu\rho}$, providing an alternative form of the Einstein–Hilbert action. This is, in fact, an alternative way of deriving Palatini's identity Eq. (L.4).

It is worth stressing here that the building blocks of the Riemann curvature tensor of the Levi-Civita connection in the above expression (the anholonomy coefficients/torsion and contorsion) are tensors, whereas in the standard expression for the curvature the building blocks are the Christoffel symbols, which are not tensors.

The main property of the Weitzenböck spacetime (the vanishing of the curvature) implies that parallel transport is path independent and it is possible to define parallelism of vectors *at different spacetime points*:[13] two vectors $v^\mu(x_1), w^\mu(x_2)$ are parallel if their components in the Vielbein basis $\{e_a{}^\mu\}$ are proportional. This is a consistent definition because the components in the Vielbein basis are invariant under the parallel transport defined by the W connection associated with that Vielbein basis. Indeed, the vector $v^\mu(x)$, parallel-transported to $x^\mu + \epsilon^\mu$ is

$$v^\mu(x+\epsilon) = v^\mu(x) - \epsilon^\nu v^\rho(x) W_{\nu\rho}{}^\mu(x), \tag{1.112}$$

and its tangent-space components can be found with the inverse Vielbein basis at $x^\mu + \epsilon^\mu$:

$$\begin{aligned} e^a{}_\mu(x+\epsilon)v^\mu(x+\epsilon) &= [e^a{}_\mu(x) + \epsilon^\nu \partial_\nu e^a{}_\mu(x)][v^\mu(x) - \epsilon^\nu v^\rho(x) W_{\nu\rho}{}^\mu(x)] \\ &= e^a{}_\mu(x) v^\mu(x). \end{aligned} \tag{1.113}$$

Also, it can be shown that the vanishing of the curvature is equivalent to the existence of d vector fields (the Vielbeins) covariantly constant with respect to the W connection,

$$\overset{W}{\nabla}_\mu\, e^a{}_\nu = \partial_\mu e^a{}_\nu - W_{\mu\nu}{}^\rho e^a{}_\rho = 0. \tag{1.114}$$

1.5 Killing vectors

If, given a metric $g_{\mu\nu}$, there exists a vector field k^μ such that the Lie derivative of $g_{\mu\nu}$ with respect to it vanishes,

$$\mathcal{L}_k g_{\mu\nu} = 2\nabla_{(\mu} k_{\nu)} = 0, \tag{1.115}$$

we say that $g_{\mu\nu}$ admits the *Killing vector* k^μ. The above equation is the *Killing equation*. It means that the metric does not change along the integral curves of k^μ and it is also said that the metric possesses an *isometry* in the direction k^μ. If the metric does not change along the integral curves of a Killing vector, and we use as a coordinate the parameter of those integral curves (*adapted coordinates*), then the metric does not depend on that coordinate.

The Ricci identity implies the following consistency condition:[14]

$$\nabla_\alpha \nabla_\beta k_\nu = -R^\lambda{}_{\alpha\beta\nu} k_\lambda, \quad \Rightarrow \nabla^2 k^\mu = R^\mu{}_\nu k^\nu. \tag{1.116}$$

---

[13] Also known as *teleparallelism* or *absolute parallelism*.

[14] These equations can be obtained as follows: from the Killing equation we have

$$\nabla_\alpha \nabla_{(\beta} k_{\gamma)} = 0, \qquad \text{and} \qquad \nabla_\alpha \nabla_{(\beta} k_{\gamma)} + \nabla_\beta \nabla_{(\gamma} k_{\alpha)} - \nabla_\gamma \nabla_{(\alpha} k_{\beta)} = 0.$$

The last equation can be rewritten in the form

$$\nabla_{(\alpha} \nabla_{\beta)} k_\gamma = -\tfrac{1}{2}[\nabla_\alpha, \nabla_\gamma] k_\beta - \tfrac{1}{2}[\nabla_\beta, \nabla_\gamma] k_\alpha,$$

A weaker but also interesting property that a metric can have is a *conformal isometry*. This happens when there is a vector field c^μ along whose integral curves the metric changes only by a conformal factor,

$$\mathcal{L}_c g_{\mu\nu} = 2\nabla_{(\mu}c_{\nu)} = 2\lambda g_{\mu\nu}. \tag{1.117}$$

On taking the trace of the above equation, we find in d dimensions

$$\lambda = \frac{1}{d}\nabla_\mu c^\mu, \quad \Rightarrow \nabla_{(\mu}c_{\nu)} - \frac{1}{d}g_{\mu\nu}\nabla_\rho c^\rho = 0, \tag{1.118}$$

called the *conformal Killing equation*; c^μ is then known as a *conformal Killing vector*.

1.6 Duality operations

The antisymmetric Levi-Civita tensor is defined in d dimensions in tangent space by

$$\epsilon^{01\cdots(d-1)} = +1, \qquad \Rightarrow \epsilon_{01\cdots(d-1)} = (-1)^{d-1}, \tag{1.119}$$

and in curved indices by

$$\epsilon^{\mu_1\cdots\mu_d} = \sqrt{|g|}\, e^{\mu_1}{}_{a_1}\cdots e^{\mu_d}{}_{a_d}\epsilon^{a_1\cdots a_d}, \tag{1.120}$$

so, with upper indices, it is independent of the metric and, in curved indices, which we underline to distinguish them from the tangent-space ones,

$$\epsilon^{\underline{0}\cdots\underline{(d-1)}} = +1, \qquad \epsilon_{\underline{0}\cdots\underline{(d-1)}} = g = (-1)^{d-1}|g|. \tag{1.121}$$

The contraction of n indices of two ϵ symbols gives

$$\epsilon^{\mu_1\cdots\mu_n\rho_1\cdots\rho_{(d-n)}}\epsilon_{\mu_1\cdots\mu_n\sigma_1\cdots\sigma_{(d-n)}} = n!(d-n)!\, g\, g^{\rho_1\cdots\rho_{(d-n)}}{}_{\sigma_1\cdots\sigma_{(d-n)}}, \tag{1.122}$$

where

$$\begin{aligned} g^{\rho_1\cdots\rho_{(d-n)}}{}_{\sigma_1\cdots\sigma_{(d-n)}} &= g_{[\rho_1}{}^{\sigma_1}\cdots g_{\rho_{(d-n)}]}{}^{\sigma_{(d-n)}} \\ &= \frac{1}{(d-n)!}\begin{vmatrix} g_{\rho_1}{}^{\sigma_1} & \cdots & g_{\rho_1}{}^{\sigma_{(d-n)}} \\ \vdots & \vdots & \vdots \\ g_{\rho_{(d-n)}}{}^{\sigma_1} & \cdots & g_{\rho_{(d-n)}}{}^{\sigma_{(d-n)}} \end{vmatrix}. \end{aligned} \tag{1.123}$$

---

and, using the Ricci identities for the l.h.s.,

$$\nabla_{(\alpha}\nabla_{\beta)}k_\gamma = \tfrac{1}{2}k_\lambda R_{\alpha\gamma\beta}{}^\lambda + \tfrac{1}{2}k_\lambda R_{\beta\gamma\alpha}{}^\lambda.$$

Now, using the Bianchi identities for the metric-compatible torsionless curvature we get

$$\nabla_{(\alpha}\nabla_{\beta)}k_\gamma = -k_\lambda R^\lambda{}_{\alpha\beta\gamma} + \tfrac{1}{2}k_\lambda R^\lambda{}_{\gamma\beta\alpha}.$$

Combining this equation with the Ricci identity

$$\nabla_{[\alpha}\nabla_{\beta]}k_\gamma = -\tfrac{1}{2}k_\lambda R_{\alpha\beta\gamma}{}^\lambda = \tfrac{1}{2}k_\lambda R^\lambda{}_{\gamma\alpha\beta},$$

we obtain Eq. (1.116).

4.5 Gravity as a gauge theory

In Ref. [916] MacDowell and Mansouri formulated gravity as the gauge theory of the Poincaré group and supergravity as the gauge theory of the super-Poincaré group.[18] This approach was later extended successfully to many other situations, and it is interesting enough to review it briefly here because the similarities with and differences of gravity from the gauge theories of internal symmetries (some of which we have already mentioned) are manifest in this formulation. Here we will loosely follow Refs. [983, 565].

One of the differences we observed in Section 4.4 between the first-order formalism for gravity using Vielbeins and spin connection and a pure gauge theory is that we did not have an interpretation of the Vielbeins as gauge fields. Furthermore, our intuition tells us that, if gravity can be interpreted as a gauge theory at all, it cannot be a gauge theory of the Lorentz group alone and that at least gauge translations should be introduced into the game. We should then consider the gauging of the Poincaré group. It is worth stressing here that we are talking about the "Poincaré group of the tangent space." That is, at each point in the base manifold, which may but need not be invariant under any translational isometry, we consider inhomogeneous transformations of Lorentz vectors preserving the Minkowski metric. The relation between these gauge transformations and GCTs is one of the subtle points of this formulation of gravity.

To find the generators of the Poincaré group and their commutation relations, we can use the representation in position space (as differential operators) or alternatively we can use the following representation by $(d+1)\times(d+1)$ matrices of Poincaré transformations composed of a translation a^a and a Lorentz transformation $\Lambda^a{}_b$:

$$\begin{pmatrix} 1 \\ v'^{\,a} \end{pmatrix} = \left(\begin{array}{c|c} 1 & 0 \\ \hline a^a & \Lambda^a{}_b \end{array}\right) \begin{pmatrix} 1 \\ v^b \end{pmatrix}. \tag{4.146}$$

This representation is suggestive because of its $(d+1)$-dimensional homogeneous form. We will see later that there is a reason for its existence.

We give here again the non-vanishing commutators of the generators $\{M_{ab}, P_a\}$:

$$\begin{aligned} [M_{ab}, M_{cd}] &= -M_{eb}\Gamma_{\rm v}(M_{cd})^e{}_a - M_{ae}\Gamma_{\rm v}(M_{cd})^e{}_b, \\ [P_c, M_{ab}] &= -P_d\Gamma_{\rm v}(M_{ab})^d{}_c. \end{aligned} \tag{4.147}$$

Here $\Gamma_{\rm v}(M_{ab})^d{}_c$ is the matrix corresponding to the generator M_{ab} in the vector representation of the Lorentz group. The last commutator says that the d generators of translations P_a can be understood as the components of a Lorentz vector. Observe that P_a acts trivially on objects with Lorentz indices. It would act non-trivially on objects with a non-trivial "$(d+1)$th" index in the above representation, but by construction they do not exist.

For each generator we would introduce a gauge field: the spin connection $\omega_\mu{}^{ab}$ for the Lorentz subalgebra plus d new gauge fields for the translation subalgebra. Our theory has d Vielbein fields with Lorentz-vector indices and it is natural to try to interpret them as the gauge fields of translations; the gauge field of the Poincaré group would, tentatively, be, in some representation Γ,

$$A_\mu = \tfrac{1}{2}\omega_\mu{}^{ab}\Gamma(M_{ab}) + e_\mu{}^a\Gamma(P_a)\,. \tag{4.148}$$

---

[18] The earliest work on this subject is in Ref. [1207].

Observe that, since P_a does not act on objects with Lorentz indices, the covariant derivative contains in practice only the spin connection.

If we can reproduce Einstein's theory with these elements, we could say that Einstein's theory is the pure gauge theory of the Poincaré group. We are going to see whether this is possible. First we determine the effect of gauge transformations using the standard formalism of Appendix A. If σ^{ab} and ξ^a are the infinitesimal gauge parameters of Lorentz rotations and translations, then

$$\delta\omega_\mu{}^{ab} = -\mathcal{D}_\mu\sigma^{ab}, \qquad \delta e_\mu{}^a = -\mathcal{D}_\mu\xi^a + \sigma^a{}_b e_\mu{}^b. \tag{4.149}$$

In both cases $\mathcal{D}$ stands for the gauge-covariant derivative (no Levi-Civita connection is contained in it because, for the moment, we have no metric but a gauge field $e_\mu{}^a$). It is useful to compare the second Eq. (4.149) with the effect of an infinitesimal GCT generated by the world vector ξ^μ (unrelated in principle to the Lorentz vector ξ^a):

$$\begin{aligned} \delta_\xi x^\mu &= \xi^\mu, \\ \delta_\xi e^a{}_\mu &= -\xi^\nu\partial_\nu e^a{}_\mu - \partial_\mu\xi^\nu e^a{}_\nu = -\mathcal{D}_\mu(\xi^\nu e^a{}_\nu) + 2\xi^\nu\mathcal{D}_{[\mu}e^a{}_{\nu]} - (\xi^\nu\omega_\nu{}^a{}_b)e^b{}_\mu. \end{aligned} \tag{4.150}$$

The covariant derivative is, again, the Poincaré (Lorentz) gauge one. The effect of an infinitesimal reparametrization is identical to the effect of a P_a gauge transformation with parameter $\xi^a = \xi^\mu e^a{}_\mu$ plus a local Lorentz transformation with parameter $\sigma^{ab} = \xi^\mu\omega_\mu{}^{ab}$ *if* $\mathcal{D}_{[\mu}e^a{}_{\nu]}$ *vanishes*.

We know that this condition is equivalent to the vanishing of torsion and we know that this constraint allows us to express $\omega_\mu{}^{ab}$ in terms of $e^a{}_\mu$. If we implement this constraint in our gauge theory, it will automatically become invariant under reparametrizations.[19] It is implemented in the first-order formalism of Section 4.4, where it appears as the equation of motion of $\omega_\mu{}^{ab}$.

The next step is to construct the gauge field strength:

$$\begin{aligned} R_{\mu\nu} &= \tfrac{1}{2}R_{\mu\nu}{}^{ab}\Gamma(M_{ab}) + R_{\mu\nu}{}^a\Gamma(P_a)\,, \\ R_{\mu\nu}{}^{ab} &= 2\partial_{[\mu}\omega_{\nu]}{}^{ab} - 2\omega_{[\mu}{}^a{}_c\omega_{\nu]}{}^{cb}, \\ R_{\mu\nu}{}^a &= 2\mathcal{D}_{[\mu}e^a{}_{\nu]}. \end{aligned} \tag{4.151}$$

The last line is identically equal to $-T_{\mu\nu}{}^a$. Thus, we have just learned that torsion can be interpreted in this formalism as the part of the gauge field strength that is associated with translations.

Now the moment to construct the action arrives. As already mentioned, in order to recover the constraint $R_{\mu\nu}{}^a$, the action has to be linear in the curvature components $R_{\mu\nu}{}^{ab}$. The requirement of Lorentz invariance also makes it very difficult to build quadratic actions (different from $\mathrm{Tr}(R \wedge \star R)$, which is wrong for gravity) that are not trivial (i.e. they do not correspond to topological invariants). We are then led to the action Eq. (4.129), which we know is correct.

---

[19] In supergravity formulated as the gauge theory of a supergroup the problem is how to relate supersymmetry transformations (in general super-reparametrizations in superspace) to gauge transformations associated with the supersymmetry and translation generators.

What have we learned by considering the gauge theory of the Poincaré group? Essentially we have given a gauge-field interpretation to Vielbeins (although we have not justified why they have to be invertible) and we have found that constraints are necessary in order to relate Poincaré gauge invariance to reparametrization invariance. The construction of the action is still rather ad hoc.

A slight improvement of the situation was achieved by MacDowell and Mansouri [916] (see also Refs. [339, 330, 1153]), who used it to construct supergravity actions [565]. Working in four dimensions, they considered the anti-de Sitter group $\mathrm{SO}(2,3)$. Upon performing a Wigner–Inönü contraction [817] (which is essentially the zero-cosmological-constant limit), this group becomes the Poincaré group $\mathrm{ISO}(1,3)$ and one recovers our previous results.

More precisely, we introduce $\mathrm{SO}(2,3)$ indices $\hat{a},\hat{b},\dots=-1,0,1,2,3$. The metric is $\hat{\eta}^{\hat{a}\hat{b}}=\mathrm{diag}(++---)$, and the algebra $\mathfrak{so}(2,3)$ can be written in the general form

$$\left[\hat{M}_{\hat{a}\hat{b}},\hat{M}_{\hat{c}\hat{d}}\right]=-\hat{\eta}_{\hat{a}\hat{c}}\hat{M}_{\hat{b}\hat{d}}-\hat{\eta}_{\hat{b}\hat{d}}\hat{M}_{\hat{a}\hat{c}}+\hat{\eta}_{\hat{a}\hat{d}}\hat{M}_{\hat{b}\hat{c}}+\hat{\eta}_{\hat{b}\hat{c}}\hat{M}_{\hat{a}\hat{d}}. \tag{4.152}$$

To perform the contraction, we need to introduce a dimensional parameter. This is, naturally, g, the gauge coupling constant in gauged $d=4$, $N=2$ supergravity; g is related to the AdS_4 radius R and to the cosmological constant Λ by

$$R=1/g=\sqrt{-3/\Lambda}. \tag{4.153}$$

We can now perform a $1+4$ splitting of the indices $\hat{a}=(-1,a)$, $a=0,1,2,3$, to interpret this algebra from the point of view of the Lorentz subalgebra $\mathfrak{so}(1,3)$. On defining

$$\hat{M}_{ab}=M_{ab}, \qquad \hat{M}_{a-1}=-g^{-1}P_a, \tag{4.154}$$

we can rewrite the AdS_4 algebra as follows:

$$\begin{aligned}
[M_{ab},M_{cd}]&=-\eta_{ac}M_{bd}-\eta_{bd}M_{ac}+\eta_{ad}M_{bc}+\eta_{bc}M_{ad},\\
[P_c,M_{ab}]&=-2P_{[a}\eta_{b]c}, \qquad [P_a,P_b]=-g^2M_{ab}.
\end{aligned} \tag{4.155}$$

Taking the limit $g\to 0$, we recover the Poincaré algebra.

We could equally well have started with the four-dimensional de Sitter group $\mathrm{SO}(1,4)$. The difference is that, instead of having an extra timelike direction (which we have denoted with a -1 index), we have an extra spacelike direction (which we would denote with a 4 index). The two spaces (and groups) are related by analytic continuation $x^{-1}\to x^4$, and, in the contraction of the extra dimension, we would find that the sign of the cosmological constant is reversed ($g\to ig$). We will use a general notation and point out where differences between the two groups could arise. However, one should keep in mind that only the anti-de Sitter space is a good background for QFT and only its group can consistently be supersymmetrized.

The gauge theory of the AdS_4 group is just a particular case of the general construction in Appendix A.2.3. We can also perform the contraction in the gauge field and curvature. First, we split the indices in the connection and then we rescale the gauge fields inversely to the generators:

$$\begin{aligned}\hat{\omega}_\mu &= \tfrac{1}{2}\hat{\omega}_\mu{}^{\hat{a}\hat{b}}\Gamma\left(\hat{M}_{\hat{a}\hat{b}}\right) = \tfrac{1}{2}\hat{\omega}_\mu{}^{ab}\Gamma\left(\hat{M}_{ab}\right) + \hat{\omega}_\mu{}^{a,-1}\Gamma\left(\hat{M}_{a,-1}\right) \\ &= \tfrac{1}{2}\omega_\mu{}^{ab}\Gamma(M_{ab}) + e^a{}_\mu\Gamma(P_a)\,, \end{aligned} \tag{4.156}$$

where

$$\hat{\omega}_\mu{}^{ab} = \omega_\mu{}^{ab}, \qquad \hat{\omega}_\mu{}^{a,-1} = -g e^a{}_\mu. \tag{4.157}$$

In this scheme, linear momentum and Vierbeins are on the same footing as the rest of the generators and gauge fields. This is obviously due to the semisimple nature of the AdS_4 group. There is some resemblance between this structure and the idea of grand unification in particle physics, although there are also obvious differences.

We can also split and rescale the curvature components, expressing everything in terms of Lorentz tensors:

$$\hat{R}_{\mu\nu}{}^{ab} = R_{\mu\nu}{}^{ab} + 2g^2 e^{[a}{}_\mu e^{b]}{}_\nu, \qquad \hat{R}_{\mu\nu}{}^{a,-1} = 2g\mathcal{D}_{[\mu}e^a{}_{\nu]}. \tag{4.158}$$

Now we can address again the construction of a quadratic action for this group. To have diffeomorphism invariance, the Lagrangian has to be a 4-form that we can integrate over a four-dimensional manifold and, therefore, the exterior product of two curvature terms $R \wedge R$. We now have to saturate the $\mathfrak{so}(2,3)$ indices. If we did it with the Killing metric, we would manifest SO(2, 3) invariance but the Lagrangian would be a total derivative, as in any Yang–Mills theory. Thus, we have to give up explicit SO(2, 3) invariance. We have to keep Lorentz invariance, though, and with the only two invariant tensors of the Lorentz group $(\eta_{ab}, \epsilon_{abcd})$ we can build two terms:

$$\hat{R}^{ab} \wedge \hat{R}^{cd}\epsilon_{abcd}, \qquad \hat{R}^{a,-1} \wedge \hat{R}^{b,-1}\eta_{ab}. \tag{4.159}$$

The second term is not invariant under parity and for this reason it is discarded. The inclusion of this term would also introduce torsion and it would also lead to the existence of non-invertible Vierbeins (see the discussion in Ref. [565]).

The first term can also be given an SO(2,3)-invariant origin [1153]: by introducing a constant vector $V^{\hat{a}} = \eta^{\hat{a}}{}_{-1}$ it can be written using the invariant tensor $\hat{\epsilon}$, and we obtain the action

$$S = \alpha \int \hat{R}^{\hat{a}\hat{b}} \wedge \hat{R}^{\hat{c}\hat{d}} V^{\hat{e}}\hat{\epsilon}_{\hat{a}\hat{b}\hat{c}\hat{d}\hat{e}}. \tag{4.160}$$

This is only formally SO(2, 3) invariant because the vector would change under AdS_4 transformations. Nevertheless, this form of the action is very suggestive.

On expanding this action in terms of Lorentz tensors, we have

$$S = \alpha \int d^4x\, R_{\mu\nu}{}^{ab} R_{\rho\sigma}{}^{cd}\epsilon_{abcd}\epsilon^{\mu\nu\rho\sigma} - 16g^2\alpha \int d^4x\, e\left[R(e,\omega) + 6g^2\right]. \tag{4.161}$$

The first term is a total derivative (proportional to the Euler characteristic, a topological invariant) that does not contribute to the equations of motion, and the second term is the first-order Einstein–Hilbert action with cosmological constant $\Lambda = -3g^2$. In the

$g \to 0$ limit (provided that $\alpha \sim g^{-2}$) we recover the usual Einstein–Hilbert action plus a topological term. Observe that the variation of the action under P_a gauge transformations is proportional to torsion terms and, thus, vanishes on-shell.

This is a very attractive result, which, however, leaves some questions unanswered, such as the reason for the invertibility of the Vierbein and the value of the vector $V^{\hat{a}}$. A possible solution has been proposed by Wilczek [1255].

To finish this section, we should mention that the gauge approach has been extended to larger groups, such as the full d-dimensional affine group. A comprehensive review on these developments may be found in Ref. [738].

4.6 Teleparallelism

In this section we provide a short introduction to relativistic theories of gravity based on *teleparallelism*, i.e. theories in which there is a well-defined notion of parallelism of vectors defined at different points. In GR and other generalizations based on the Riemannian or Riemann–Cartan geometry, gravity, described by the metric or Vielbein fields, is characterized by a curvature; therefore, parallel transport is path dependent and there is no such well-defined (path-independent) notion of parallelism. Teleparallelism is based on the Weitzenböck geometry and the Weitzenböck connection $W_{\mu\nu}{}^{\rho}$ described in Section 1.4.1, which has identically vanishing curvature (but non-vanishing torsion[20]).

These theories are interesting for several reasons: first of all, GR can be viewed as a particular theory of teleparallelism and, thus, teleparallelism could be considered at the very least as a different point of view that can lead to the same results. Of course, there are teleparallel theories different from and even inconsistent with GR. Second, in this framework, one can define an energy–momentum tensor for the gravitational field that is a true tensor under all GCTs. This is the reason why teleparallelism was reconsidered[21] by Møller in 1961 [962] when he was studying the problem of defining an energy–momentum *tensor* for the gravitational field [960, 961]. The idea was taken over by Pellegrini and Plebański in Ref. [1025], which constructed the general Lagrangian for these theories. The third reason why these theories are interesting is that they can be seen as gauge theories of the translation group [735, 351] (not the full Poincaré group) and, thus, they give an alternative interpretation of GR.

The basic field in these theories is the Vielbein $e^{a}{}_{\mu}$. This field has d^2 independent components, while the metric has only $d(d+1)/2$. The extra independent components that the Vielbein field has are those of an antisymmetric $d \times d$ tensor, such as the electromagnetic-field-strength tensor $F_{\mu\nu}$, and that is why Einstein thought that these theories could describe gravitation and electromagnetism in a unified way. In the standard Vielbein formalism (Weyl's), the extra $d(d-1)/2$ independent components of the Vielbein field are removed by introducing local Lorentz invariance, with a Lorentz connection that is not an independent field but is built out of the Vielbeins. Here, we are not interested a priori in having this local invariance, and, in principle, we will construct only theories that are invariant under GCTs and global Lorentz transformations. Thus, as we will see, these theories describe in general more degrees of freedom than just those of a graviton.

---

[20] It is possible to have a non-trivial theory with vanishing curvature and torsion if the non-metricity tensor does not vanish. In Ref. [977] a theory equivalent to GR based on this geometry was constructed.

[21] Teleparallelism had originally been considered by Einstein, who studied it as a unified theory of gravitation and electromagnetism in Refs. [493, 494, 495, 496, 497] (see also Ref. [891]) until Ref. [502] showed that the particular theory considered by him was inconsistent.

The construction of the Lagrangian of these theories is fairly simple: we look for terms that have the required invariances and are, at most, quadratic in derivatives of the Vielbeins. The elementary building blocks are the Ricci rotation coefficients $\Omega_{\mu\nu}{}^{a} = \partial_{[\mu}e^{a}{}_{\nu]}$ that transform as tensors (2-forms) under GCTs and as vectors under (global) Lorentz transformations. In the context of the Weitzenböck geometry, the $-2\Omega_{\mu\nu}{}^{a}$s are the components of the torsion of Weitzenböck connection and, since there is no curvature tensor available, it is only natural to construct the Lagrangian using them.

In any dimension there are three terms with the required properties (they transform as densities under GCTs and as scalars under Lorentz transformations, being quadratic in first partial derivatives of the Vielbeins): the *Weitzenböck invariants* $I_1, \ldots, I_3$,

$$I_1 = e\,\Omega_{\mu\nu\rho}\Omega^{\mu\nu\rho}, \qquad I_2 = e\,\Omega_{\mu\nu\rho}\Omega^{\rho\nu\mu}, \qquad I_3 = e\,\Omega_{\mu\rho}{}^{\rho}\Omega^{\mu}{}_{\sigma}{}^{\sigma}. \tag{4.162}$$

There is another invariant I_4, which is quadratic only in $d = 4$:

$$I_4 = \epsilon^{\mu_1\cdots\mu_{d-3}\nu_1\nu_2\nu_3}\Omega_{\mu_1\rho_1}{}^{\rho_1}\Omega_{\mu_2\rho_2}{}^{\rho_2}\cdots\Omega_{\mu_{d-3}\rho_{d-3}}{}^{\rho_{d-3}}\Omega_{\nu_1\nu_2\nu_3}, \tag{4.163}$$

but it is not invariant under parity transformations (a further requirement) and it is usually not considered. Also, e by itself is another invariant (a cosmological-constant term) that we will not consider. Observe that all the Weitzenböck invariants involve the inverse Vielbeins $e_a{}^{\mu}$ and are, therefore, highly non-linear in the Vielbeins.

The general teleparallel Lagrangian of Pellegrini and Plebański [1025] is the integral of a linear combination of the Weitzenböck invariants with arbitrary coefficients:

$$\mathcal{L}_{\mathrm{T}} = \sum_{i=1}^{3} c^i I_i. \tag{4.164}$$

Only two of them are really independent since we can choose the overall normalization.

This general Lagrangian, written in differential-form language to relate it to the Poincaré gauge theory of gravity which is customarily written in it (see e.g. Ref. [738]), is known as the *Rumpf Lagrangian* [1088] (see also Refs. [683, 967]).

There are other ways to parametrize this Lagrangian, for instance by splitting Ω_{abc} into several pieces ${}^{(1)}\Omega$, ${}^{(2)}\Omega$, and ${}^{(3)}\Omega$ (*tentor, trator, and axitor*, respectively [683]). First we define

$$\begin{aligned} v_a &\equiv \Omega_{ab}{}^{b}, & {}^{(2)}\Omega_{abc} &= \frac{2}{1-d}\eta_{a[b}v_{c]}, \\ {}^{(3)}\Omega_{abc} &= \Omega_{[abc]}, & {}^{(1)}\Omega_{abc} &= \Omega_{abc} - {}^{(2)}\Omega_{abc} - {}^{(3)}\Omega_{abc}. \end{aligned} \tag{4.165}$$

Then, a Lagrangian equivalent to Pellegrini and Plebański's is [683]

$$\mathcal{L}_{\mathrm{T}} = e\,\Omega^{abc}\sum_{i=1}^{3} a_i\,{}^{(i)}\Omega_{abc}. \tag{4.166}$$

The relation between these two parametrizations is

$$a_1 = c_1 + \tfrac{1}{2}c_2, \quad a_2 = c_1 + \tfrac{1}{2}c_2 + \frac{d-1}{2}c_3, \quad a_3 = c_1 - c_2. \tag{4.167}$$

Another parametrization based on v_a, the tensors

$$a^{a_1\cdots a_{d-3}} = \frac{1}{3!}\epsilon^{a_1\cdots a_{d-3}b_1b_2b_3}\Omega_{b_1b_2b_3}, \qquad t_{abc} = \Omega_{a(bc)} - {}^{(2)}\Omega_{a(bc)}, \tag{4.168}$$

and the invariants $v^2, t^2,$ and a^2 can be found in Ref. [736].

4.6.1 The linearized limit

Our goal now is to try to understand which kind of theories are those defined by the Lagrangian Eq. (4.164). First, we observe with Møller [962] that, for $c_1 = 1, c_2 = 2,$ and $c_4 = -4$, this Lagrangian is identical (up to total derivatives) to the Einstein–Hilbert Lagrangian, and, therefore, gives the vacuum Einstein equations.[22] The Lagrangian turns out to be invariant under not just global but also local Lorentz transformations, and the only degrees of freedom left are (we know) those of the graviton. For general values of the parameters, the analysis is more complicated and it is convenient to start by studying the linear limit. To this end, we split the Vielbeins into their vacuum (Minkowski) values plus perturbations. Working in Cartesian coordinates for simplicity, we write

$$e^a{}_\mu = \delta^a{}_\mu + A^a{}_\mu. \tag{4.169}$$

For the inverse Vielbeins, we have

$$e_a{}^\mu = \delta_a{}^\mu - \delta_b{}^\mu\delta_a{}^\nu A^b{}_\nu + \mathcal{O}(A^2). \tag{4.170}$$

To this order we can unambiguously trade curved and flat indices, and the above formula can be rewritten:

$$e_a{}^\mu = \delta_a{}^\mu - A^\mu{}_a + \mathcal{O}(A^2), \qquad A^\mu{}_a \equiv \delta_b{}^\mu\delta_a{}^\nu A^b{}_\nu. \tag{4.171}$$

The metric perturbation that we have called $h_{\mu\nu}$ in previous chapters is given by the symmetric part of A at lowest order:

$$g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu} + \mathcal{O}(A^2), \quad h_{\mu\nu} \equiv 2A_{(\mu\nu)}, \quad b_{\mu\nu} \equiv 2A_{[\mu\nu]}, \quad A_{\mu\nu} \equiv \delta_{a\mu}A^a{}_\mu. \tag{4.172}$$

With these definitions it is straightforward to obtain, up to total derivatives, the linear limit of the action for the Lagrangian density Eq. (4.164):

$$\begin{aligned} S_{\mathrm{T}}[h,b] = \int d^dx \Big\{ & \frac{1}{16}(2c_1 + c_2)\partial_\mu h_{\nu\rho}\partial^\mu h^{\nu\rho} - \frac{1}{16}(2c_1 + c_2 - c_3)\partial_\mu h_{\nu\rho}\partial^\nu h^{\mu\rho} \\ & - \frac{1}{8}c_3\partial_\mu h\partial_\nu h^{\nu\mu} + \frac{1}{16}c_3(\partial h)^2 - \frac{1}{16}[4c_1 + 2(c_2 + c_3)]\partial_\mu h_{\nu\rho}\partial^\rho b^{\nu\mu} \\ & + \frac{1}{16}\partial_\mu b_{\nu\rho}\partial^\mu b^{\nu\rho} - \frac{1}{16}(2c_1 - 3c_2 - c_3)\partial_\mu b_{\nu\rho}\partial^\rho b^{\nu\mu} \Big\}. \end{aligned} \tag{4.173}$$

---

[22] In fact, this theory is sometimes referred to as the *teleparallel equivalent of GR*.

Table 4.1. Values of the parameters c_i in the general Lagrangian of Pellegrini and Plebański Eq. (4.164) for several theories: GR, the viable models, the Yang–Mills-type model (YM), and the von der Heyde model (vdH) [751] (which is one of the viable ones with $\lambda = 0$)

	GR	Viable	YM	vdH
c_1	1	$2 - \lambda$	2	2
c_2	2	2λ	0	0
c_3	-4	-4	0	-4

The first four terms are familiar to us: up to coefficients, they are the same terms as those that appear in the Fierz–Pauli Lagrangian Eq. (3.84). The last two terms are also well known: up to coefficients, they are exactly those that appear in the Lagrangian of the Kalb–Ramond 2-form field, which we still have not seen. The third term in the second line represents a coupling (already at the linear level) between these two fields.

Now, it is clear that it is not possible to recover solutions of the vacuum Fierz–Pauli theory if the coupling terms have a non-zero coefficient: a non-vanishing h field is a source for a non-vanishing b field and vice versa. Thus, the only theories which we expect to be phenomenologically viable are those in the family

$$2c_1 + c_2 + c_3 = 0. \tag{4.174}$$

Furthermore, both in the Kalb–Ramond and in the Fierz–Pauli cases, for certain choices of the coefficients, the action has a gauge invariance,

$$\delta_\epsilon h_{\mu\nu} = -2\partial_{(\mu}\epsilon_{\nu)}, \qquad \delta_\eta b_{\mu\nu} = 2\partial_{[\mu}\eta_{\nu]}, \tag{4.175}$$

whose existence is crucial for its consistent quantization. We also expect that only when these gauge invariances are present will the theory be consistent. It turns out that all these conditions are simultaneously met: let us eliminate c_3 using Eq. (4.174) and then, calling $c_2 = 2\lambda$, the action can be rewritten in the form

$$S_{\mathrm{T}}[h, b] = \frac{c_1 + \lambda}{2} S_{\mathrm{FP}}[h] + \frac{c_1 - \lambda}{2} S_{\mathrm{KR}}[b], \tag{4.176}$$

where $S_{\mathrm{FP}}[h]$ is the Fierz–Pauli action given in Eq. (3.84) and $S_{\mathrm{KR}}[b]$ is the Kalb–Ramond action

$$S_{\mathrm{KR}}[b] = \int d^d x \, \frac{1}{12} H^2, \qquad H_{\mu\nu\rho} \equiv 3\partial_{[\mu} b_{\nu\rho]}, \qquad H^2 = H_{\mu\nu\rho} H^{\mu\nu\rho}. \tag{4.177}$$

For $c_1 = \lambda$ ($c_2 = 2\lambda$, $c_3 = -4\lambda$), the Kalb–Ramond Lagrangian disappears. Up to an overall normalization constant and a total derivative, this teleparallel Lagrangian is completely equivalent to the Einstein–Hilbert Lagrangian, as we mentioned before. For $c_1 = -\lambda$ the Fierz–Pauli Lagrangian disappears and only the Kalb–Ramond Lagrangian remains. This theory does not describe gravity. If we are always going to keep the Fierz–Pauli Lagrangian, then it makes sense to set $c_1 = 2 - \lambda$ ($c_3 = -4,\ c_2 = 2\lambda$) and keep the one-parameter family of actions

$$S_{\rm T}[h, b] = S_{\rm FP}[h] + (1 - \lambda) S_{\rm KR}[b], \tag{4.178}$$

which represent viable models of gravity (in the sense that they fulfill the above requirements) based on teleparallelism (see Table 4.1). The case $\lambda = 0$ is the model proposed in Ref. [751].

Of course, we know that the full non-linear theory will be consistent only if additional conditions are satisfied. In particular, we know from our results in Chapter 3 that the quantization of the spin-2 field $h_{\mu\nu}$ will be consistent only if it couples to the total energy–momentum tensor, the sum of the spin-2 energy–momentum tensor and the Kalb–Ramond energy–momentum tensor, although the presence of the Kalb–Ramond field could modify this result. Checking that this is (or not) the case in the above family of theories requires an expansion to order $\mathcal{O}(A^3)$ that would be interesting to do.

It is amusing to compare these results with the linearized limit of the low-energy string effective action (see Chapter 21). The linearized actions are identical, except for the presence of the dilaton in the string case. However, the non-linear actions are quite different: in the string case, we simply have standard gravity coupled to matter (the Kalb–Ramond field) that appears only quadratically (at least to lowest order in α'), whereas, in the teleparallel case, the Kalb–Ramond field should also appear non-linearly in the full action.

It is possible to view the theories of teleparallelism as gauge theories of the group of translations [735, 351], with the Vielbeins playing the role of gauge vectors, but we will not enter into this interesting aspect.

From this point of view, if BHs can be understood as particle-like objects, looking for BHs with a well-defined scalar charge is utterly hopeless. One should look instead for "black strings" and instantons, and in due time we will do so and find them.[4]

There is another point of view concerning scalar fields: in some cases they should be interpreted not as matter fields but as "local coupling constants" (as in the case of the string-theory dilaton) or, more generally, as *moduli fields*, which we will define in Chapter 15, in which case they should be treated as backgrounds and there would be no room for the notion of scalar charge.

In conclusion, if we want to find new BH solutions, we need to couple the Einstein–Hilbert action to matter fields that have associated conserved charges. The charges must be those of point-particles or we will naturally obtain solutions describing extended objects instead of black holes. Thus, we have to consider vector fields, and the simplest one is an Abelian vector field A_μ. We are going to study in some detail the resulting system because later we will find generalizations of all the concepts and formulae developed here.

12.2 The Einstein–Maxwell system

The action for gravity coupled to an Abelian vector field A_μ is the so-called Einstein–Maxwell action[5] obtained by adding the Einstein–Hilbert and the Maxwell action with $\eta_{\mu\nu}, \partial_\mu$, and d^4x replaced by $g_{\mu\nu}, \nabla_\mu$, and d^4x:

$$\boxed{S_{\rm EM}[g_{\mu\nu}, A_\mu] = S_{\rm EH}[g] + \frac{1}{c}\int d^4x\sqrt{|g|}\,\left[-\tfrac{1}{4}F^2\right].} \tag{12.15}$$

$F_{\mu\nu}$ is the field strength of the electromagnetic vector field A_μ and is again given by

$$F_{\mu\nu} = 2\partial_{[\mu}A_{\nu]}, \qquad F^2 = F_{\mu\nu}F^{\mu\nu}, \tag{12.16}$$

since, in the absence of torsion, $\nabla_{[\mu}A_{\nu]} = \partial_{[\mu}A_{\nu]}$. The components of A_μ and $F_{\mu\nu}$ in a given coordinate system are customarily split in this way,

$$(A_\mu) = (\phi, -\vec{A}), \qquad (F_{\mu\nu}) = \begin{pmatrix} 0 & E_1 & E_2 & E_3 \\ -E_1 & 0 & -B_3 & B_2 \\ -E_2 & B_3 & 0 & -B_1 \\ -E_3 & -B_2 & B_1 & 0 \end{pmatrix}, \tag{12.17}$$

---

[4] This argument really applies to pseudoscalar fields.

[5] In this section we work in the Heaviside system of units, so the Coulomb force between two charges is

$$\frac{1}{4\pi}\frac{q_1 q_2}{r_{12}^2}. \tag{12.14}$$

In the Gaussian system we should replace $1/(4c)$ by $1/(16\pi c)$ and the factor of 4π disappears from the Coulomb force. The dimensions of the vector field A_μ are $\mathrm{M}^{1/2}\mathrm{L}^{1/2}\mathrm{T}^{-1}$ (that is, L^{-1} in natural units $\hbar = c = 1$) and the electric charge's units are $M^{1/2}L^{3/2}T^{-1}$, so it is dimensionless in natural units. At the end we will introduce another system of units, which will be the one we more often will work with, taking $c = 1$ and replacing the factor of $1/(4c)$ in front of F^2 by $1/\big(64G_{\rm N}^{(4)}\big)$.

where $\vec{E} = (E_1, E_2, E_3)$ and $\vec{B} = (B_1, B_2, B_3)$ are the electric and magnetic 3-vector fields in that coordinate system, and, thus, with $\vec{\nabla} = (\partial_{\underline{1}}, \partial_{\underline{2}}, \partial_{\underline{3}})$,

$$\begin{cases} E_i = F_{\underline{0i}}, \\ B_i = -\frac{1}{2}\epsilon_{ijk} F_{\underline{kl}}, \end{cases} \qquad \Leftrightarrow \qquad \begin{cases} \vec{E} = -\vec{\nabla}\phi - \dfrac{1}{c}\dfrac{\partial}{\partial t}\vec{A}, \\ \vec{B} = \vec{\nabla} \times \vec{A}. \end{cases} \tag{12.18}$$

The field strength (and the action) are invariant under the Abelian gauge transformations

$$A'_\mu = A_\mu + \partial_\mu \Lambda \tag{12.19}$$

with smooth, gauge parameter Λ. Depending on which gauge group we consider ($\mathbb{R}$ or $\mathrm{U}(1)$), Λ must be a single-valued or multivalued function.[6] In differential-form language

$$A = A_\mu dx^\mu, \qquad A' = A + d\Lambda, \qquad F = \tfrac{1}{2} F_{\mu\nu} dx^\mu \wedge dx^\nu = dA, \tag{12.20}$$

and the gauge invariance of F is a consequence of $d^2 = 0$. Using these differential forms, the Maxwell action can be rewritten as follows:

$$S_{\mathrm{M}}[A] = \frac{1}{8c} \int F \wedge \star F. \tag{12.21}$$

Observe that there is no matter charged with respect to A_μ in this system. This is analogous to the presence of no matter fields in the Einstein–Hilbert action. However, the Einstein–Hilbert action contains the self-coupling of gravity and therefore the presence of a coupling constant in it makes sense, whereas in the Maxwell theory there are no *direct* interactions between photons and, in principle, there is neither an electromagnetic coupling constant nor a unit of electric charge. We will see that things are a bit more complicated in the presence of gravity, through which photons do interact.

The equations of motion of $g_{\mu\nu}$ and A_μ are

$$G_{\mu\nu} - \frac{8\pi G_{\mathrm{N}}^{(4)}}{c^4} T_{\mu\nu} = 0, \tag{12.22}$$

$$\nabla_\mu F^{\mu\nu} = 0 \quad \text{(Maxwell's equation)}, \tag{12.23}$$

where

$$T_{\mu\nu} = \frac{-2c}{\sqrt{|g|}} \frac{\delta S_{\mathrm{M}}[A]}{\delta g^{\mu\nu}} = F_{\mu\rho} F_\nu{}^\rho - \tfrac{1}{4} g_{\mu\nu} F^2 \tag{12.24}$$

is the energy–momentum tensor of the vector field, which is traceless[7] in $d = 4$. The

---

[6] If the gauge group is $\mathbb{R}$, the elements of the group will be $e^{\Lambda/L}$, whereas, if it is U(1), they will be $e^{i\Lambda/L}$, where L is a constant introduced to make the exponent dimensionless because Λ is dimensionful. In the second case Λ will have to be identified with $\Lambda + 2\pi L$. When there is a unit of charge, L is related to it.

[7] This property is associated with the invariance of the Maxwell Lagrangian in curved spacetime under Weyl rescalings of the metric,

$$g'_{\mu\nu} = \Omega^2(x) g_{\mu\nu}. \tag{12.25}$$

In fact, if $\Omega = e^\sigma$, then for infinitesimal transformations $\delta_\sigma g_{\mu\nu} = 2\sigma(x) g_{\mu\nu}$ we have

$$\delta_\sigma S_{\mathrm{M}} = \frac{\delta S_{\mathrm{M}}}{\delta g_{\mu\nu}} \delta_\sigma g_{\mu\nu} \sim \sigma T^{\mu\nu} g_{\mu\nu} = 0. \tag{12.26}$$

tracelessness of the electromagnetic energy–momentum tensor implies that $R = 0$ and the Einstein equation takes the simpler form

$$R_{\mu\nu} = \frac{8\pi G_{\mathrm{N}}^{(4)}}{c^4} T_{\mu\nu}. \tag{12.27}$$

On taking the divergence of the Einstein equation and using the contracted Bianchi identity for the Einstein tensor $\nabla_\mu G^{\mu\nu} = 0$, we find

$$F_{\nu\rho} \nabla_\mu F^{\mu\rho} - \tfrac{3}{2} F^{\mu\rho} \nabla_{[\mu} F_{\rho\nu]} = 0. \tag{12.28}$$

Since the Levi-Civita connection is symmetric,

$$\nabla_{[\mu} F_{\rho\nu]} = \partial_{[\mu} F_{\rho\nu]} = 0 \quad \text{(the Bianchi identity)} \tag{12.29}$$

identically, using the definition of $F_{\mu\nu}$, and then we see that the Einstein equation implies generically the Maxwell equation. Using Eq. (1.70), the Maxwell equation can also be written in a simpler, equivalent, form:

$$\partial_\mu \left(\sqrt{|g|} F^{\mu\nu} \right) = 0. \tag{12.30}$$

The equations are written in terms of the field strength F and usually they are solved in terms of it. However, we are ultimately interested in the vector field A itself and we have to make sure that the F we obtain is such that it is related to some vector field by Eq. (12.16) or Eq. (12.20). It turns out that, locally, A exists if the electromagnetic Bianchi identity Eq. (12.29) is satisfied.[8]

---

[8] In fact, if we are given F and the Bianchi identity is satisfied, we can always find the corresponding vector potential by using, e.g., the formula

$$\boxed{A_\mu(x) = -\int_0^1 d\lambda \lambda x^\nu F_{\mu\nu}(\lambda x).} \tag{12.31}$$

To check this formula it is necessary to use the Bianchi identity: taking the curl of the l.h.s.,

$$\partial_{[\rho} A_{\mu]}(x) = -\int_0^1 d\lambda \lambda \partial_{[\rho} [x^\nu F_{\mu]\nu}(\lambda x)], \tag{12.32}$$

and operating,

$$\partial_{[\rho} \big(F_{\mu]\nu}(\lambda x) \big) = \lambda \partial_{[\rho} F_{\mu]\nu}(\lambda x) - \tfrac{1}{2} \lambda (\partial_\nu F_{\rho\mu})(\lambda x), \tag{12.33}$$

where the Bianchi identity Eq. (12.29) has been used in the last identity, we obtain

$$\begin{aligned} \partial_{[\rho} A_{\mu]}(x) &= \tfrac{1}{2} \int_0^1 d\lambda \big\{ \lambda^2 x^\nu \partial_\nu F_{\rho\mu}(\lambda x) - \lambda F_{\mu\rho}(\lambda x) \big\} = \tfrac{1}{2} \int_0^1 d\lambda \frac{d}{d\lambda} \big[\lambda^2 F_{\rho\mu}(\lambda x) \big] \\ &= \frac{1}{2} F_{\rho\mu}(x). \end{aligned} \tag{12.34}$$

This means that, up to gauge transformations, the field strength determines completely the potential in the Maxwell theory, which one can see as the simplest Abelian Yang–Mills theory. Interestingly, this is no longer true in the non-Abelian Yang–Mills case, as first noticed in Refs. [1278, 448].

The Bianchi identity can also be written in this form (by contracting Eq. (12.29) with $\epsilon^{\mu\nu\rho\sigma}$, introducing it into the partial derivative (because it is constant), and using the definition of the Hodge dual and Eq. (12.30) for the divergence):

$$\nabla_\mu \star F^{\mu\sigma} = 0. \tag{12.35}$$

In the language of differential forms, the Maxwell equation and Bianchi identity are

$$d \star F = 0, \tag{12.36}$$

$$dF = 0, \tag{12.37}$$

and the Bianchi identity is just a consequence of the definition Eq. (12.20) and $d^2 = 0$.

Then, if we work with the field strength, we find that there are two pairs of equations, (12.23) and (12.35) and (12.36) and (12.23), which are (as pairs) invariant if one replaces F by $\star F$ (by virtue of $\star \star F = -F$). This is an *electric–magnetic-duality* transformation. The name is due to the fact that this transformation interchanges the electric and magnetic fields in any given coordinate system according to

$$\vec{E}\,' = \vec{B}, \qquad \vec{B}\,' = -\vec{E}. \tag{12.38}$$

Actually, this pair of homogeneous equations (the Maxwell equation and the Bianchi identity) would be invariant under the (invertible) substitution for F of any linear combination of F and $\star F$. We would have a symmetry of all the equations of motion if the Einstein equation were also invariant under this replacement. We will see in Section 12.7 when this is the case and how the Einstein–Maxwell theory is invariant under electric–magnetic duality.

The four Maxwell equations in Minkowski spacetime can be deduced from the Maxwell equation and the Bianchi identity (two of them imply the existence of the potential A_μ and are equivalent to the latter). We have

$$\begin{aligned} \partial_\mu F^{\mu\nu} = 0 \quad &\Leftrightarrow \quad \begin{cases} \vec{\nabla} \cdot \vec{E} = 0, \\ \vec{\nabla} \times \vec{B} - \dfrac{1}{c}\dfrac{\partial}{\partial t}\vec{E} = 0, \end{cases} \\ \partial_\mu \star F^{\mu\nu} = 0 \quad &\Leftrightarrow \quad \begin{cases} \vec{\nabla} \cdot \vec{B} = 0, \\ \vec{\nabla} \times \vec{E} + \dfrac{1}{c}\dfrac{\partial}{\partial t}\vec{B} = 0. \end{cases} \end{aligned} \tag{12.39}$$

12.2.1 Electric charge

The electric charge can be defined in terms of a source coupled to the electromagnetic field (this is analogous to the energy–momentum-pseudotensor approach for the gravitational field) or in terms of the Noether current associated with the gauge invariance (the approach that leads to Komar's formula and its generalizations for the gravitational field). The two definitions are equivalent and are very closely related to each other because the gauge invariance of the free theory imposes strong constraints on the possible couplings.

Let us first introduce the electric charge using sources. A source for the Maxwell field is described by a current j^{μ}, which naturally couples to the vector field through a term in the action of the form

$$\frac{1}{c^2}\int d^4x\sqrt{|g|}\ [-A_{\mu}j^{\mu}]. \tag{12.40}$$

This additional interaction term spoils the action's gauge invariance unless the source j^{μ} is divergence free,

$$\nabla_{\mu}j^{\mu}=0 \ \Leftrightarrow\ d\star j=0 \qquad (j\equiv j_{\mu}dx^{\mu}), \tag{12.41}$$

which implies the *continuity equation* for the vector density $\mathfrak{j}^{\mu}\equiv\sqrt{|g|}\,j^{\mu}$,

$$\partial_{\mu}\mathfrak{j}^{\mu}=0. \tag{12.42}$$

The continuity equation can be used to establish the local conservation of the electric charge, as explained in Section 2.3, if the electric charge contained in a three-dimensional volume at a given time t, V^3_t, is defined by[9]

$$q(t)=-\frac{1}{c}\int_{\mathrm{V}^3_t}d^3x\,\mathfrak{j}^0, \tag{12.43}$$

or, in a more covariant form,

$$q(t)=\frac{1}{c}\int_{\mathrm{V}^3_t}\star j. \tag{12.44}$$

As explained in Section 2.3, this quantity is not constant: its variation is related to the flux of charge through the boundary of V^3_t. If V^3_t is a constant-time slice of the whole spacetime with no boundary, then the above integrals give the total charge, which will be constant in time. If we can foliate our spacetime with constant-time hypersurfaces, then we take the four-dimensional spacetime V^4 contained in between two constant-time slices $\mathrm{V}^3_{t_1}$ and $\mathrm{V}^3_{t_2}$, integrate the continuity equation over it, and use Stokes' theorem. The boundary of the four-dimensional region we have proposed is made up of the two constant-time slices with opposite orientations, so

$$0=\int_{\mathrm{V}^4}d\star j=\int_{\mathrm{V}^3_{t_1}}\star j-\int_{\mathrm{V}^3_{t_2}}\star j, \tag{12.45}$$

and the total electric charge is constant in time.

Thus, gauge invariance of the action implies that the source is divergence free, and from this the local conservation of the electric charge (and the global conservation of the total electric charge) follows.

On the other hand, in the presence of the source, the Maxwell equation is modified into

$$\nabla_{\mu}F^{\mu\nu}=\frac{1}{c}j^{\nu}, \tag{12.46}$$

---

[9] The sign is conventional.

or, equivalently,

$$d \star F = \frac{1}{c} \star j, \tag{12.47}$$

and, using the antisymmetry of $F_{\mu\nu}$ or $d^2 = 0$, it is trivial to see that, since the l.h.s. of the equation is divergence free, the r.h.s. of the equation is also, for consistency, divergence free, as we knew it had to be in order to preserve the gauge invariance of the action. This is no coincidence: the fact that the r.h.s. of the Maxwell equation is divergence free is in fact the gauge identity associated with the invariance under $\delta A_\mu = \partial_\mu \Lambda$, as we are going to see.

Finally, using the Maxwell equation (12.47), we can rewrite the definition of the total electric charge Eq. (12.44) in terms of the field strength and again use Stokes' theorem. If the boundary of a constant-time slice has the topology of a sphere, S^2, at infinity, we obtain

$$\boxed{q = \int_{\mathrm{S}^2_\infty} \star F} \tag{12.48}$$

which is a useful definition of the total electric charge of a spacetime in terms of the field strength (the electric flux) and which we will generalize further in Part III.

This is the kind of formula that we will use because in the Einstein–Maxwell system there are no fields explicitly written that act as sources for A_μ. Just as in the case of the Maxwell equations in vacuum, we can obtain solutions describing the field of charges. These solutions are singular near the place where the charge ought to be and the solution is not a solution there (there are no charges explicitly included in the system). However, the above expression allows us to calculate the charge that ought to be placed there to produce the flux of electromagnetic field that we observe.[10] We have introduced sources as a device for understanding the definition.

We could also have used the invariance of the Einstein–Maxwell action to find the conserved Noether current and define the electric charge through it.

We studied the invariance of the Maxwell action and found the corresponding Noether current in Minkowski spacetime in Section 3.2.1. The coupling to gravity introduces only minor changes and the conclusion is, again, that the electric charge can be defined by Eq. (12.48).

It is useful to consider a simple example of a source: the current associated with a particle of electric charge q and worldline γ parametrized by $X^\mu(\xi)$. In a manifestly covariant form it is given by

$$j^\mu(x) = qc \int_\gamma dX^\mu \frac{1}{\sqrt{|g|}} \delta^{(4)}[x - X(\xi)], \tag{12.49}$$

where $dX^\mu = d\xi dX^\mu/d\xi$. On making the choice $\xi = X^0$ and integrating over X^0, we obtain

---

[10] Of course, this is just a covariant generalization of the Gauss theorem that relates the flux of electric field through a closed surface to the charge enclosed by it.

$$\begin{aligned} j^\mu(x^0,\vec{x}) &= qc\int dX^0 \frac{dX^\mu}{dX^0}\frac{1}{\sqrt{|g|}}\delta^{(3)}(\vec{x}-\vec{X})\delta(x^0-X^0) \\ &= -qc\frac{dX^\mu}{dx^0}\frac{\delta^{(3)}[\vec{x}-\vec{X}(x^0)]}{\sqrt{|g|}}. \end{aligned} \tag{12.50}$$

If the particle is at rest at the origin in the chosen coordinate system, the current is

$$j^\mu(x^0,\vec{x}) = -qc\delta^{\mu 0}\frac{\delta^{(3)}(\vec{x})}{\sqrt{|g|}}, \tag{12.51}$$

and it is easy to see that q is indeed the electric charge according to the above definitions. The current j^μ is conserved:

$$\begin{aligned} \nabla_\mu j^\mu &\sim \frac{\partial}{\partial x^\mu}\left\{\sqrt{|g(x)|}\int d\xi \dot{X}^\mu \frac{1}{\sqrt{|g(X)|}}\delta^{(4)}[x-X(\xi)]\right\} \\ &= \int d\xi \dot{X}^\mu \frac{\partial}{\partial x^\mu}\delta^{(4)}[x-X(\xi)] = -\int d\xi \dot{X}^\mu \frac{\partial}{\partial X^\mu}\delta^{(4)}[x-X(\xi)] \\ &= -\int d\xi \frac{d}{d\xi}\delta^{(4)}[x-X(\xi)] = -\delta^{(4)}[x-X(\xi)]\Big|_{\xi_1}^{\xi_2} = 0, \end{aligned} \tag{12.52}$$

generically, except for the initial and final positions of the particle $X^\mu(\xi_1)$ and $X^\mu(\xi_2)$, which look like a one-particle source and a sink and can be taken to infinity.

Observe that, for the current Eq. (12.49), the interaction term Eq. (12.40) becomes the integral of the 1-form A over the worldline γ:

$$-\frac{q}{c}\int_{\gamma(\xi)} A_\mu \dot{x}^\mu d\xi = -\frac{q}{c}\int_\gamma A. \tag{12.53}$$

This term has to be added to the action of the particle, Eq. (3.255), (3.257), or (3.258), in order to obtain the worldline action of a massive electrically charged particle,

$$\boxed{S[X^\mu(\xi)] = -Mc\int d\xi\,\sqrt{g_{\mu\nu}(X)\dot{X}^\mu\dot{X}^\nu} - \frac{q}{c}\int d\xi A_\mu \dot{X}^\mu,} \tag{12.54}$$

or that of a massless one. That kind of term is known as a *Wess–Zumino* (WZ) term. In this form it is easy to see that, under a gauge transformation, the action changes by a total derivative. The integral of the total derivative vanishes exactly only for special boundary conditions, though.

This action can be used as a source, but it also describes the motion of a charged particle in a gravitational/electromagnetic background. In the special-relativistic limit, taking $\xi = X^0 = ct$, the action takes the standard form

$$S \sim \int dt\left\{-Mc^2 + \tfrac{1}{2}Mv^2 - q\phi + \frac{q}{c}\vec{A}\cdot\vec{v}\right\}. \tag{12.55}$$

If there is a point-like charge q at rest at the origin the only non-vanishing components of F are $F_{\underline{0}r}$ and they should depend only on r because of the spherical symmetry of the problem. Using the above definition of charge and working in general static spherical coordinates Eq. (11.22), we find

$$q = \int_{\mathrm{S}^2_\infty} \frac{\epsilon_{\mu\nu\rho\sigma}}{4\sqrt{|g|}} F^{\rho\sigma} dx^\mu \wedge dx^\nu = \int_{\mathrm{S}^2_\infty} d\Omega^2 r^2 F_{\underline{0}r} = \omega_{(2)} \lim_{r\to\infty} \left(r^2 F_{\underline{0}r}\right), \tag{12.56}$$

where $\omega_{(2)}$ is the volume of the 2-sphere 4π. Then, the electromagnetic field of a point-like charge must behave for large r as follows:

$$E_r = F_{\underline{0}r} \sim +\frac{1}{4\pi}\frac{q}{r^2}, \qquad \phi \sim +\frac{1}{4\pi}\frac{q}{r}. \tag{12.57}$$

(Of course, this result is exact in the absence of gravity, in Minkowski spacetime.) On plugging this result into Eq. (12.55), we find that the electrostatic force between two particles is, in this unit system, $q_1 q_2/(4\pi r^2)$, as we said.

In the units that we are using, M appears multiplied by $G_{\mathrm{N}}^{(4)}$ in the metric (as in the Schwarzschild solution) and q does not. Some simplification is achieved by using the following normalization and units that are standard in this field; we set $c = 1$ and rewrite the Einstein–Maxwell action as follows:

$$\boxed{S_{\mathrm{EM}}[g,A] = \frac{1}{16\pi G_{\mathrm{N}}^{(4)}} \int d^4x \sqrt{|g|}\, \left[R - \tfrac{1}{4}F^2\right].} \tag{12.58}$$

In these units both A_μ and $g_{\mu\nu}$ are dimensionless. The factor $16\pi G_{\mathrm{N}}^{(4)}$ disappears from the equations of motion. Furthermore, if we keep (by definition) the WZ term as in Eq. (12.54) without any additional normalization factor, the electric charge is now

$$\boxed{q = \frac{1}{16\pi G_{\mathrm{N}}^{(4)}} \int_{\mathrm{S}^2_\infty} \star F,} \tag{12.59}$$

and has dimensions of mass (energy). Finally, for a point-like charge we expect, for large r,

$$E_r = F_{0r} \sim \frac{4G_{\mathrm{N}}^{(4)} q}{r^2}, \tag{12.60}$$

which implies that the force between two charges is

$$F_{12} = 4G_{\mathrm{N}}^{(4)} \frac{q_1 q_2}{r_{12}^2}. \tag{12.61}$$

12.2.2 Massive electrodynamics

Before concluding this section it is worth considering which facts would be modified if the vector field were massive. A massive vector field in Minkowski spacetime is described by the Proca Lagrangian Eq. (3.67) and its generalization to curved spacetime is straightforward. The equation of motion is

$$\nabla_\nu F^{\nu\mu} + m^2 A^\mu = 0. \tag{12.62}$$

We immediately see that this equation is completely different from the Bianchi identity Eq. (12.35), which is also valid in the massive case, which implies that massive electrodynamics, apart from gauge invariance, has no electric–magnetic duality. This implies that, in principle, there will be no Dirac magnetic monopoles dual to the electric ones, which explains the results of Ref. [816].

If we take the divergence of this equation, we find the integrability condition

$$\nabla_\nu A^\nu = 0, \tag{12.63}$$

which removes one of the degrees of freedom described by the vector field, leaving only three that correspond to the three possible helicities of a massive spin-1 particle $(-1, 0, +1)$.

The quanta of the Proca field, being massive, will propagate at a speed smaller than 1 (c) and the interaction they mediate will be short ranged. We can see this by finding the static, spherically symmetric solution that describes the field of an electric monopole in this theory in Minkowski spacetime. On substituting the ansatz

$$A_\mu = \delta_{\mu 0} \frac{f(r)}{r} \tag{12.64}$$

into the equation of motion, we obtain the differential equation

$$f'' - m^2 f = 0, \tag{12.65}$$

whose solution is (with the boundary condition $A_\mu \rightarrow 0$ when $r \rightarrow \infty$)

$$A_\mu = Q\delta_{\mu 0} \frac{e^{-mr}}{r}, \tag{12.66}$$

where Q is an integration constant that is somehow related to the "electric charge." However, the lack of gauge invariance suggests that the "electric charge" is not conserved in this system. In fact, it is not easy to define what is meant by electric charge here. It is then useful to consider a slightly more general system with the following classically equivalent action for A_μ and a scalar auxiliary field ϕ:

$$S[A_\mu, \phi] = \int d^4x \sqrt{|g|} \left[-\tfrac{1}{4} F^2 + \tfrac{1}{2} (\partial\phi + mA)^2 \right]. \tag{12.67}$$

This action is invariant under the following *massive gauge transformations*:

$$\delta A_\mu = \partial_\mu \Lambda, \qquad \delta\phi = -m\Lambda. \tag{12.68}$$

Observe that, for consistency, the scalar ϕ has to live in the gauge group manifold: either $\mathbb{R}$ or S^1 (if the gauge group is U(1)). On fixing the gauge $\phi = 0$ we recover the Proca Lagrangian, and any solution of the equations of motion of the original system is also a solution of this one in this gauge.

It is sometimes said that the scalar ϕ is "eaten" by the vector field, which acquires a mass in the process; ϕ is then referred to as a *Stückelberg field* [1162]. Observe that the number of degrees of freedom before and after the gauge fixing are the same. Observe also that this procedure for obtaining a massive vector field is different from the standard spontaneous symmetry-breaking mechanism. There are two main differences: the scalar is real and carries no charge with respect to the vector field and there is no potential for the scalar. (Actually, there is no way to write a gauge-invariant potential with only one real scalar.)

The equations of motion corresponding to the new Lagrangian are

$$\nabla_\nu F^{\nu\mu} + m\big(\nabla^\mu \phi + m A^\mu\big) = 0, \qquad \nabla^2 \phi + m\partial_\mu A^\mu = 0. \tag{12.69}$$

To define a conserved charge, we can either introduce a source j^μ into the first equation or use the conserved Noether current associated with *constant*[11] shifts of ϕ:

$$j^\mu_{\mathrm{N}} = \partial_\nu F^{\nu\mu} + m\big(\partial^\mu \phi + m A^\mu\big). \tag{12.70}$$

The source j^μ is conserved, but only on-shell (upon use of the ϕ equation of motion) and the same applies to the Noether current, which is associated with a global symmetry. In both cases we can define the electric charge in this system by

$$q = \int d^3x \sqrt{|g|}\, j^0_{\mathrm{N}} = \int d^3x \sqrt{|g|}\, \big[\nabla_\nu F^{\nu 0} + m\big(\nabla^0 \phi + m A^0\big)\big]. \tag{12.71}$$

On applying this definition to the electric monopole solution Eq. (12.66) and using

$$\vec{\nabla}^2 \Big(\frac{e^{-mr}}{r}\Big) = -4\pi \delta^{(3)}(\vec{x}) + \frac{m^2 e^{-mr}}{r}, \tag{12.72}$$

we find $q = 4\pi Q$, as we naively expected. It should be stressed, though, that this charge is of a completely different nature from the usual electric charge since it is associated with a *global* symmetry of a different field. In principle, the no-hair conjecture should apply (negatively) to charges of this kind associated with short-range interactions and global (rather than local) symmetries.

Finally, note that neither the original Proca action nor the new one with the Stückelberg field ϕ has any duality *symmetry*. However, the new action can be dualized (i.e. written in *dual variables*), as we will see in Section 12.7.5.

12.3 The electric Reissner–Nordström solution

We are now ready to find BH-type solutions of the equations of motion derived from the Einstein–Maxwell action normalized as in Eqs. (12.58). Since the Maxwell equation is

---

[11] If we use the full gauge invariance of the theory, we recover exactly the same Noether current and Bianchi identity as in the massless case. The definition Eq. (12.59) then gives zero charge because F goes to zero too fast at infinity.

The Einstein–Langevin Equation

Whereas semiclassical gravity is based on the semiclassical Einstein equation with sources given by the expectation value of the stress-energy tensor of quantum fields, stochastic semiclassical gravity is based on the Einstein–Langevin equation, which has in addition sources due to the noise kernel. The noise kernel is the vacuum expectation value of the stress-energy bitensor which describes the fluctuations of quantum matter fields in curved spacetimes. A new improved criterion for the validity of semiclassical gravity may also be formulated from the viewpoint of this theory. In this chapter we describe the fundamentals of this theory via two approaches: the axiomatic and the functional. The axiomatic approach is useful to see the structure of the theory from the framework of semiclassical gravity, showing the link from the mean value of the stress-energy tensor to the correlation functions. The functional approach uses the Feynman–Vernon influence functional and the Schwinger-Keldysh closed time path (CTP) effective action methods.

In Sections 10.1 and 10.2 we formulate *stochastic semiclassical gravity*, or *stochastic gravity* for short, in an axiomatic way. It is introduced as an extension of semiclassical gravity motivated by the search of self-consistent equations which describe the backreaction of the quantum stress-energy fluctuations on the gravitational field. We then discuss the equivalence between the stochastic correlation functions for the metric perturbations and the quantum correlation functions in the large N expansion, i.e. the quantum theory describing the interaction of the gravitational field with N arbitrary free fields expanded in powers of $1/N$, and illustrate the equivalence with a simple toy model. Based on the stochastic formulation a test is proposed for the validity of the semiclassical theory in Section 10.3. In the second part of the chapter, in Section 10.4, semiclassical gravity as well as stochastic gravity are formulated using a functional approach based on the open quantum system paradigm, discussed in the earlier chapters, in which the system of interest (the gravitational field) interacts with an environment (the matter fields). The functional approach brings familiar quantum field theory techniques into play and provides powerful tools for explicit perturbative calculation. Finally, using this formalism an explicit form of the Einsein–Langevin equation is derived in Section 10.5.

In subsequent chapters we describe some applications of stochastic gravity. In Chapter 11 we consider metric perturbations in a Minkowski spacetime, compute the two-point correlation functions of these perturbations and prove that Minkowski spacetime is a stable solution of semiclassical gravity. In Chapter 12 we discuss the backreaction problem in cosmology when the gravitational field couples to a quantum conformal matter field, and derive the Einstein–Langevin equations describing the metric fluctuations on the cosmological background. In Chapter 13, we discuss structure formation, stochastic gravity is an alternative framework to study the generation of primordial inhomogeneities in inflationary models, which can easily incorporate effects that go beyond the linear perturbations of the inflaton field. In Chapter 14 using the Einstein–Langevin equation we discuss the backreaction of Hawking radiation and the behavior of metric fluctuations for both the quasi-equilibrium condition of a black hole in a box and the fully nonequilibrium condition of an evaporating black hole spacetime.

10.1 Semiclassical Gravity: Axiomatic Approach

Semiclassical gravity describes the interaction of a classical gravitational field with quantum matter fields. This theory can be formally derived as the leading $1/N$ approximation of quantum gravity interacting with N independent and identical free quantum fields which interact with gravity only [194, 684, 685, 686]. By keeping the value of $NG_{\rm N}$ finite, where $G_{\rm N}$ is Newton's gravitational constant, one arrives at a theory in which formally the gravitational field can be treated as a c-number field, i.e., quantized at tree level, while matter fields are fully quantized. The semiclassical theory may be summarized as follows.

Let $(\mathcal{M}, g_{ab})$ be a globally hyperbolic four-dimensional spacetime manifold $\mathcal{M}$ with metric g_{ab} and consider a real scalar quantum field ϕ of mass m propagating on that manifold; we just assume a scalar field for simplicity. The classical action $S_{\rm m}$ for this matter field is given by the functional

$$S_{\rm m}[g,\phi] = -\frac{1}{2}\int d^4x\sqrt{-g}\left[g^{ab}\nabla_a\phi\nabla_b\phi + \left(m^2+\xi R\right)\phi^2\right], \qquad (10.1)$$

where ∇_a is the covariant derivative associated to the metric g_{ab}, ξ is a dimensionless coupling parameter between the field and the scalar curvature of the underlying spacetime R, and $g = \det g_{ab}$.

The field may be quantized in the manifold using the standard canonical quantization formalism [47, 48, 49]. The field operator in the Heisenberg picture $\hat{\phi}$ is an operator-valued distribution solution of the Klein–Gordon equation,

$$(\Box - m^2 - \xi R)\hat{\phi} = 0, \qquad (10.2)$$

where $\Box = \nabla_a \nabla^a$. We may write the field operator as $\hat{\phi}[g;x)$ to indicate that it is a functional of the metric g_{ab} and a function of the spacetime point x. This notation will be used also for other operators and tensors.

The classical stress-energy tensor is obtained by functional derivation of this action in the usual way $T^{ab}(x) = (2/\sqrt{-g})\delta S_{\rm m}/\delta g_{ab}$, leading to

$$T^{ab}[g,\phi] = \nabla^a\phi\nabla^b\phi - \frac{1}{2}g^{ab}\left(\nabla^c\phi\nabla_c\phi + m^2\phi^2\right) + \xi\left(g^{ab}\Box - \nabla^a\nabla^b + G^{ab}\right)\phi^2, \tag{10.3}$$

where G_{ab} is the Einstein tensor. With the notation $T^{ab}[g,\phi]$ we explicitly indicate that the stress-energy tensor is a functional of the metric g_{ab} and the field ϕ. This is the same as the stress-energy tensor (2.59) where $(1-\xi)\xi_n$ has been replaced by ξ, so that now $\xi = 0$ and $\xi = \xi_n$ correspond to minimal and conformal couplings, respectively.

The next step is to define a stress-energy tensor operator $\hat{T}^{ab}[g;x)$. Naively one would replace the classical field $\phi[g;x)$ in the above functional by the quantum operator $\hat{\phi}[g;x)$, but this procedure involves taking the product of two distributions at the same spacetime point. This is ill-defined and a regularization procedure is needed. There are several regularization methods which one may use, one is the point-splitting or point-separation regularization method introduced by Christensen [100, 101] in which one takes a point y in a neighborhood of the point x and then uses as the regulator the vector tangent at the point x of the geodesic joining x and y; this method is discussed in a previous chapter.

Another well known method is dimensional regularization in which one works in n dimensions, where n is not necessarily an integer, and then uses as the regulator the parameter $\epsilon = n-4$; this method is implicitly used in this Section. The regularized stress-energy operator using the Weyl ordering prescription, i.e., symmetrical ordering, can be written as

$$\hat{T}^{ab}[g] = \frac{1}{2}\{\nabla^a\hat{\phi}[g]\,,\,\nabla^b\hat{\phi}[g]\} + \mathcal{D}^{ab}[g]\,\hat{\phi}^2[g], \tag{10.4}$$

where $\mathcal{D}^{ab}[g]$ is the differential operator:

$$\mathcal{D}^{ab} \equiv (\xi - 1/4)\,g^{ab}\Box + \xi\left(R^{ab} - \nabla^a\nabla^b\right). \tag{10.5}$$

Note that if dimensional regularization is used, the field operator $\hat{\phi}[g;x)$ propagates in a n-dimensional spacetime. Once the regularization prescription has been introduced a regularized and renormalized stress-energy operator $\hat{T}^{\rm R}_{ab}[g;x)$ may be defined as

$$\hat{T}^{\rm R}_{ab}[g;x) = \hat{T}_{ab}[g;x) + F^C_{ab}[g;x)\hat{I}, \tag{10.6}$$

which differs from the regularized $\hat{T}_{ab}[g;x)$ by the identity operator times some tensor counterterms $F^C_{ab}[g;x)$, which depend on the regulator and are local functionals of the metric. The field states can be chosen in such a way that for any pair of physically acceptable states, i.e., Hadamard states in the sense of [49], $|\psi\rangle$ and $|\varphi\rangle$, the matrix element $\langle\psi|T^{\mathrm{R}}_{ab}|\varphi\rangle$, defined as the limit when the regulator takes the physical value, is finite and satisfies Wald's axioms [102, 48]. These counterterms can be extracted from the singular part of a Schwinger–DeWitt series [48, 100, 101, 91]. The choice of these counterterms is not unique but this ambiguity can be absorbed into the renormalized coupling constants which appear in the equations of motion for the gravitational field.

10.1.1 Semiclassical Einstein Equation

The *semiclassical Einstein equation* for the metric g_{ab} can then be written as

$$G_{ab}[g] + \Lambda g_{ab} - 2(\alpha_d A_{ab} + \beta_d B_{ab})[g] = 8\pi G_{\mathrm{N}} \langle \hat{T}^{\mathrm{R}}_{ab}[g]\rangle, \qquad (10.7)$$

where $\langle \hat{T}^{\mathrm{R}}_{ab}[g]\rangle$ is the expectation value of the operator $\hat{T}^{\mathrm{R}}_{ab}[g,x)$ after the regulator takes the physical value in some physically acceptable state of the field on $(\mathcal{M}, g_{ab})$. Note that both the stress-energy tensor and the quantum state are functionals of the metric, hence the notation.

The parameters G_{N}, Λ, α_d and β_d are the renormalized coupling constants, respectively, the gravitational constant, the cosmological constant and two parameters which are zero in the classical Einstein equation and have dimensions of square length (we use units in which $\hbar = c = 1$). In the effective field theory description of general relativity [192] these two parameters are naturally of the order of the Planck length square $\ell_{\mathrm{P}}^2 = G_{\mathrm{N}}$ and in later Chapters will be convenient to use instead dimensionless parameters a_1 and a_2 defined by $\alpha_d \equiv 8\pi\ell_{\mathrm{P}}^2 a_1$ and $\beta_d \equiv 8\pi\ell_{\mathrm{P}}^2 a_2$. The renormalized four constants of the semiclassical equation must be understood as the result of "dressing" the bare constants which appear in the classical action before renormalization. The values of these constants must be determined by experiment.

The left-hand side of Eq. (10.7) may be derived from the gravitational action

$$S_{\mathrm{g}}[g] = \frac{1}{8\pi G_{\mathrm{N}}} \int d^4x \sqrt{-g} \left[\frac{1}{2} R - \Lambda + \alpha_d C_{abcd} C^{abcd} + \beta_d R^2 \right], \qquad (10.8)$$

where C_{abcd} is the Weyl tensor. The parameters α_d and β_d are related to the parameters a, b, c introduced in the action (2.67). By writing the Ricci and the Riemann squares in terms of Ricci scalar and Weyl squares and the Euler density G, given in (2.61), and taking into account that by the Gauss–Bonnet theorem the Euler density does not contribute to the field equations one can see that these two actions are equivalent with $\alpha_d = b/4 + c$ and $\beta_d = a/2 + (b + c)/6$.

The tensors A_{ab} and B_{ab} come from the functional derivatives with respect to the metric of the terms quadratic in the curvature in Eq. (10.8), and are explicitly given by

$$
\begin{aligned}
A^{ab} &= \frac{1}{\sqrt{-g}} \frac{\delta}{\delta g_{ab}} \int d^4 \sqrt{-g} C_{cdef} C^{cdef} \\
&= \frac{1}{2} g^{ab} C_{cdef} C^{cdef} - 2R^{acde} R^{b}_{cde} + 4R^{ac} R^{b}_{c} - \frac{2}{3} R R^{ab} \\
&\quad - 2\Box R^{ab} + \frac{2}{3} \nabla^a \nabla^b R + \frac{1}{3} g^{ab} \Box R, \qquad (10.9) \\
B^{ab} &= \frac{1}{\sqrt{-g}} \frac{\delta}{\delta g_{ab}} \int d^4 \sqrt{-g} R^2 \\
&= \frac{1}{2} g^{ab} R^2 - 2R R^{ab} + 2\nabla^a \nabla^b R - 2g^{ab} \Box R, \qquad (10.10)
\end{aligned}
$$

where R_{abcd} and R_{ab} are the Riemann and Ricci tensors, respectively. These two tensors are, like the Einstein and metric tensors, symmetric and divergenceless, $\nabla^a A_{ab} = 0 = \nabla^a B_{ab}$, and they have been introduced previously in (2.71) and (2.69) with different names: $A_{ab} = {}^{(C)}H_{ab}$ and $B_{ab} = {}^{(1)}H_{ab}$.

A solution of semiclassical gravity consists of a spacetime $(\mathcal{M}, g_{ab})$, a quantum field operator $\hat{\phi}[g]$ which satisfies the evolution Eqs. (10.2), and a physically acceptable state $|\psi[g]\rangle$ for this field, such that Eq. (10.7) is satisfied when the expectation value of the renormalized stress-energy operator is evaluated in this state.

For a free quantum field this theory is robust in the sense that it is self-consistent and fairly well understood. As long as the gravitational field is assumed to be described by a classical metric, the above semiclassical Einstein equations seems to be the only plausible dynamical equation for this metric: the metric couples to matter fields via the stress-energy tensor and for a given quantum state the only physically observable c-number stress-energy tensor that one can construct is the above renormalized expectation value. However, lacking a full quantum theory of gravity the scope and limits of the theory are not so well understood. It is assumed that the semiclassical theory should break down at Planck scales, which is when simple order of magnitude estimates suggest that the quantum effects of gravity should not be ignored because the energy of a quantum fluctuation in a Planck size region, as determined by the Heisenberg uncertainty principle, is comparable to the gravitational energy of that fluctuation.

The theory is expected to break down when the fluctuations of the stress-energy operator are large [195]. A criterion based on the ratio of the fluctuations to the mean was proposed by Kuo and Ford [196] (see also work via zeta-function methods in [197, 205]). This proposal was questioned by Hu and Phillips [198, 199, 200] because it does not contain a scale at which the theory is probed or how accurately the theory can be resolved. They suggested the use of a smearing scale or point-separation distance, for integrating over the bitensor quantities, equivalent to a stipulation of the resolution level of measurements; see also the response by Ford and Wu [206, 207]. A different criterion was suggested by Anderson et al. [208, 209] based on linear response theory.

Later, Hu et al. [190, 214] proposed a criterion for the validity of semiclassical gravity which is based on the stability of the solutions of the semiclassical Einstein equations with respect to quantum metric fluctuations. The two-point correlations for the metric perturbations can be described in the framework of stochastic gravity, which is closely related to the quantum theory of gravity interacting with N matter fields, to the next to leading order in a $1/N$ expansion. We describe these developments in the following sections.

10.2 Stochastic Gravity: Axiomatic Approach

The purpose of stochastic gravity is to extend the semiclassical theory to account for the stress-energy tensor fluctuations in a self-consistent way. A physical observable that describes these fluctuations to lowest order is the *noise kernel* bitensor, which is defined through the two-point correlation of the stress-energy operator as

$$N_{abc'd'}[g;x,y] = \frac{1}{2}\langle\{\hat{t}_{ab}[g;x], \hat{t}_{c'd'}[g;y]\}\rangle, \tag{10.11}$$

where the curly brackets mean anticommutator,

$$\hat{t}_{ab}[g;x] \equiv \hat{T}_{ab}[g;x] - \langle\hat{T}_{ab}[g;x]\rangle, \tag{10.12}$$

and we use unprimed and primed indices to emphasize that this bitensor is a tensor with respect to the first two indices at the point x and a tensor with respect to the last two indices at the point y.

The noise kernel is defined in terms of the unrenormalized stress-energy tensor operator $\hat{T}_{ab}[g;x)$ on a given background metric g_{ab}, thus a regulator is implicitly assumed on the right-hand side of Eq. (10.11). However, for a linear quantum field the above kernel – the expectation function of a bitensor – is free of ultraviolet divergences because the regularized $T_{ab}[g;x)$ differs from the renormalized $T^{\mathrm{R}}_{ab}[g;x)$ by the identity operator times some tensor counterterms, see Eq. (10.6), so that in the subtraction (10.12) the counterterms cancel. Consequently the ultraviolet behavior of $\langle\hat{T}_{ab}(x)\hat{T}_{c'd'}(y)\rangle$ is the same as that of $\langle\hat{T}_{ab}(x)\rangle\langle\hat{T}_{c'd'}(y)\rangle$, and $\hat{T}_{ab}$ can be replaced by the renormalized operator $\hat{T}^{\mathrm{R}}_{ab}$ in Eq. (10.11). The noise kernel should be thought of as a distribution function; the limit of coincidence points has meaning only in the sense of distributions.

The bitensor $N_{abc'd'}[g;x,y)$, or $N_{abc'd'}(x,y)$ for short, is real and positive semi-definite, as a consequence of $\hat{T}^{R}_{ab}$ being self-adjoint. A simple proof of this property can be given as follows. Let $|\psi\rangle$ be a given quantum state and let $\hat{Q}$ be a self-adjoint operator, $\hat{Q}^{\dagger} = \hat{Q}$, then one can write $\langle\psi|\hat{Q}\hat{Q}|\psi\rangle = \langle\psi|\hat{Q}^{\dagger}\hat{Q}|\psi\rangle = |\hat{Q}|\psi\rangle|^2 \geq 0$. Now let $\hat{t}(x)$ be a self-adjoint operator (this is shorthand for $\hat{t}_{ab}$), then if we define $\hat{Q} = \int dx f(x)\hat{t}(x)$ for an arbitrary well defined function $f(x)$, the previous inequality can be written as follows $\int dxdy f(x)\langle\psi|\hat{t}(x)\hat{t}(y)|\psi\rangle f(y) \geq 0$,

11

Metric Fluctuations in Minkowski Spacetime

Although the Minkowski vacuum is an eigenstate of the total four-momentum operator of a field in Minkowski spacetime, it is not an eigenstate of the stress-energy operator. Hence, even for those solutions of semiclassical gravity such as the Minkowski metric, for which the expectation value of the stress-energy operator can always be chosen to be zero, the fluctuations of this operator are non-vanishing. This fact leads to consider the stochastic metric perturbations induced by these fluctuations.

Here we derive the Einstein–Langevin equation for the metric perturbations in a Minkowski background. We solve this equation for the linearized Einstein tensor and compute the associated two-point correlation functions, as well as the two-point correlation functions for the metric perturbations. Even though, in this case, we expect to have negligibly small values for these correlation functions for points separated by lengths larger than the Planck length, there are several reasons why it is worth carrying out this calculation.

On the one hand, these are the first backreaction solutions of the full Einstein–Langevin equation. There are analogous solutions to a "reduced" version of this equation inspired in a "mini-superspace" model in [218, 219].

On the other hand, the results of this calculation, which confirm our expectations that gravitational fluctuations are negligible at length scales larger than the Planck length, but also predict that the fluctuations are strongly suppressed on small scales, can be considered a first test of stochastic semiclassical gravity. These results also reveal an important connection between stochastic gravity and the large N expansion of quantum gravity. In addition, they are used in Section 11.5 to study the stability of the Minkowski metric as a solution of semiclassical gravity, which constitutes an application of the validity criterion introduced in Section 10.3. This calculation requires also a discussion of the problems posed by the so called *runaway* solutions, which arise in the backreaction equations of semiclassical and stochastic gravity, and some of the methods to deal with them. As a result we conclude that Minkowski spacetime is a stable and valid solution of semiclassical gravity.

11.1 Perturbations around Minkowski Spacetime

The Minkowski metric η_{ab}, in a manifold $\mathcal{M}$ which is topologically $\mathbb{R}^4$, and the usual Minkowski vacuum, denoted as $|0\rangle$, is the simplest solution to the semiclassical Einstein equation (10.7), the so-called trivial solution of semiclassical gravity [128]. It constitutes the ground state of semiclassical gravity. In fact, we can always choose a renormalization scheme in which the renormalized expectation value of the stress-energy tensor vanishes: $\langle 0|\,\hat{T}_{\mathrm{R}}^{ab}\,[\eta]|0\rangle = 0$. Thus, Minkowski spacetime $(\mathbb{R}^4, \eta_{ab})$ and the vacuum state $|0\rangle$ are a solution to the semiclassical Einstein equation with renormalized cosmological constant $\Lambda = 0$.

The fact that the vacuum expectation value of the renormalized stress-energy operator in Minkowski spacetime should vanish was originally proposed by Wald [102] and it may be understood as a renormalization convention [48, 51]. Note that other possible solutions of semiclassical gravity with zero vacuum expectation value of the stress-energy tensor are the exact gravitational plane waves, since these are known to be vacuum solutions of Einstein equations which induce neither particle creation nor vacuum polarization [719, 720, 721].

As we have already mentioned the vacuum $|0\rangle$ is an eigenstate of the total four-momentum operator in Minkowski spacetime, but not an eigenstate of $\hat{T}^{\mathrm{R}}_{ab}[\eta]$. Hence, even in the Minkowski background, there are quantum fluctuations in the stress-energy tensor and, as a result, the noise kernel does not vanish. This fact leads to consider the stochastic corrections to this class of trivial solutions of semiclassical gravity. Since, in this case, the Wightman and Feynman functions (10.55), their values in the two-point coincidence limit, and the products of derivatives of two of such functions appearing in expressions (10.56) and (10.57) are known in dimensional regularization, we can compute the Einstein–Langevin equation using the methods outlined in Chapter 10.

To perform explicit calculations it is convenient to work in a global inertial coordinate system $\{x^\mu\}$ and in the associated basis, in which the components of the flat metric are simply $\eta_{\mu\nu} = \mathrm{diag}(-1, 1, \ldots, 1)$. In Minkowski spacetime, the components of the classical stress-energy tensor (10.3) reduce to

$$T^{\mu\nu}[\eta,\phi] = \partial^\mu\phi\partial^\nu\phi - \frac{1}{2}\,\eta^{\mu\nu}\partial^\rho\phi\partial_\rho\phi - \frac{1}{2}\,\eta^{\mu\nu}m^2\phi^2 + \xi\left(\eta^{\mu\nu}\Box - \partial^\mu\partial^\nu\right)\phi^2, \quad (11.1)$$

where $\Box \equiv \partial_\mu\partial^\mu$, and the formal expression for the components of the corresponding "operator" in dimensional regularization, see Eq. (10.4), is

$$\hat{T}_n^{\mu\nu}[\eta] = \frac{1}{2}\{\partial^\mu\hat{\phi}_n, \partial^\nu\hat{\phi}_n\} + \mathcal{D}^{\mu\nu}\hat{\phi}_n^2, \quad (11.2)$$

where $\mathcal{D}^{\mu\nu}$ is the differential operator (10.5), with $g_{\mu\nu} = \eta_{\mu\nu}, R_{\mu\nu} = 0$, and $\nabla_\mu = \partial_\mu$. The field $\hat{\phi}_n(x)$ is the field operator in the Heisenberg picture in a n-dimensional Minkowski spacetime, which satisfies the Klein–Gordon equation (10.2). We use here a stress-energy tensor which differs from the canonical one, which corresponds to $\xi = 0$, both tensors, however, define the same total momentum.

The Wightman and Feynman functions (10.55) when $g_{\mu\nu} = \eta_{\mu\nu}$, are well known:

$$G_n^+(x,y) = \Delta_n^+(x-y), \quad G_{F_n}(x,y) = \Delta_{F_n}(x-y), \tag{11.3}$$

with

$$\begin{aligned}\Delta_n^+(x) &= -2\pi i \int \frac{d^n k}{(2\pi)^n}\, e^{ik\cdot x}\, \delta(k^2+m^2)\, \theta(k^0),\\ \Delta_{F_n}(x) &= -\int \frac{d^n k}{(2\pi)^n}\, \frac{e^{ik\cdot x}}{k^2+m^2-i\epsilon}, \epsilon \to 0^+,\end{aligned} \tag{11.4}$$

where $k^2 \equiv \eta_{\mu\nu}k^\mu k^\nu$ and $k\cdot x \equiv \eta_{\mu\nu}k^\mu x^\nu$. Note that the derivatives of these functions satisfy $\partial_\mu^x \Delta_n^+(x-y) = \partial_\mu \Delta_n^+(x-y)$ and $\partial_\mu^y \Delta_n^+(x-y) = -\partial_\mu \Delta_n^+(x-y)$, and similarly for the Feynman propagator $\Delta_{F_n}(x-y)$.

To write down the semiclassical Einstein equation (10.7) in n-dimensions for this case, we need to compute the vacuum expectation value of the stress-energy operator components (11.2). Since, from (11.3), we have that $\langle 0|\hat{\phi}_n^2(x)|0\rangle = i\Delta_{F_n}(0) = i\Delta_n^+(0)$, which is a constant (independent of x), we have simply

$$\langle 0|\hat{T}_n^{\mu\nu}[\eta]|0\rangle = -i\int \frac{d^n k}{(2\pi)^n}\, \frac{k^\mu k^\nu}{k^2+m^2-i\epsilon} = \frac{\eta^{\mu\nu}}{2}\left(\frac{m^2}{4\pi}\right)^{n/2} \Gamma\left(-\frac{n}{2}\right), \tag{11.5}$$

where the integrals in dimensional regularization have been computed in the standard way and where $\Gamma(z)$ is the Euler's gamma function. The semiclassical Einstein equation (10.7) in n-dimensions before renormalization reduces now to

$$\frac{\Lambda_B}{8\pi G_B}\, \eta^{\mu\nu} = \mu^{-(n-4)} \langle 0|\hat{T}_n^{\mu\nu}[\eta]|0\rangle. \tag{11.6}$$

This equation, thus, simply sets the value of the bare coupling constant Λ_B/G_B. Note, from (11.5), that in order to have $\langle 0|\,\hat{T}_{\mathrm{R}}^{\mu\nu}\,|0\rangle[\eta] = 0$, the renormalized and regularized stress-energy tensor "operator" for a scalar field in Minkowski spacetime, see Eq. (10.6), has to be defined as

$$\hat{T}_{\mathrm{R}}^{\mu\nu}[\eta] = \mu^{-(n-4)}\, \hat{T}_n^{\mu\nu}[\eta] - \frac{\eta^{\mu\nu}}{2}\, \frac{m^4}{(4\pi)^2} \left(\frac{m^2}{4\pi\mu^2}\right)^{\frac{n-4}{2}} \Gamma\left(-\frac{n}{2}\right), \tag{11.7}$$

which corresponds to a renormalization of the cosmological constant

$$\frac{\Lambda_B}{G_B} = \frac{\Lambda}{G_{\mathrm{N}}} - \frac{2}{\pi}\, \frac{m^4}{n(n-2)}\, \kappa_n + \mathcal{O}(n-4), \tag{11.8}$$

where

$$\kappa_n \equiv \frac{1}{(n-4)} \left(\frac{e^{\gamma} m^2}{4\pi\mu^2} \right)^{\frac{n-4}{2}} = \frac{1}{n-4} + \frac{1}{2} \ln \left(\frac{e^{\gamma} m^2}{4\pi\mu^2} \right) + \mathcal{O}(n-4), \tag{11.9}$$

being γ the Euler's constant. In the case of a massless scalar field, $m^2 = 0$, one simply has $\Lambda_B / G_B = \Lambda / G_{\mathrm{N}}$. Introducing this renormalized coupling constant into Eq. (11.6), we can take the limit $n \to 4$. We find that, for $(\mathbb{R}^4, \eta_{ab}, |0\rangle)$ to satisfy the semiclassical Einstein equation, we must take $\Lambda = 0$.

We can now write down the Einstein–Langevin equations for the components $h_{\mu\nu}$ of the stochastic metric perturbation in dimensional regularization. In our case, using $\langle 0|\hat{\phi}_n^2(x)|0\rangle = i\Delta_{F_n}(0)$ and the explicit expression of Eq. (10.52) we obtain

$$\begin{aligned} \frac{1}{8\pi G_B} & \left[G^{(1)\mu\nu} + \Lambda_B \left(h^{\mu\nu} - \frac{1}{2}\, \eta^{\mu\nu} h \right) \right] (x) \\ & - \frac{4}{3}\, \alpha_B D^{(1)\mu\nu}(x) - 2\beta_B B^{(1)\mu\nu}(x) - \xi G^{(1)\mu\nu}(x) \mu^{-(n-4)} i\Delta_{F_n}(0) \\ & + \frac{1}{2} \int d^n y \mu^{-(n-4)} H_n^{\mu\nu\alpha'\beta'}(x,y) h_{\alpha'\beta'}(y) = \xi^{\mu\nu}(x). \end{aligned} \tag{11.10}$$

The indices in $h_{\mu\nu}$ are raised with the Minkowski metric, $h \equiv h^{\rho}_{\rho}$, and here a superscript (1) denotes the components of a tensor linearized around the flat metric. Note that in n-dimensions the two-point correlation functions for the field $\xi^{\mu\nu}$ is written as

$$\langle \xi^{\mu\nu}(x) \xi^{\alpha'\beta'}(y) \rangle_s = \mu^{-2(n-4)} N_n^{\mu\nu\alpha'\beta'}(x,y), \tag{11.11}$$

Explicit expressions for $D^{(1)\mu\nu}$ and $B^{(1)\mu\nu}$ are given by

$$D^{(1)\mu\nu}(x) = \frac{1}{2}\, \underset{x}{\mathcal{F}}^{\mu\nu\alpha'\beta'}\, h_{\alpha'\beta'}(x), \qquad B^{(1)\mu\nu}(x) = 2 \underset{x}{\mathcal{F}}^{\mu\nu} \underset{x}{\mathcal{F}}^{\alpha\beta} h_{\alpha\beta}(x), \tag{11.12}$$

where we introduced the differential operators $\underset{x}{\mathcal{F}}^{\mu\nu} \equiv \eta^{\mu\nu} \Box_x - \partial^{\mu}_{x} \partial^{\nu}_{x}$ and $\underset{x}{\mathcal{F}}^{\mu\nu\alpha'\beta'} \equiv 3 \underset{x}{\mathcal{F}}^{\mu(\alpha'} \underset{x}{\mathcal{F}}^{\beta')\nu} - \underset{x}{\mathcal{F}}^{\mu\nu} \underset{x}{\mathcal{F}}^{\alpha'\beta'}$. Note that to distinguish tensor indices in x from tensor indices in y is unnecessary in the Minkowski background with standard coordinates. However, we will follow the convention of keeping the last two indices primed in bitensors in order to have an homogeneous notation with previous chapters.

11.2 The Kernels in the Minkowski Background

Since the two kernels (10.54) are free of ultraviolet divergences in the limit $n \to 4$, we can deal directly with the $F^{\mu\nu\alpha'\beta'}(x-y) \equiv \lim_{n\to 4} \mu^{-2(n-4)} F_n^{\mu\nu\alpha'\beta'}$ in Eq. (10.53). Also $N^{\mu\nu\alpha'\beta'}(x,y) = \operatorname{Re} F^{\mu\nu\alpha'\beta'}(x-y)$ and $H_{\mathrm{A}}^{\mu\nu\alpha'\beta'}(x,y) = \operatorname{Im} F^{\mu\nu\alpha'\beta'}(x-y)$ are actually the components of the "physical" noise and dissipation kernels that will appear in the Einstein–Langevin equations once the renormalization procedure has been carried out. The bitensor $F^{\mu\nu\alpha'\beta'}$ can be expressed in terms of the positive Wightman function in four spacetime dimensions, according to (10.56). The different terms in this kernel can be easily computed using the integrals

$$I(p) \equiv \int \frac{d^4k}{(2\pi)^4}\, \delta(k^2+m^2)\, \theta(-k^0)\, \delta[(k-p)^2+m^2]\, \theta(k^0-p^0), \tag{11.13}$$

and $I^{\mu_1\cdots\mu_r}(p)$ which are defined as the previous one by inserting the momenta $k^{\mu_1}\dots k^{\mu_r}$ with $r=1,2,3,4$ in the integrand. All these integrals can be expressed in terms of $I(p)$; see [189] for the explicit expressions.

It is convenient to separate $I(p)$ in its even and odd parts with respect to the variables p^μ as

$$I(p) = I_{\rm S}(p) + I_{\rm A}(p), \tag{11.14}$$

where $I_{\rm S}(-p) = I_{\rm S}(p)$ and $I_{\rm A}(-p) = -I_{\rm A}(p)$. These two functions are explicitly given by

$$\begin{aligned} I_{\rm S}(p) &= \frac{1}{8\,(2\pi)^3}\, \theta(-p^2-4m^2)\, \sqrt{1+4\,\frac{m^2}{p^2}}, \\ I_{\rm A}(p) &= \frac{-1}{8\,(2\pi)^3}\, \mathrm{sign}(p^0)\theta(-p^2-4m^2)\, \sqrt{1+4\,\frac{m^2}{p^2}}. \end{aligned} \tag{11.15}$$

After some manipulations, we find

$$\begin{aligned} F^{\mu\nu\alpha'\beta'}(x) &= \frac{\pi^2}{45}\, \mathcal{F}_x^{\mu\nu\alpha'\beta'} \int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot x} \left(1+4\frac{m^2}{p^2}\right)^2 I(p) \\ &\quad + \frac{8\pi^2}{9} \mathcal{F}_x^{\mu\nu} \mathcal{F}_x^{\alpha'\beta'} \int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot x} \left(3\Delta\xi + \frac{m^2}{p^2}\right)^2 I(p), \end{aligned} \tag{11.16}$$

where $\Delta\xi \equiv \xi - 1/6$. The real and imaginary parts of the last expression, which yield the noise and dissipation kernels, are easily recognized as the terms containing $I_{\rm S}(p)$ and $I_{\rm A}(p)$, respectively.

To write them explicitly, it is useful to introduce the new kernels

$$\begin{aligned} N_{\rm A}(x;m^2) &\equiv \frac{1}{480\pi} \int \frac{d^4p}{(2\pi)^4}\, e^{ip\cdot x}\, \theta(-p^2-4m^2)\, \sqrt{1+4\,\frac{m^2}{p^2}} \left(1+4\,\frac{m^2}{p^2}\right)^2, \\ N_{\rm B}(x;m^2,\Delta\xi) &\equiv \frac{1}{72\pi} \int \frac{d^4p}{(2\pi)^4}\, e^{ip\cdot x}\, \theta(-p^2-4m^2) \\ &\qquad \times \sqrt{1+4\,\frac{m^2}{p^2}} \left(3\Delta\xi + \frac{m^2}{p^2}\right)^2, \end{aligned}$$

$$
\begin{aligned}
D_{\mathrm{A}}(x;m^2) &\equiv \frac{-i}{480\pi}\int \frac{d^4p}{(2\pi)^4}\, e^{ip\cdot x}\,\mathrm{sign}(p^0)\theta(-p^2-4m^2)\\
&\quad\times\sqrt{1+4\,\frac{m^2}{p^2}}\left(1+4\,\frac{m^2}{p^2}\right)^2,\\
D_{\mathrm{B}}(x;m^2,\Delta\xi) &\equiv \frac{-i}{72\pi}\int \frac{d^4p}{(2\pi)^4}\, e^{ip\cdot x}\,\mathrm{sign}(p^0)\theta(-p^2-4m^2)\\
&\quad\times\sqrt{1+4\,\frac{m^2}{p^2}}\left(3\Delta\xi+\frac{m^2}{p^2}\right)^2,
\end{aligned}
\tag{11.17}
$$

and we finally obtain

$$
\begin{aligned}
N^{\mu\nu\alpha'\beta'}(x,y) &= \frac{1}{6}\mathcal{F}_x^{\mu\nu\alpha'\beta'}N_{\mathrm{A}}(x-y;m^2)+\mathcal{F}_x^{\mu\nu}\mathcal{F}_x^{\alpha'\beta'}N_{\mathrm{B}}(x-y;m^2,\Delta\xi),\\
H_{\mathrm{A}}^{\mu\nu\alpha'\beta'}(x,y) &= \frac{1}{6}\mathcal{F}_x^{\mu\nu\alpha'\beta'}D_{\mathrm{A}}(x-y;m^2)+\mathcal{F}_x^{\mu\nu}\mathcal{F}_x^{\alpha'\beta'}D_{\mathrm{B}}(x-y;m^2,\Delta\xi).
\end{aligned}
\tag{11.18}
$$

Notice that the noise and dissipation kernels defined in (11.17) are actually real because, for the noise kernels, only the $\cos(p\cdot x)$ terms of the exponentials $e^{ip\cdot x}$ contribute to the integrals, and, for the dissipation kernels, the only contribution of such exponentials comes from the $i\sin(p\cdot x)$ terms.

The evaluation of the kernel $H_{\mathrm{S}_n}^{\mu\nu\alpha'\beta'}(x,y)$ is a more involved task. Since this kernel contains divergences in the limit $n\to 4$, we use dimensional regularization. Using Eq. (10.57), this kernel can be written in terms of the Feynman propagator (11.4) as

$$
\mu^{-(n-4)}H_{\mathrm{S}_n}^{\mu\nu\alpha'\beta'}(x,y)=\mathrm{Im}\,K^{\mu\nu\alpha'\beta'}(x-y),
\tag{11.19}
$$

where

$$
\begin{aligned}
K^{\mu\nu\alpha'\beta'}(x) \equiv -\mu^{-(n-4)}\Big\{&2\partial^{\mu}\partial^{(\alpha'}\Delta_{F_n}(x)\,\partial^{\beta')}\partial^{\nu}\Delta_{F_n}(x)\\
&+2\mathcal{D}^{\mu\nu}\left(\partial^{\alpha'}\Delta_{F_n}(x)\partial^{\beta'}\Delta_{F_n}(x)\right)+2\mathcal{D}^{\alpha'\beta'}\left(\partial^{\mu}\Delta_{F_n}(x)\,\partial^{\nu}\Delta_{F_n}(x)\right)\\
&+2\mathcal{D}^{\mu\nu}\mathcal{D}^{\alpha'\beta'}\left(\Delta_{F_n}^2(x)\right)+\Big[\eta^{\mu\nu}\partial^{(\alpha'}\Delta_{F_n}(x)\partial^{\beta')}+\eta^{\alpha'\beta'}\partial^{(\mu}\Delta_{F_n}(x)\partial^{\nu)}\\
&+\Delta_{F_n}(0)\left(\eta^{\mu\nu}\mathcal{D}^{\alpha'\beta'}+\eta^{\alpha'\beta'}\mathcal{D}^{\mu\nu}\right)\\
&+\frac{1}{4}\eta^{\mu\nu}\eta^{\alpha'\beta'}\left(\Delta_{F_n}(x)\Box-m^2\Delta_{F_n}(0)\right)\Big]\delta^n(x)\Big\}.
\end{aligned}
\tag{11.20}
$$

Let us define the integrals

$$
J_n(p)\equiv\mu^{-(n-4)}\int\frac{d^nk}{(2\pi)^n}\,\frac{1}{(k^2+m^2-i\epsilon)\left[(k-p)^2+m^2-i\epsilon\right]},
\tag{11.21}
$$

and $J_n^{\mu_1\cdots\mu_r}(p)$ obtained by inserting the momenta $k^{\mu_1}\dots k^{\mu_r}$ into the previous integral, together with

$$I_{0_n} \equiv \mu^{-(n-4)} \int \frac{d^n k}{(2\pi)^n} \, \frac{1}{(k^2+m^2-i\epsilon)}, \tag{11.22}$$

and $I_{0_n}^{\mu_1\dots\mu_r}$ which are also obtained by inserting momenta in the integrand. Then, the different terms in Eq. (11.20) can be computed. These integrals are explicitly given in [189]. It is found that $I_{0_n}^{\mu}=0$ and the remaining integrals can be written in terms of I_{0_n} and $J_n(p)$. It is useful to introduce the projector $P^{\mu\nu}$ orthogonal to p^μ and the tensor $P^{\mu\nu\alpha'\beta'}$ as

$$p^2 P^{\mu\nu} \equiv \eta^{\mu\nu} p^2 - p^\mu p^\nu, \qquad P^{\mu\nu\alpha'\beta'} \equiv 3P^{\mu(\alpha'}P^{\beta')\nu} - P^{\mu\nu}P^{\alpha'\beta'}, \tag{11.23}$$

then the action of the operator $\mathcal{F}_x^{\mu\nu}$ is simply written as $\mathcal{F}_x^{\mu\nu} \int d^n p \, e^{ip\cdot x} f(p) = -\int d^n p \, e^{ip\cdot x} f(p) \, p^2 P^{\mu\nu}$ where $f(p)$ is an arbitrary function of p^μ.

Finally after a rather long but straightforward calculation, and after expanding around $n=4$, we get,

$$\begin{aligned} K^{\mu\nu\alpha'\beta'}(x) = \frac{i}{(4\pi)^2}\Bigg\{ & \kappa_n \left[\frac{1}{90}\mathcal{F}_x^{\mu\nu\alpha'\beta'}\delta^n(x) + 4\Delta\xi^2 \mathcal{F}_x^{\mu\nu}\mathcal{F}_x^{\alpha'\beta'}\delta^n(x)\right. \\ & + \frac{2}{3}\frac{m^2}{(n-2)}\left(\eta^{\mu\nu}\eta^{\alpha'\beta'}\Box_x - \eta^{\mu(\alpha'}\eta^{\beta')\nu}\Box_x + \eta^{\mu(\alpha'}\partial_x^{\beta')}\partial_x^{\nu}\right. \\ & \left. + \eta^{\nu(\alpha'}\partial_x^{\beta')}\partial_x^{\mu} - \eta^{\mu\nu}\partial_x^{\alpha'}\partial_x^{\beta'} - \eta^{\alpha'\beta'}\partial_x^{\mu}\partial_x^{\nu}\right)\delta^n(x) \\ & \left. + \frac{4m^4}{n(n-2)}\left(2\eta^{\mu(\alpha'}\eta^{\beta')\nu} - \eta^{\mu\nu}\eta^{\alpha'\beta'}\right)\delta^n(x)\right] \\ & + \frac{1}{180}\mathcal{F}_x^{\mu\nu\alpha'\beta'}\int \frac{d^n p}{(2\pi)^n} e^{ip\cdot x}\left(1+4\,\frac{m^2}{p^2}\right)^2 \bar{\phi}(p^2) \\ & + \frac{2}{9}\,\mathcal{F}_x^{\mu\nu}\mathcal{F}_x^{\alpha'\beta'}\int \frac{d^n p}{(2\pi)^n}\, e^{ip\cdot x}\left(3\Delta\xi + \frac{m^2}{p^2}\right)^2 \bar{\phi}(p^2) \\ & - \left[\frac{4}{675}\,\mathcal{F}_x^{\mu\nu\alpha'\beta'} + \frac{1}{270}\,(60\xi - 11)\,\mathcal{F}_x^{\mu\nu}\mathcal{F}_x^{\alpha'\beta'}\right]\delta^n(x) \\ & - m^2\left[\frac{2}{135}\,\mathcal{F}_x^{\mu\nu\alpha'\beta'} + \frac{1}{27}\,\mathcal{F}_x^{\mu\nu}\mathcal{F}_x^{\alpha'\beta'}\right]\Delta_n(x)\Bigg\} + \mathcal{O}(n-4), \end{aligned} \tag{11.24}$$

where κ_n has been defined in (11.9), and $\bar{\phi}(p^2)$ and $\Delta_n(x)$ are given by

$$\begin{aligned} \bar{\phi}(p^2) &\equiv \int_0^1 d\alpha \, \ln\!\left(1+\frac{p^2}{m^2}\alpha(1-\alpha) - i\epsilon\right) \\ &= -i\pi\theta(-p^2-4m^2)\sqrt{1+4\frac{m^2}{p^2}} + \varphi(p^2), \end{aligned} \tag{11.25}$$

$$\Delta_n(x) \equiv \int \frac{d^n p}{(2\pi)^n}\, e^{ip\cdot x}\, \frac{1}{p^2}, \tag{11.26}$$

where $\varphi(p^2) \equiv \int_0^1 d\alpha \, \ln|1+\frac{p^2}{m^2}\,\alpha(1-\alpha)|$. The imaginary part of (11.24) gives the kernel components $\mu^{-(n-4)} H_{\mathrm{S}_n}^{\mu\nu\alpha'\beta'}(x,y)$, according to (11.19). It can be easily obtained multiplying this expression by $-i$ and retaining only the real part, $\varphi(p^2)$, of the function $\bar{\phi}(p^2)$.

11.3 Einstein–Langevin Equation

With the previous results for the kernels we can now write the n-dimensional Einstein–Langevin equation (11.24), previous to the renormalization. Taking also into account Eqs. (11.5) and (11.6), we may finally write:

$$\begin{aligned}
&\frac{1}{8\pi G_B} G^{(1)\mu\nu}(x) - \frac{4}{3}\,\alpha_B D^{(1)\mu\nu}(x) - 2\beta_B B^{(1)\mu\nu}(x) \\
&\quad + \frac{\kappa_n}{(4\pi)^2}\left[-4\Delta\xi\,\frac{m^2}{(n-2)}\,G^{(1)\mu\nu} + \frac{1}{90}\,D^{(1)\mu\nu}\Delta\xi^2 B^{(1)\mu\nu}\right](x) \\
&\quad + \frac{1}{2880\pi^2}\left\{-\frac{16}{15}\,D^{(1)\mu\nu}(x) + \left(\frac{1}{6} - 10\Delta\xi\right) B^{(1)\mu\nu}(x)\right. \\
&\quad + \int d^n y \int \frac{d^n p}{(2\pi)^n}\, e^{ip\cdot(x-y)}\,\varphi(p^2)\,\left[\left(1+4\frac{m^2}{p^2}\right)^2 D^{(1)\mu\nu}(y)\right. \\
&\qquad\qquad\qquad\qquad\qquad \left. +10\left(3\Delta\xi + \frac{m^2}{p^2}\right)^2 B^{(1)\mu\nu}(y)\right] \\
&\quad \left. - \frac{m^2}{3}\int d^n y\,\Delta_n(x-y)\left(8D^{(1)\mu\nu} + 5B^{(1)\mu\nu}\right)(y)\right\} \\
&\quad + \frac{1}{2}\int d^n y\,\mu^{-(n-4)} H_{\mathrm{A}_n}^{\mu\nu\alpha'\beta'}(x,y)\,h_{\alpha'\beta'}(y) + \mathcal{O}(n-4) = \xi^{\mu\nu}(x).
\end{aligned} \tag{11.27}$$

Notice that the terms containing the bare cosmological constant have cancelled. These equations can now be renormalized, that is, we can now write the bare coupling constants as renormalized coupling constants plus some suitably chosen counterterms and take the limit $n \to 4$. In order to carry out such a procedure, it is convenient to distinguish between massive and massless scalar fields.

It is convenient to introduce the two new kernels

$$\begin{aligned}
H_{\mathrm{A}}(x;m^2) \equiv \frac{1}{480\pi^2}\int \frac{d^4 p}{(2\pi)^4}\, e^{ip\cdot x}\left\{\left(1+4\,\frac{m^2}{p^2}\right)^2\right. \\
\left. \times\left[-i\pi\mathrm{sign}(p^0)\theta(-p^2-4m^2)\sqrt{1+4\frac{m^2}{p^2}} + \varphi(p^2)\right] - \frac{8}{3}\,\frac{m^2}{p^2}\right\},
\end{aligned}$$

$$H_{\rm B}(x;m^2,\Delta\xi) \equiv \frac{1}{72\pi^2}\int \frac{d^4p}{(2\pi)^4} e^{ip\cdot x}\Bigg\{\left(3\Delta\xi+\frac{m^2}{p^2}\right)^2 \times\left[-i\pi\mathrm{sign}(p^0)\theta(-p^2-4m^2)\sqrt{1+4\frac{m^2}{p^2}}+\varphi(p^2)\right]-\frac{1}{6}\frac{m^2}{p^2}\Bigg\}, \tag{11.28}$$

where $\varphi(p^2)$ is given by the restriction to $n=4$ of expression (11.25). The renormalized coupling constants $1/G_{\rm N}$, α and β are easily computed as it was done in Eq. (11.8). Substituting their expressions into Eq. (11.27), we can take the limit $n\to 4$, using the fact that, for $n=4$, $D^{(1)\mu\nu}(x)=(3/2)\,A^{(1)\mu\nu}(x)$, we obtain the corresponding semiclassical Einstein–Langevin equation.

For the massless case one needs the limit $m\to 0$ of Eq. (11.27). In this case it is convenient to separate κ_n in (11.9) as $\kappa_n=\tilde{\kappa}_n+\frac{1}{2}\ln(m^2/\mu^2)+\mathcal{O}(n-4)$, where

$$\tilde{\kappa}_n \equiv \frac{1}{(n-4)}\left(\frac{e^\gamma}{4\pi}\right)^{\frac{n-4}{2}} = \frac{1}{n-4}+\frac{1}{2}\ln\left(\frac{e^\gamma}{4\pi}\right)+\mathcal{O}(n-4), \tag{11.29}$$

and use that, from Eq. (11.25), we have

$$\lim_{m^2\to 0}\left[\varphi(p^2)+\ln(m^2/\mu^2)\right] = -2+\ln\left|\frac{p^2}{\mu^2}\right|. \tag{11.30}$$

The coupling constants are then easily renormalized. We note that in the massless limit, the Newtonian gravitational constant is not renormalized and, in the conformal coupling case, $\Delta\xi=0$, we have that $\beta_B=\beta$. Note also that, by making $m=0$ in (11.17), the noise and dissipation kernels can be written as

$$\begin{aligned} &N_{\rm A}(x;m^2=0)=N(x), \qquad N_{\rm B}(x;m^2=0,\Delta\xi)=60\Delta\xi^2 N(x),\\ &D_{\rm A}(x;m^2=0)=D(x), \qquad D_{\rm B}(x;m^2=0,\Delta\xi)=60\Delta\xi^2 D(x), \end{aligned} \tag{11.31}$$

where

$$N(x)\equiv\frac{1}{480\pi}\int\frac{d^4p}{(2\pi)^4}e^{ip\cdot x}\theta(-p^2), \qquad D(x)\equiv\frac{-i}{480\pi}\int\frac{d^4p}{(2\pi)^4}e^{ip\cdot x}\mathrm{sign}\,p^0\theta(-p^2). \tag{11.32}$$

It is also convenient to introduce the new kernel

$$\begin{aligned} H(x;\mu^2) &\equiv \frac{1}{480\pi^2}\int\frac{d^4p}{(2\pi)^4}\,e^{ip\cdot x}\left[\ln\left|\frac{p^2}{\mu^2}\right|-i\pi\,\mathrm{sign}(p^0)\theta(-p^2)\right]\\ &=\frac{1}{480\pi^2}\lim_{\epsilon\to 0^+}\int\frac{d^4p}{(2\pi)^4}\,e^{ip\cdot x}\,\ln\left(\frac{-(p^0+i\epsilon)^2+p^ip_i}{\mu^2}\right). \end{aligned} \tag{11.33}$$

This kernel is real and can be written as the sum of an even part and an odd part in the variables x^μ, where the odd part is the dissipation kernel $D(x)$. The Fourier transforms (11.32) and (11.33) can actually be computed and, thus, in this case we have explicit expressions for the kernels in position space; see for instance [722, 723, 213].

Finally, the Einstein–Langevin equation for the physical stochastic perturbations $h_{\mu\nu}$ can be written in both cases, for $m \neq 0$ and for $m = 0$, as

$$\frac{1}{8\pi G_{\mathrm{N}}} G^{(1)\mu\nu}(x) - 2\left(\bar{\alpha} A^{(1)\mu\nu}(x) + \bar{\beta} B^{(1)\mu\nu}(x)\right) + \frac{1}{4}\int d^4y \left[H_{\mathrm{A}}(x-y) A^{(1)\mu\nu}(y) + H_{\mathrm{B}}(x-y) B^{(1)\mu\nu}(y)\right] = \xi^{\mu\nu}(x), \quad (11.34)$$

where in terms of the renormalized constants α_d and β_d the new constants are $\bar{\alpha} = \alpha_d (8\pi G_{\mathrm{N}})^{-1} + (3600\pi^2)^{-1}$ and $\bar{\beta} = \beta_d (8\pi G_{\mathrm{N}})^{-1} - (1/12 - 5\Delta\xi)(2880\pi^2)^{-1}$. The kernels $H_{\mathrm{A}}(x)$ and $H_{\mathrm{B}}(x)$ are given by Eqs. (11.28) when $m \neq 0$, and $H_{\mathrm{A}}(x) = H(x;\mu^2)$, $H_{\mathrm{B}}(x) = 60\Delta\xi^2 H(x;\mu^2)$ when $m = 0$.

In the massless case, we can use the arbitrariness of the mass scale μ to eliminate one of the parameters $\bar{\alpha}$ or $\bar{\beta}$. The components of the Gaussian stochastic source $\xi^{\mu\nu}$ have zero mean value and their two-point correlation functions are given by $\langle \xi^{\mu\nu}(x) \xi^{\alpha'\beta'}(y) \rangle_s = N^{\mu\nu\alpha'\beta'}(x,y)$, where the noise kernel is given in (11.18), which in the massless case reduces to (11.31).

It is interesting to consider the massless conformally coupled scalar field, i.e., the case $\Delta\xi = 0$, of particular interest because of its similarities with the electromagnetic field, and also because of its interest in cosmology: matter fields in the standard model of particle physics become effectively conformally invariant in the very early universe. We have already mentioned that for a conformally coupled field, the stochastic source tensor must be traceless (up to first-order perturbations around semiclassical gravity), in the sense that the stochastic variable $\xi^{\mu}_{\mu} \equiv \eta_{\mu\nu}\xi^{\mu\nu}$ behaves deterministically as a vanishing scalar field. This can be directly checked by noticing, from Eqs. (11.18) and (11.31), that, when $\Delta\xi = 0$, one has $\langle \xi^{\mu}_{\mu}(x) \xi^{\alpha'\beta'}(y) \rangle_s = 0$, since $\mathcal{F}^{\mu}_{\mu} = 3\Box$ and $\mathcal{F}^{\mu\alpha}\mathcal{F}^{\beta}_{\mu} = \Box \mathcal{F}^{\alpha\beta}$. The Einstein–Langevin equations for this particular case (and generalized to a spatially flat FLRW background) were first obtained by Campos and Verdaguer [186]. We review this derivation in Chapter 12.

11.3.1 Stress-Energy Tensor

The expectation value of the renormalized stress-energy tensor for a scalar field can be obtained by comparing the previous equation (11.34) with the Einstein–Langevin equation (10.14).

For a massive scalar field, $m \neq 0$, we get

$$\begin{aligned}\langle \hat{T}^{(1)\mu\nu}_{\mathrm{R}}(x) \rangle = & \frac{1}{2880\pi^2}\left[\frac{8}{5} A^{(1)\mu\nu}(x) - \left(\frac{1}{6} - 10\Delta\xi\right) B^{(1)\mu\nu}(x)\right] \\ & - \int d^4y \left[H_{\mathrm{A}}(x-y;m^2) A^{(1)\mu\nu}(y)\right. \\ & \left. + H_{\mathrm{B}}(x-y;m^2,\Delta\xi) B^{(1)\mu\nu}(y)\right] + \mathcal{O}(h^2). \qquad (11.35)\end{aligned}$$

For a massless scalar field, $m = 0$, we get

$$\begin{aligned}\langle \hat{T}_{\mathrm{R}}^{(1)\mu\nu}(x)\rangle = \frac{1}{2880\pi^2}\left[\frac{8}{5}\,A^{(1)\mu\nu}(x) - \left(\frac{1}{6} - 10\Delta\xi\right) B^{(1)\mu\nu}(x)\right]& \\ -\int d^4y\, H(x-y;\mu^2)\left[A^{(1)\mu\nu}(y)\right.& \\ \left.+60\Delta\xi^2 B^{(1)\mu\nu}(y)\right] + \mathcal{O}(h^2),& \qquad (11.36)\end{aligned}$$

Notice that in the massive case we have chosen, as usual, a renormalization scheme such that the expectation value of the renormalized stress-energy tensor does not have local terms proportional to the metric and the Einstein tensor.

The result (11.36) for a massless field agree with the general form found by Horowitz [213, 698] using an axiomatic approach and coincides with that given in [128]. The particular cases of conformal coupling, $\Delta\xi = 0$, and minimal coupling, $\Delta\xi = -1/6$, are also in agreement with the results for this cases given in [213, 698, 724, 423, 677], modulo local terms proportional to $A^{(1)\mu\nu}$ and $B^{(1)\mu\nu}$ due to different choices of the renormalization scheme. For the case of a massive minimally coupled scalar field, $\Delta\xi = -1/6$, the result (11.35) is equivalent to that found by Tichy and Flanagan [725].

11.4 Solutions of the Einstein–Langevin Equation

Here we solve the Einstein–Langevin equations (11.34) for the components $G^{(1)\mu\nu}$ of the linearized Einstein tensor. Then we use these solutions to compute the corresponding two-point correlation functions, which give a measure of the gravitational fluctuations predicted by the stochastic semiclassical theory of gravity in the present case. Since the linearized Einstein tensor is invariant under gauge transformations of the metric perturbations, these two-point correlation functions are also gauge-invariant. Once we have computed the two-point correlation functions for the linearized Einstein tensor, we find the solutions for the metric perturbations and compute the associated two-point correlation functions. The procedure used to solve the Einstein–Langevin equation is similar to the one used by Horowitz [213], see also [128], to analyze the stability of Minkowski spacetime in semiclassical gravity.

We first note that the tensors $A^{(1)\mu\nu}$ and $B^{(1)\mu\nu}$ can be written in terms of $G^{(1)\mu\nu}$ as

$$A^{(1)\mu\nu} = \frac{2}{3}\,(\mathcal{F}^{\mu\nu} G^{(1)\alpha}_{\alpha} - \mathcal{F}^{\alpha}_{\alpha} G^{(1)\mu\nu}), \qquad B^{(1)\mu\nu} = 2\mathcal{F}^{\mu\nu} G^{(1)\alpha}{}_{\alpha}, \qquad (11.37)$$

where we have used that $3\Box = \mathcal{F}^{\alpha}_{\alpha}$. Therefore, the Einstein–Langevin equation (11.34) can be seen as a linear integro-differential stochastic equation for the components $G^{(1)\mu\nu}$. In order to find solutions to Eq. (11.34), it is convenient to Fourier transform this equation. With the convention $\tilde{f}(p) = \int d^4x e^{-ip\cdot x} f(x)$ for a given field $f(x)$, one finds, from (11.37),

$$\begin{aligned}
\tilde{A}^{(1)\mu\nu}(p) &= 2p^2\tilde{G}^{(1)\mu\nu}(p) - \frac{2}{3}p^2 P^{\mu\nu}\tilde{G}^{(1)\alpha}_{\ \ \alpha}(p), \\
\tilde{B}^{(1)\mu\nu}(p) &= -2p^2 P^{\mu\nu}\tilde{G}^{(1)\alpha}_{\ \ \alpha}(p).
\end{aligned} \tag{11.38}$$

The Fourier transform of the Einstein–Langevin equation (11.34) now reads

$$F^{\mu\nu}_{\alpha'\beta'}(p)\,\tilde{G}^{(1)\alpha'\beta'}(p) = 8\pi G_{\mathrm{N}}\,\tilde{\xi}^{\mu\nu}(p), \tag{11.39}$$

where

$$F^{\mu\nu}_{\alpha'\beta'}(p) \equiv F_1(p)\,\delta^{\mu}_{(\alpha'}\delta^{\nu}_{\beta')} + F_2(p)\,p^2 P^{\mu\nu}\eta_{\alpha'\beta'}, \tag{11.40}$$

with

$$\begin{aligned}
F_1(p) &\equiv 1 + 16\pi G_{\mathrm{N}}\,p^2\left[\frac{1}{4}\tilde{H}_{\mathrm{A}}(p) - 2\bar{\alpha}\right], \\
F_2(p) &\equiv -\frac{16}{3}\,\pi G_{\mathrm{N}}\left[\frac{1}{4}\tilde{H}_{\mathrm{A}}(p) + \frac{3}{4}\tilde{H}_{\mathrm{B}}(p) - 2\bar{\alpha} - 6\bar{\beta}\right].
\end{aligned} \tag{11.41}$$

In the Fourier transformed Einstein–Langevin equation (11.39), $\tilde{\xi}^{\mu\nu}(p)$, the Fourier transform of $\xi^{\mu\nu}(x)$, is a Gaussian stochastic source of zero average and

$$\langle\tilde{\xi}^{\mu\nu}(p)\tilde{\xi}^{\alpha'\beta'}(p')\rangle_s = (2\pi)^4\,\delta^4(p+p')\,\tilde{N}^{\mu\nu\alpha'\beta'}(p), \tag{11.42}$$

where we have introduced the Fourier transform of the noise kernel. The explicit expression for $\tilde{N}^{\mu\nu\alpha'\beta'}(p)$ is found from (11.17) and (11.18) to be

$$\begin{aligned}
\tilde{N}^{\mu\nu\alpha'\beta'}(p) = \frac{1}{720\pi}\theta(-p^2-4m^2)\sqrt{1+4\,\frac{m^2}{p^2}}\,&\left[\frac{1}{4}\left(1+4\,\frac{m^2}{p^2}\right)^2(p^2)^2P^{\mu\nu\alpha'\beta'}\right. \\
&\left.+10\left(3\Delta\xi+\frac{m^2}{p^2}\right)^2(p^2)^2P^{\mu\nu}P^{\alpha'\beta'}\right],
\end{aligned} \tag{11.43}$$

which in the massless case reduces to

$$\lim_{m\to 0}\tilde{N}^{\mu\nu\alpha'\beta'}(p) = \frac{1}{480\pi}\theta(-p^2)\left[\frac{1}{6}\,(p^2)^2\,P^{\mu\nu\alpha'\beta'} + 60\Delta\xi^2(p^2)^2P^{\mu\nu}P^{\alpha'\beta'}\right]. \tag{11.44}$$

11.4.1 Linearized Einstein Tensor Correlator

In general, we can write $G^{(1)\mu\nu} = \langle G^{(1)\mu\nu}\rangle_s + G^{(1)\mu\nu}_{\mathrm{f}}$, where $G^{(1)\mu\nu}_{\mathrm{f}}$ is a solution to Eq. (11.34) with zero average, or (11.39) in the Fourier transformed version. The average $\langle G^{(1)\mu\nu}\rangle_s$ must be a solution of the linearized semiclassical Einstein equation obtained by averaging Eq. (11.34), or (11.39). Solutions to this semiclassical equation (specially in the massless case, $m=0$) have been studied [213, 698, 726, 727, 728, 729, 730, 194, 287, 677, 128], particularly in connection with the problem of the stability of the ground state of semiclassical gravity. The two-point correlation functions for the linearized Einstein tensor are defined by

$$\begin{aligned}\mathcal{G}^{\mu\nu\alpha'\beta'}(x,x') &\equiv \langle G^{(1)\mu\nu}(x)G^{(1)\alpha'\beta'}(x')\rangle_s - \langle G^{(1)\mu\nu}(x)\rangle_s \langle G^{(1)\alpha'\beta'}(x')\rangle_s \\ &= \langle G^{(1)\mu\nu}_{\rm f}(x)G^{(1)\alpha'\beta'}_{\rm f}(x')\rangle_s. \qquad (11.45)\end{aligned}$$

Now we shall seek the family of solutions to the Einstein–Langevin equation which can be written as a linear functional of the stochastic source and whose Fourier transform, $\tilde{G}^{(1)\mu\nu}(p)$, depends locally on $\tilde{\xi}^{\alpha\beta}(p)$. Each of such solutions is a Gaussian stochastic field and, thus, it can be completely characterized by the averages $\langle G^{(1)\mu\nu}\rangle_s$ and the two-point correlation functions (11.45). For such a family of solutions, $\tilde{G}^{(1)\mu\nu}_{\rm f}(p)$ is the most general solution to Eq. (11.39) which is linear, homogeneous and local in $\tilde{\xi}^{\alpha\beta}(p)$. It can be written as

$$\tilde{G}^{(1)\mu\nu}_{\rm f}(p) = 8\pi G_{\rm N}\, D^{\mu\nu}_{\alpha'\beta'}(p)\, \tilde{\xi}^{\alpha'\beta'}(p), \qquad (11.46)$$

where $D^{\mu\nu}_{\alpha'\beta'}(p)$ are the components of a Lorentz invariant tensor field distribution in Minkowski spacetime (by "Lorentz-invariant" we mean invariant under the transformations of the orthochronous Lorentz subgroup; see [213] for more details on the definition and properties of these tensor distributions). This tensor is symmetric under the interchanges of $\alpha \leftrightarrow \beta$ and $\mu \leftrightarrow \nu$, and is the most general solution of

$$F^{\mu\nu}_{\hat{\rho}\hat{\sigma}}(p)\, D^{\hat{\rho}\hat{\sigma}}_{\alpha'\beta'}(p) = \delta^{\mu}_{(\alpha'}\delta^{\nu}_{\beta')}. \qquad (11.47)$$

In addition, we must impose the conservation condition: $p_\nu \tilde{G}^{(1)\mu\nu}_{\rm f}(p) = 0$, where this zero must be understood as a stochastic variable which behaves deterministically as a zero vector field. We can write $D^{\mu\nu}_{\alpha'\beta'}(p) = D^{\mu\nu}_{p\,\alpha'\beta'}(p) + D^{\mu\nu}_{h\,\alpha'\beta'}(p)$, where $D^{\mu\nu}_{p\,\alpha'\beta'}(p)$ is a particular solution to Eq. (11.47) and $D^{\mu\nu}_{h\,\alpha'\beta'}(p)$ is the most general solution to the homogeneous equation. Consequently, see Eq. (11.46), we can write $\tilde{G}^{(1)\mu\nu}_{\rm f}(p) = \tilde{G}^{(1)\mu\nu}_{p}(p) + \tilde{G}^{(1)\mu\nu}_{h}(p)$.

To find the particular solution, we try an ansatz of the form

$$D^{\mu\nu}_{p\,\alpha'\beta'}(p) = d_1(p)\, \delta^{\mu}_{(\alpha'}\delta^{\nu}_{\beta')} + d_2(p)\, p^2 P^{\mu\nu}\eta_{\alpha'\beta'}. \qquad (11.48)$$

Substituting this ansatz into Eq. (11.47), it is easy to see that it solves this equation if we take

$$d_1(p) = \left[\frac{1}{F_1(p)}\right]_r, \qquad d_2(p) = -\left[\frac{F_2(p)}{F_1(p)F_3(p)}\right]_r, \qquad (11.49)$$

with

$$F_3(p) \equiv F_1(p) + 3p^2F_2(p) = 1 - 48\pi G_{\rm N}\, p^2 \left[\frac{1}{4}\tilde{H}_{\rm B}(p) - 2\bar{\beta}\right], \qquad (11.50)$$

and where the notation $[\quad]_r$ means that the zeros of the denominators are regulated with appropriate prescriptions in such a way that $d_1(p)$ and $d_2(p)$

are well defined Lorentz-invariant scalar distributions. This yields a particular solution to the Einstein–Langevin equation:

$$\tilde{G}_p^{(1)\mu\nu}(p) = 8\pi G_{\rm N}\, D^{\mu\nu}_{p\,\alpha'\beta'}(p)\, \tilde{\xi}^{\alpha'\beta'}(p), \tag{11.51}$$

which, since the stochastic source is conserved, satisfies the conservation condition. Note that, in the case of a massless scalar field, $m = 0$, the above solution has a functional form analogous to that of the solutions of linearized semiclassical gravity found in the appendix of [128]. Notice also that, for a massless conformally coupled field, $m = 0$ and $\Delta\xi = 0$, the second term on the right-hand side of Eq. (11.48) will not contribute in the correlation functions (11.45), since in this case the stochastic source is traceless.

A detailed analysis given in [189] concludes that the homogeneous solution $\tilde{G}_h^{(1)\mu\nu}(p)$ gives no contribution to the correlation functions (11.45). Consequently $\mathcal{G}^{\mu\nu\alpha'\beta'}(x,x') = \langle G_p^{(1)\mu\nu}(x) G_p^{(1)\alpha'\beta'}(x')\rangle_s$, where $G_p^{(1)\mu\nu}(x)$ is the inverse Fourier transform of (11.51), and the correlation functions (11.45) are

$$\langle \tilde{G}_p^{(1)\mu\nu}(p) \tilde{G}_p^{(1)\alpha'\beta'}(p')\rangle_s = 64(2\pi)^6 G_{\rm N}^2 \delta^4(p+p') D^{\mu\nu}_{p\hat{\rho}\hat{\sigma}}(p) D^{\alpha'\beta'}_{p\bar{\lambda}\bar{\gamma}}(-p) \tilde{N}^{\hat{\rho}\hat{\sigma}\bar{\lambda}\bar{\gamma}}(p). \tag{11.52}$$

It is easy to see from the above analysis that the prescriptions $[\ \ ]_r$ in the factors D_p are irrelevant in the last expression and, thus, they can be suppressed. Taking into account that $F_l(-p) = F_l^*(p)$, with $l = 1, 2, 3$, we get from Eqs. (11.48) and (11.49)

$$\begin{aligned}
\langle \tilde{G}_p^{(1)\mu\nu}(p)\, \tilde{G}_p^{(1)\alpha'\beta'}(p')\rangle_s = {}& 64(2\pi)^6\, G_{\rm N}^2\, \frac{\delta^4(p+p')}{|F_1(p)|^2} \\
& \times \left[\tilde{N}^{\mu\nu\alpha'\beta'}(p) - \frac{F_2(p)}{F_3(p)}\, p^2 P^{\mu\nu}\, \tilde{N}^{\alpha'\beta'}{}_{\rho}^{\rho}(p) \right. \\
& - \frac{F_2^*(p)}{F_3^*(p)}\, p^2 P^{\alpha'\beta'}\, \tilde{N}^{\mu\nu}{}_{\rho'}^{\rho'}(p) \\
& \left. + \frac{|F_2(p)|^2}{|F_3(p)|^2} p^2 P^{\mu\nu} p^2 P^{\alpha'\beta'}\, \tilde{N}^{\rho}{}_{\rho}{}^{\sigma'}{}_{\sigma'}(p) \right].
\end{aligned} \tag{11.53}$$

This last expression is well defined as a bi-distribution and can be easily evaluated using Eq. (11.43). The final explicit result for the Fourier transformed correlation function for the Einstein tensor is thus

$$\begin{aligned}
\langle \tilde{G}_p^{(1)\mu\nu}(p)\, \tilde{G}_p^{(1)\alpha'\beta'}(p')\rangle_s = {}& \frac{2G_{\rm N}^2}{45}(2\pi)^5 \frac{\delta^4(p+p')}{|F_1(p)|^2} \theta(-p^2-4m^2) \sqrt{1+4\frac{m^2}{p^2}} \\
& \times \left[\frac{1}{4}\left(1+4\,\frac{m^2}{p^2}\right)^2 (p^2)^2\, P^{\mu\nu\alpha'\beta'} \right. \\
& \left. +10\left(3\Delta\xi + \frac{m^2}{p^2}\right)^2 (p^2)^2 P^{\mu\nu} P^{\alpha'\beta'} \left|1 - 3p^2 \frac{F_2(p)}{F_3(p)}\right|^2 \right].
\end{aligned} \tag{11.54}$$

To obtain the correlation functions in coordinate space, i.e., Eq. (11.45), we take the inverse Fourier transform. The final result is:

$$\mathcal{G}^{\mu\nu\alpha'\beta'}(x,x') = \frac{\pi G_{\rm N}^2}{45}\mathcal{F}_x^{\mu\nu\alpha'\beta'}\mathcal{G}_{\rm A}(x-x') + \frac{8\pi G_{\rm N}^2}{9}\mathcal{F}_x^{\mu\nu}\mathcal{F}_x^{\alpha'\beta'}\mathcal{G}_{\rm B}(x-x'), \quad (11.55)$$

with

$$\begin{aligned}\tilde{\mathcal{G}}_{\rm B}(p) &\equiv \theta(-p^2-4m^2)\sqrt{1+4\frac{m^2}{p^2}}\left(3\Delta\xi+\frac{m^2}{p^2}\right)^2\frac{1}{|F_1(p)|^2}\left|1-3p^2\frac{F_2(p)}{F_3(p)}\right|^2,\\ \tilde{\mathcal{G}}_{\rm A}(p) &\equiv \theta(-p^2-4m^2)\sqrt{1+4\,\frac{m^2}{p^2}}\left(1+4\frac{m^2}{p^2}\right)^2\frac{1}{|F_1(p)|^2},\end{aligned} \quad (11.56)$$

where $F_l(p), l=1,2,3$, are given in (11.41) and (11.50).

Notice that, for a massless field ($m=0$), we have

$$\begin{aligned}F_1(p) &= 1+4\pi G_{\rm N}p^2\tilde{H}(p;\bar{\mu}^2),\\ F_2(p) &= -\frac{16}{3}\pi G_{\rm N}\left[(1+180\Delta\xi^2)\frac{1}{4}\tilde{H}(p;\bar{\mu}^2)-6\Upsilon\right],\\ F_3(p) &= 1-48\pi G_{\rm N}p^2\left[15\Delta\xi^2\tilde{H}(p;\bar{\mu}^2)-2\Upsilon\right],\end{aligned} \quad (11.57)$$

with $\bar{\mu} \equiv \mu\exp(1920\pi^2\bar{\alpha})$ and $\Upsilon \equiv \bar{\beta}-60\Delta\xi^2\bar{\alpha}$, and where $\tilde{H}(p;\mu^2)$ is the Fourier transform of $H(x;\mu^2)$ given in (11.33).

11.4.2 Two-Point Correlations for Metric Perturbations

Starting from the solutions found for the linearized Einstein tensor, which are characterized by the two-point correlation functions (11.55) or, in terms of Fourier transforms, (11.54), we can now solve the equations for the metric perturbations. Working in the harmonic gauge, $\partial_\nu\bar{h}^{\mu\nu}=0$ (this zero must be understood in a statistical sense) where $\bar{h}_{\mu\nu} \equiv h_{\mu\nu}-(1/2)\eta_{\mu\nu}h^\alpha_\alpha$, the equations for the metric perturbations in terms of the Einstein tensor are

$$\Box\bar{h}^{\mu\nu}(x) = -2G^{(1)\mu\nu}(x), \quad (11.58)$$

or, in terms of Fourier transforms, $p^2\tilde{\bar{h}}^{\mu\nu}(p) = 2\tilde{G}^{(1)\mu\nu}(p)$. Similarly to the analysis of the equation for the Einstein tensor, we can write $\bar{h}^{\mu\nu} = \langle\bar{h}^{\mu\nu}\rangle_s+\bar{h}^{\mu\nu}_{\rm f}$, where $\bar{h}^{\mu\nu}_{\rm f}$ is a solution to these equations with zero average, and the two-point correlation functions are defined by

$$\begin{aligned}\mathcal{H}^{\mu\nu\alpha'\beta'}(x,x') &\equiv \langle\bar{h}^{\mu\nu}(x)\bar{h}^{\alpha'\beta'}(x')\rangle_s-\langle\bar{h}^{\mu\nu}(x)\rangle_s\langle\bar{h}^{\alpha'\beta'}(x')\rangle_s\\ &= \langle\bar{h}^{\mu\nu}_{\rm f}(x)\bar{h}^{\alpha'\beta'}_{\rm f}(x')\rangle_s.\end{aligned} \quad (11.59)$$

We can now seek solutions of the Fourier transform of Eq. (11.58) of the form $\tilde{\bar{h}}^{\mu\nu}_{\rm f}(p) = 2D(p)\tilde{G}^{(1)\mu\nu}_{\rm f}(p)$, where $D(p)$ is a Lorentz-invariant scalar distribution

15

Stress-Energy Tensor Fluctuations in de Sitter Space

The geometry of most inflationary models as well as the late time behavior of our expanding universe are well approximated by the de Sitter geometry. For this reason quantum metric perturbations around de Sitter and near-de Sitter spacetimes have been extensively studied in the context of inflationary models. The standard analysis is based on the linearized computation of the two-point function of the metric perturbations [954, 734, 753]. But the need for matter loop corrections was emphasized by Weinberg [427], who pointed out also the importance of testing perturbation theory in cosmology given the success of the tree-level approximation; see also Senatore and Zaldarriaga [567]. A series of works including matter loop corrections in different models have been performed using different approaches and models [955, 956, 957] including stochastic gravity [958, 203].

However, certain aspects such as the significance of possible large infrared effects, have not been completely settled yet. The standard theoretical framework also assumes that the background dynamics of de Sitter and near-de Sitter spacetimes is not affected by large quantum corrections. However, there is also a number of studies that claim that one-loop corrections could give a significant backreaction in inflationary models [959, 960, 961, 576, 577]. It has also been argued that higher-order radiative corrections from graviton two-loops could give rise to a secular screening of the cosmological constant for pure gravity in de Sitter spacetime [962, 963]. Such nonlinear effects are dominated by infrared modes which are copiously generated by the exponential expansion and should be fairly insensitive to the short-distance behavior of quantum gravity. However, whether these large effects really take place is still uncertain, mainly due to the gauge dependence of the results [964, 965, 966, 508, 575].

The existence of large quantum nonlinear effects like those mentioned above could lead to a breaking of de Sitter invariance, as suggested by Tsamis and Woodard [962, 963] or by Polyakov [967]. In order to gain insight into this possibility, it seems convenient to study quantum metric perturbations around de Sitter spacetime keeping de Sitter invariance always manifest. This can be achieved with the formalism of the de Sitter-invariant bitensors introduced by Allen and Jacobson [476]. The tree-level graviton two-point function has been computed using this formalism by different authors such as Allen and Turyn [968], Antoniadis and Mottola [969] and Higuchi and Kouris [970]. A conclusion that can be drawn from their results is that the two-point function of the linearized Riemann tensor ${R_{ab}}^{cd}$, which is gauge-invariant around de Sitter spacetime, decays like the fourth power of the physical distance between the two points; see Kouris [971].

We wish to go beyond the linear level and study the effects of matter loops on the quantum metric fluctuations. However, a first step in this direction is to study the stress-energy tensor fluctuations of the matter fields described by the noise kernel. Calculating the noise kernel in de Sitter spacetime, in a de Sitter-invariant vacuum, and with the formalism of de Sitter-invariant bitensors, is the main goal of this chapter. In subsequent chapters quantum gravitational field correlations, including one-loop corrections from matter fields, in de Sitter spacetime are studied.

We start by reviewing in Section 15.1 the basic geometric properties of de Sitter spacetime and the invariant bitensors that will be used in the rest of the chapter and in later chapters. These tools are employed in Section 15.2 to write the noise kernel for spacelike separated points in de Sitter-invariant form, and explicit expressions for the case of a free minimally coupled scalar field are derived. Furthermore, closed results in terms of elementary functions can be given for the particular cases of small masses, vanishing mass, and large separations. A massless limit discontinuity is found and is discussed in some detail. In Section 15.3 an alternative analysis of the noise kernel based on the approximate solutions of the field modes is given, which also helps to clarify the above discontinuity. Finally we discuss the implications of our results for the quantum metric fluctuations around de Sitter spacetime in Section 15.4.

15.1 De Sitter Geometry and Invariant Bitensors

The D-dimensional de Sitter spacetime, dS_D, may be defined as a submanifold embedded in $(D+1)$-dimensional Minkowski spacetime, whose points satisfy the equation

$$\eta_{AB}X^A(x)X^B(x) = H^{-2}, \tag{15.1}$$

where H is a parameter with dimensions of mass or inverse length (we use $\hbar = c = 1$), η_{AB} the Minkowski metric, and $X^A(x)$ is the position vector in Minkowski spacetime of the point x. The hyperboloid is invariant under Lorentz transformations $X^A = \Lambda^A_B X^B$ and these define the isometries σ of dS_D: $X^A(\sigma(x)) = \Lambda^A_B X^B(x)$. Thus, the isometries of de Sitter form the Lorentz group

$O(D,1)$. Another isometry that will also play a role is the antipodal isometry $\alpha(x)$ defined by $X^A(\alpha(x)) = -X^A(x)$.

One may introduce spatially flat coordinates by labelling the points in dS_D with the coordinates $\{t, x^i\}$, with $i = 1, \ldots, D-1$, defined by

$$\begin{aligned} X^0 &= \frac{1}{H}\sinh(Ht) + \frac{1}{2}He^{Ht}\delta_{ij}x^i x^j, \\ X^i &= x^i e^{Ht}, \\ X^D &= \frac{1}{H}\cosh(Ht) - \frac{1}{2}He^{Ht}\delta_{ij}x^i x^j, \end{aligned} \tag{15.2}$$

then the line element induced on the hypersurface takes the form

$$ds^2 = \eta_{AB}dX^A(x)dX^B(x) = -dt^2 + e^{2Ht}\delta_{ij}dx^i dx^j, \tag{15.3}$$

so that the hypersurfaces Σ_t of constant t are flat. These coordinates do not cover the whole de Sitter spacetime (they cover the Poincaré patch), but it is not difficult to introduce coordinates that do and which, moreover, are useful to construct a conformal diagram for de Sitter spacetime. To see this we first rewrite the previous metric using the conformal time $ad\eta = dt$, where a is the scale factor $a = \exp(Ht)$, and spherical coordinates,

$$ds^2 = \frac{1}{H^2\eta^2}\left(-d\eta^2 + dr^2 + r^2\left(d\theta^2 + \sin^2\theta d\varphi^2\right)\right), \tag{15.4}$$

where $-\infty < \eta < 0$, $0 \leq r < \infty$, $0 \leq \theta < \pi$ and $0 \leq \varphi < 2\pi$. We may then introduce new time and space coordinates $(\tilde{\eta}, \chi)$ which span a finite range as [745],

$$\eta = \frac{\sin\tilde{\eta}}{\cos\tilde{\eta} + \cos\chi}, \quad r = \frac{\sin\chi}{\cos\tilde{\eta} + \cos\chi}. \tag{15.5}$$

where $-\pi < \tilde{\eta} < 0$ and $0 \leq \chi < \pi$, and the metric now reads

$$ds^2 = \frac{1}{H^2\sin^2\tilde{\eta}}\left(-d\tilde{\eta}^2 + d\chi^2 + \sin^2\chi\left(d\theta^2 + \sin^2\theta d\varphi^2\right)\right). \tag{15.6}$$

the section of $\tilde{\eta} = \text{const}$ are three spheres. These coordinates cover the entire de Sitter spacetime. They represent a closed universe which contracts for $-\pi < \tilde{\eta} < -\pi/2$ and expands for $-\pi/2 < \tilde{\eta} < 0$. The de Sitter conformal diagram, for the conformal metric $(H^2\sin^2\tilde{\eta})\, ds^2$, may be represented in terms of these coordinates $(\chi, \tilde{\eta})$, each point of the conformal diagram represents a S^2 sphere of radius $\sin\chi$.

The metric of de Sitter spacetime is a solution of Einstein equation in vacuum with a cosmological constant

$$G_{ab} + \Lambda g_{ab} = 0, \tag{15.7}$$

where the cosmological constant is $\Lambda = [(D-1)(D-2)/2]\, H^2$. The metric can be interpreted as a cosmological FLRW metric for a perfect fluid whose pressure equals the constant energy density (vacuum energy). Because the energy density is constant any hypersurface is an hypersurface of constant energy density.

15.1.1 De Sitter Invariant Bitensors

To introduce the formalism of the de Sitter invariant bitensors it is convenient to define the basic biscalar

$$Z(x,x') = H^2 \eta_{AB} X^A(x) X^B(x'), \tag{15.8}$$

where $x, x' \in dS_D$. Note that Z is invariant under the de Sitter group; if σ is an isometry, then $Z(\sigma(x), \sigma(x')) = Z(x,x')$ and under the antipodal transformation $Z(\alpha(x), x') = -Z(x,x')$. This biscalar is related to the Minkowskian distance, defined by

$$d^2(x,x') = \eta_{AB}[X^A(x) - X^A(x')][X^B(x) - X^B(x')], \tag{15.9}$$

which is the length of the straight line in the embedding $(D+1)$-Minkowski spacetime that joins x and x'. It follows from the two previous equations that Z and d are related through

$$d^2(x,x') = 2H^{-2}(1 - Z(x,x')). \tag{15.10}$$

Therefore, $Z = 1$ when x' is on the light cone of x, $Z > 1$ when the points are timelike separated, and $Z < 1$ when the points are spacelike separated. It should also be noted that, as the squared Minkowskian distance between two points on the hyperboloid can take any value, $Z \in (-\infty, \infty)$.

Now, without loss of generality we can take the point x in the conformal diagram $(\chi = 0, \tilde{\eta} = -\pi/2)$ and consider the spacelike straight curve with $\tilde{\eta} =$ const connecting x and its antipodal $\alpha(x)$ which in that diagram is given by $(\chi = \pi, \tilde{\eta} = -\pi/2)$. This curve is a geodesic, because it is a straight line on a cylinder tangent to the hyperboloid. The Minkowskian distance between x and any other point x' in this geodesic satisfies $0 \leq d(x,x') \leq 2$. This implies

$$-1 \leq Z(x,x') \leq 1. \tag{15.11}$$

Any other spacelike geodesic passing through x can be obtained from this one by an isometry that leaves x invariant (it also leaves $\alpha(x)$ invariant). This is analogous to the case of the sphere, where any geodesic (meridian) passing through the north pole is obtained from a given one by a rotation that leaves the north pole (and south pole) invariant. This means that any point y' connected to x by a spacelike geodesic satisfies $y' = \sigma(x')$ for some x' in the above geodesic, and where σ is an isometry such that $\sigma(x) = x$. De Sitter invariance of Z then implies $Z(x,y') = Z(\sigma(x), \sigma(x')) = Z(x,x')$. Consequently, Eq. (15.11) holds for any point x' connected with x by a spacelike geodesic. In other words, spacelike separated points x, x' such that $Z(x,x') < -1$ cannot be joined by a geodesic.

17

Riemann Tensor Correlator in de Sitter

The Riemann tensor correlation function exhibits a number of interesting features. First, with appropriately raised indices it is gauge-invariant even when including contributions from loops of matter fields but excluding graviton loops, which as we have seen before can be implemented systematically within a large N expansion for N matter fields. Second, it is compatible with de Sitter invariance, in contrast with other gauge-invariant quantities more commonly used in cosmology. In fact, whether de Sitter invariance is preserved can be manifestly seen by expressing the result in terms of maximally symmetric bitensors. Thirdly, the Riemann tensor provides a complete and suitable characterization of the local geometry: geometrical observables associated with a finite region of spacetime can be obtained from it. Thus, they are insensitive to potentially infrared divergent superhorizon contributions which cannot be probed by observables involving finite spacetime regions.

In this chapter the linearized Riemann tensor correlator on a de Sitter background including one-loop corrections from conformal fields is derived, following Fröb et al. [572]. In Section 17.1 we revisit the formalism described in Section 15.1 of de Sitter-invariant bitensors, and introduce an alternative set of bitensors which are useful for this computation. The main result of the chapter is obtained in Section 17.2: by taking suitable derivatives of the metric correlator function found in Section 16.5, the connected two-point correlator function of the Riemann tensor $R^{ab}{}_{cd}$ is computed. The result is written in a manifestly de Sitter-invariant form in terms of the bitensors introduced by Allen and Jacobson. Moreover, given the decomposition of the Riemann tensor in terms of Weyl and Ricci tensors, we write the explicit results for the Weyl and Ricci tensors correlators as well as the Weyl–Ricci tensors correlator and study both their subhorizon and superhorizon behavior. These results are extended to general conformal field theories in Section 17.3.

We also derive the Riemann tensor correlator in Minkowski spacetime in a manifestly Lorentz invariant form in Section 17.4, by carefully taking the flat-space limit of our result in de Sitter. To the best of our knowledge, this result for the Riemann tensor correlator in Minkowski spacetime including loop corrections from general conformal fields had not been obtained previously to the calculation in de Sitter by Fröb et al. [572]. There were results in the literature for the metric correlator by Tomboulis [686] and Martín and Verdaguer [189], and the correlator of the Einstein tensor by Osborn and Shore [204], which is closely related to the stress-energy tensor correlator, but not for the full Riemann tensor correlator.

17.1 De Sitter-Invariant Bitensors

We have seen in Section 15.1 that any de Sitter-invariant two-point correlation function can be expressed in terms of maximally symmetric bitensors. Here we adapt the formalism to our problem. The basic de Sitter-invariant biscalar $Z(x,x')$ was defined in (15.8) The geodesic distance $\mu(x,x')$ along the shortest geodesic connecting the points x and x' is related to the biscalar $Z(x,x')$ by Eq. (15.18), which we now write re-introducing the Hubble parameter H as

$$Z(x,x') = \cos\left(H\mu(x,x')\right). \tag{17.1}$$

For points such that $Z(x,x') < -1$, i.e., points not connected by a geodesic, μ can still be defined by a suitable analytic continuation from (17.1).

As we have seen in Section 15.1 a theorem by Allen and Jacobson [476] establishes that there exists a complete set of de Sitter-invariant bitensors from which all maximally symmetric bitensors can be constructed. This set is given by the metric $\hat{g}_{ab}(x)$, the geodesic distance $\mu(x,x')$, the unit tangent vectors to the geodesic at the points x and x', $n_a(x,x')$ and $n_{a'}(x,x')$, defined by Eq. (15.14), and the propagator $\hat{g}_{ab'}(x,x')$ which parallely transports a vector from x' to x along the geodesic connecting them. Here as in Chapter 16 we use a hat over a symbol to refer to quantities which are defined on the background de Sitter space, see Eq. (16.18).

By inverting Eq. (17.1), we can write the complete set of bitensors described above in terms of covariant derivatives of $Z(x,x')$ as follows:

$$\begin{gathered} n_a = -\frac{1}{H\sqrt{1-Z^2}}\hat{\nabla}_a Z, \qquad n_{a'} = -\frac{1}{H\sqrt{1-Z^2}}\hat{\nabla}_{a'} Z, \\ H^2 \hat{g}_{ab'} = \hat{\nabla}_a \hat{\nabla}_{b'} Z - \frac{1}{1+Z}(\hat{\nabla}_a Z)(\hat{\nabla}_{b'} Z). \end{gathered} \tag{17.2}$$

In addition, as an illustration of the above theorem, see Eq. (15.17), we have that

$$\hat{\nabla}_a n_b = \frac{Z}{\sqrt{1-Z^2}} H\left(\hat{g}_{ab} - n_a n_b\right), \tag{17.3}$$

Quantum fields in Minkowski spacetime

The theory of quantum fields in curved spacetime is a generalization of the well-established theory of quantum fields in Minkowski spacetime. To a great extent, the behavior of quantum fields in curved spacetime is a direct consequence of the corresponding flat spacetime theory. Local entities, such as the field equations and commutation relations, are to a large extent determined by the principle of general covariance and the principle of equivalence. However, global entities which are unique in Minkowski spacetime lose that uniqueness in curved spacetime. For example, the vacuum state, which in Minkowski spacetime is determined by Poincaré invariance, is not unambiguously determined in curved spacetime. This ambiguity is closely tied to the phenomenon of particle creation by certain gravitational fields, as in the expanding universe or near a black hole.

It is logical, therefore, to review the relevant aspects of flat spacetime quantum field theory. This will serve to establish the necessary background, to fix our notation, and to highlight those aspects of the theory which can be carried over to curved spacetime, as well as those which lose their meaning in curved spacetime. We will often be brief, emphasizing concepts while omitting many derivations, and only touch on particular topics. Our discussion of the curved spacetime theory in later chapters will be more detailed.

In this initial chapter, we discuss the canonical formulation, including the Schwinger action principle and the relation between symmetry transformations and conserved currents (Schwinger 1951b, 1953). We review the dynamical descriptions known as the Heisenberg picture, the Schrödinger picture, and the interaction picture. We introduce the Fock representations, in which states are described in terms of their particle content, and the Schrödinger representation, in which the states are described by field configurations. We include discussions of the Maxwell and Yang–Mills gauge fields, as well as the Dirac field, and the definitions of spin and angular momentum.

1.1 Canonical formulation

Recall that in classical mechanics the equations of motion of a particle or system of particles having independent generalized coordinates $q_i(t)$ and velocities $\dot{q}_i(t)$ are given by the principle of stationary action. This principle states that the action

$$S = \int_{t_1}^{t_2} dt\, L(q, \dot{q}) \tag{1.1}$$

is stationary under arbitrary variations of the q_i which vanish on the boundary of the region of integration. Here L is the Lagrangian of the system. The Hamiltonian is defined by

$$H(q,p) = \sum_i p_i \dot{q}_i - L,$$

where

$$p_i = \frac{\partial L}{\partial \dot{q}_i} \tag{1.2}$$

is the momentum conjugate to q_i. The system is quantized by taking the qs and ps to be Hermitian operators acting on a Hilbert space, and by imposing the canonical commutation relations

$$[q_i, q_j] = 0, \quad [p_i, p_j] = 0,$$

$$[q_i, p_j] = i\delta_{i,j}. \tag{1.3}$$

Here $\delta_{i,j}$ is the Kronecker delta. We are using units with $\hbar = c = 1$. From (1.3) it follows that if $F(q,p)$ is a function of the coordinate and momentum operators, then (assuming F can be Taylor expanded in p)

$$[q_i, F] = i\frac{\partial F}{\partial p_i}. \tag{1.4}$$

The above commutation relations imply that the q_i are a complete set of commuting observables with continuous spectra consisting (in the absence of impenetrable walls) of all real numbers. The same can be said for the p_i. (An observable is an Hermitian operator with a complete set of eigenstates.) The eigenstates[1] of the q_i are the kets $|q'>$, where q' denotes the set of eigenvalues q'_i of the operators q_i. Thus,

$$q_i|q'> = q'_i|q'>,$$

with the normalization

$$<q'|q''> = \delta(q' - q''),$$

---

[1] We use the conventions of Dirac (1958) in distinguishing the eigenvalue of an operator from the operator by using a $'$.

where $\delta(q' - q'')$ is the Dirac δ-function. It also follows that

$$< q'|p_i|q'' >= -i\frac{\partial\delta(q' - q'')}{\partial q'_i},$$

and that

$$< q'|p' >= (2\pi)^{-n/2}\exp\left(i\sum_{i=1}^{n} p'_i q'_i\right),$$

where $|p' >$ is an eigenket of the p_i having delta function normalization, and we have taken the index i to run from 1 to n. (For derivations, see Messiah (1961, pp. 302–309).) If $F(q,p)$ is a function of the q_i and p_i with any well-defined ordering of factors, then

$$< q'|F(q,p)|q'' >= F\left(q', -i\frac{\partial}{\partial q'}\right)\delta(q' - q''), \tag{1.5}$$

where $F(q', -i(\partial/\partial q'))$ is the same ordered function with $-i(\partial/\partial q'_i)$ replacing p_i in each position.

In the Schrödinger or configuration space representation, the abstract operators are represented by matrix elements based on the $|q' >$, such as that of p_i above, and the states are represented by functions. For example, a state $|\psi >$ is represented by the Schrödinger wave function $\psi(q') =< q'|\psi >$. An example is the wave function $< q'|p' >$ above, representing a particle of definite momentum. Similarly, in the momentum-space representation the operators are represented by matrix elements formed from the $|p' >$ and the states are represented by functions such as $< p'|\psi >$.

Up to now the description has been purely kinematical, with time playing no role. The dynamical evolution of the system is governed by the Hamiltonian $H(q,p,t)$. We have allowed for the possibility that H may have explicit time dependence, as through an interaction with an external field. The time evolution may be described in several physically equivalent ways, known as “pictures.”

In the Schrödinger picture, the fundamental observables q and p do not change with time. Rather, the dynamical evolution of measurable quantities, such as expectation values of observables, is expressed through the time dependence of the ket describing the state of the system at each time. The fundamental dynamical equation is that of Schrödinger,

$$i\frac{d}{dt}|\psi(t) >= H(q,p,t)|\psi(t) >. \tag{1.6}$$

Because H may have explicitly time-dependent terms involving p and q, in general $H(t')$ and $H(t'')$ may not commute. (For brevity, we suppress the dependence of H on q and p.)

We note in passing that in the Schrödinger representation, the Schrödinger equation (1.6) becomes (using the completeness of the $|q' >$)

$$i < q'|\frac{d}{dt}|\psi(t) >= \int < q'|H(q,p,t)|q'' > dq'' < q''|\psi(t) >$$

or

$$i\frac{\partial}{\partial t}\psi(q',t) = H\left(q', -i\frac{\partial}{\partial q'}, t\right)\psi(q',t), \tag{1.7}$$

where $\psi(q',t) =< q'|\psi(t) >$.

The solution of (1.6) is

$$|\psi(t) >= U(t,t_0)|\psi(t_0) >,$$

with $U(t,t_0)$ satisfying

$$i\frac{d}{dt}U(t,t_0) = H(t)U(t,t_0), \tag{1.8}$$

with the boundary condition

$$U(t_0,t_0) = 1.$$

The evolution operator $U(t,t_0)$ preserves the norm of the state vector and is thus unitary, satisfying

$$UU^\dagger = U^\dagger U.$$

From $U(t_0,t)U(t,t_0) = U(t_0,t_0) = 1$, it then follows that $U(t,t_0)^\dagger = U(t_0,t)$.

In the Heisenberg picture, the ket describing the state of the system does not change with time, while the dynamical evolution of the system is expressed through the time dependence of the fundamental observables $q(t)$ and $p(t)$. By applying $U(t,t_0)^\dagger$ to the Schrödinger picture ket describing the state of the system, we obtain a time-independent ket, which can be taken as the ket describing the state of the system in the Heisenberg picture. Thus, denoting quantities in the Schrödinger picture by subscript S and those in the Heisenberg picture by subscript H, we have

$$|\psi_H >= U(t,t_0)^\dagger|\psi_S(t) >= |\psi_S(t_0) >. \tag{1.9}$$

In order that measurable expectation values remain the same as in the Schrödinger picture, the Heisenberg picture operator $F_H(t)$ corresponding to a Schrödinger picture operator F_S must be related by

$$F_H(t) = U(t,t_0)^\dagger F_S U(t,t_0). \tag{1.10}$$

Note that the Hamiltonian H in (1.8) is H_S. When H_S has no explicit time dependence, the solution of (1.8) is

$$U(t,t_0) = \exp[-i(t-t_0)H],$$

and it follows that H commutes with U so that $H_H = H_S$. When H_S does have an explicit time dependence, $H_H \neq H_S$, and we must use (1.10) to define H_H in terms of H_S. In general, F_H will depend on time through $q_H(t)$, $p_H(t)$, and through further explicit appearance of t. Denoting by $\partial F_H/\partial t$ the derivative only with respect to this further explicit appearance of t, it follows from (1.8) and (1.10) that

$$i\frac{d}{dt}F_H = [F_H,\, H_H] + i\frac{\partial}{\partial t}F_H. \tag{1.11}$$

This resembles the classical equation of motion with the Poisson bracket replaced by $-i$ times the commutator. Of course, we do not need to define the Schrödinger picture before the Heisenberg picture. The latter is fully defined by stating that the ket describing the state of the system is independent of time and that operators F, constructed from the q_i, p_i (dropping subscript H), and t obey the Heisenberg equation of motion (1.11).

When two systems interact through a term in the Hamiltonian, which can be regarded as a perturbative interaction, it is useful to introduce another picture of the dynamical evolution, known as the "interaction picture." In this picture, the ket describing the state of the system evolves as in the Schrödinger picture, but only under the influence of the interaction term in the Hamiltonian, while operators evolve as in the Heisenberg representation, but only under the influence of the unperturbed term in the Hamiltonian.

Let us now turn to the canonical quantization of a system of independent real fields $\phi_a(x)$, where x refers to the Minkowski space and time coordinates x^μ, and the index a includes tensor or spinor indices and internal quantum numbers of the field multiplet. We will deal here with bosons and discuss later the modification of canonical quantization required with fermions. For brevity, the index a will often be suppressed; we can usually think of ϕ as a column or row matrix, depending on where it appears in an expression. Canonical quantization proceeds as in the previously discussed quantization of a particle. One thinks of the classical field $\phi(x)$ as analogous to the classical $q_i(t)$, with the spatial coordinates $\vec{x}$ regarded as labels like i. Because we are now dealing with a continuous label, Dirac δ-functions involving $\vec{x}$ will appear where Kronecker deltas involving the label i previously appeared. As before, we assume that the system is described by an action

$$S = \int_{t_1}^{t_2} dt\, L[\phi, \partial\phi]_t, \tag{1.12}$$

where the Lagrangian L is now a functional of the field ϕ and its first derivatives $\partial\phi/\partial x^\mu \equiv \partial_\mu\phi$, which are denoted collectively by $\partial\phi$. The subscript t indicates that L is a function of t. The Lagrangian L can be expressed in terms of a Lagrangian density $\mathcal{L}$ as

$$L[\phi, \partial\phi]_t = \int dV_x\, \mathcal{L}\big(\phi(\vec{x}, t), \partial\phi(\vec{x}, t)\big),$$

where dV_x is the spatial volume element. Because L is now a functional, the momentum π conjugate to the field $\phi(\vec{x},t)$ is defined in analogy with (1.2) through the following functional derivative (regarding $\partial_0\phi$ as independent of ϕ at time t),

$$\begin{aligned}\pi(\vec{x},t) &= \delta L[\phi,\partial\phi]_t/\delta\big(\partial_0\phi(\vec{x},t)\big) \\ &= \partial\mathcal{L}\big(\phi(\vec{x},t),\partial\phi(\vec{x},t)\big)/\partial\big(\partial_0\phi(\vec{x},t)\big). \end{aligned} \tag{1.13}$$

Here, we have used the definition of the functional derivative, which states that if $F[\chi]$ is a functional of $\chi(\vec{x})$, then under a variation $\delta\chi(\vec{x})$ of χ, which vanishes sufficiently fast at spatial infinity, we have

$$\delta F[\chi] = \int dV_x\, \frac{\delta}{\delta\chi(\vec{x})} F[\chi]\delta\chi(\vec{x}). \tag{1.14}$$

It follows that if the functional F has the form

$$F[\chi] = \int dV_x\, f\big(\chi(\vec{x}),\vec{\partial}\chi(\vec{x})\big),$$

then

$$\frac{\delta}{\delta\chi(\vec{x})}F[\chi] = \frac{\partial}{\partial\chi}f\big(\chi,\vec{\partial}\chi\big) - \partial_i\left(\frac{\partial}{\partial(\partial_i\chi)}f\big(\chi,\vec{\partial}\chi\big)\right),$$

where χ is evaluated at $\vec{x}$. The result in (1.13) follows from this with $\chi \to \partial_0\phi$. Another consequence is that

$$\frac{\delta\chi(\vec{x}')}{\delta\chi(\vec{x})} = \delta(\vec{x}'-\vec{x}).$$

One can regard the action in (1.12) as a functional depending on the space and time dependence of ϕ. Then, the Euler–Lagrange field equation below will be recognized as another application of the above result, but for a functional depending on one more dimension.

The Hamiltonian is defined by

$$H[\phi,\pi]_t = \int dV_x\, \pi_a(\vec{x},t)\partial_0\phi_a(\vec{x},t) - L[\phi,\partial\phi]_t. \tag{1.15}$$

(Although we write $H[\phi,\pi]$, dependence on spatial derivatives of ϕ (or π) is permitted.) The principle of stationary action yields upon variation of the fields in (1.12), the Euler–Lagrange field equations

$$\partial_\mu\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)}\right) - \frac{\partial\mathcal{L}}{\partial\phi} = 0, \tag{1.16}$$

where the repeated spacetime coordinate index μ is summed over its full range of values, in accordance with the Einstein summation convention.

The field is quantized in analogy with the canonical commutators of (1.3). Thus, we postulate that

$$[\phi_a(\vec{x},t),\phi_b(\vec{x}',t)]=0,\quad [\pi_a(\vec{x},t),\pi_b(\vec{x}',t)]=0,$$

$$[\phi_a(\vec{x},t),\pi_b(\vec{x}',t)]=i\delta_{a,b}\delta(\vec{x}-\vec{x}'), \tag{1.17}$$

where, as noted earlier, $\delta(\vec{x}-\vec{x}')$ is the Dirac δ-function. (In a theory of interacting fields, if we deal directly with the renormalized fields, then (1.17) is somewhat altered by a normalization factor. We are thus dealing here with the bare fields, which by definition satisfy the field equations with unrenormalized masses and coupling constants.) The t dependence is included in the commutation relations to emphasize that in a dynamical picture like the Heisenberg picture, in which the operators ϕ and π depend on time (as do the classical fields), the canonical commutation relations must be imposed on the fields and conjugate momenta evaluated at the same time. For it follows from (1.10) that $q_H(t)$ and $p_H(t)$ evaluated at the same time do satisfy (1.3), while that is not true in general if they are evaluated at different times. Of course, in the Schrödinger picture the fields and conjugate momenta have no time dependence, and t would not appear in (1.17).

The functional analogue of (1.4) follows from the above commutators:

$$[\phi_a(\vec{x}),F[\phi,\pi]\,]=i\frac{\delta}{\delta\pi_a(\vec{x})}F[\phi,\pi], \tag{1.18}$$

where we are suppressing the time dependence, taking all fields to be at a single time t. One can now set up a Schrödinger or field representation using the eigenstates of $\phi(\vec{x})$ defined by

$$\phi(\vec{x})|\phi'>=\phi'(\vec{x})|\phi'>. \tag{1.19}$$

The ket $|\phi'>$ corresponds to a state of the system in which the field has configuration $\phi'(\vec{x})$, where ϕ' is an ordinary or c-number function, unlike the field operator ϕ. Thus, we are using the analogue of the Dirac notation in which "eigenvalues" of the operator $\phi(\vec{x})$ are functions denoted by $\phi'(\vec{x})$. (Here the prime does not denote derivative, but instead distinguishes a c-number from an operator.) In ordinary quantum mechanics, it follows from (1.5) that if $|\psi>$ is an element of the Hilbert space spanned by the eigenkets $|q'>$, then

$$<q'|F(q,p)|\psi>=F\left(q',-i\frac{\partial}{\partial q'}\right)<q'|\psi>.$$

Similarly, we can show that if $|\Psi>$ is a state in the space spanned by the eigenstates $|\phi'>$, and $F[\phi,\pi]$ is a functional formed from the field operator and conjugate momentum, then

$$<\phi'|F[\phi,\pi]|\Psi>=F\left[\phi',-i\frac{\delta}{\delta\phi'}\right]<\phi'|\Psi>. \tag{1.20}$$

Here $<\phi'|\Psi>\equiv\Psi[\phi']$ is a complex number which is a functional of ϕ'. It is interpreted as the probability amplitude for finding the field observable ϕ to have the configuration or set of values given by $\phi'(\vec{x})$ when the system is in the state described by the vector $|\Psi>$.

If we work in the Schrödinger picture, then (1.20) can be used to turn the Schrödinger equation

$$i\frac{d}{dt}|\Psi(t)>= H[\phi,\pi]|\Psi(t)>$$

into the functional differential equation

$$i\frac{\partial}{\partial t}\Psi[\phi',t] = H\left[\phi', -i\frac{\delta}{\delta\phi'}\right]\Psi[\phi',t], \tag{1.21}$$

where $\Psi[\phi',t] \equiv <\phi'|\Psi(t)>$, and ϕ, π depend on $\vec{x}$, but not on t.

On the other hand, in the Heisenberg picture the state describing the evolving system is independent of time, while a general functional F of $\phi(\vec{x},t)$ and $\pi(\vec{x},t)$ will depend on time through its dependence on ϕ and π, as well as through a possible further explicit dependence on t. Then, the Heisenberg equation of motion is

$$i\frac{d}{dt}F[\phi,\pi;t] = \big[F[\phi,\pi;t],\, H[\phi,\pi]\big] + i\frac{\partial}{\partial t}F[\phi,\pi;t]. \tag{1.22}$$

The consistency of (1.22) with the Euler–Lagrange equations (1.16) can be proved in Minkowski spacetime and in the more general curved spacetime context (Parker, 1973, see Appendix B).

Finally, we expect that when there are no time- or space-dependent external parameters in the Lagrangian, then there should exist a conserved vector observable P^μ corresponding to the total energy and momentum of the system. For such a Lagrangian, by multiplying the Euler–Lagrange equations by $\partial_\mu\phi$ and using[2]

$$\partial_\mu\mathcal{L} = \frac{\partial\mathcal{L}}{\partial(\partial_\nu\phi)}\partial_\mu\partial_\nu\phi + \frac{\partial\mathcal{L}}{\partial\phi}\partial_\mu\phi,$$

we find immediately that

$$\partial_\mu T^\mu{}_\nu = 0, \tag{1.23}$$

where

$$T^\mu{}_\nu = \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\partial_\nu\phi_a - \delta^\mu{}_\nu\mathcal{L}. \tag{1.24}$$

Here, summation over internal indices a of ϕ and, when the fields are treated as operators, symmetrization over fields and their conjugate momenta are understood. The tensor $T_{\mu\nu}$ is called the canonical energy-momentum or stress tensor.

We mention in passing that in order to serve as the source in the Einstein gravitational field equations, $T_{\mu\nu}$ should be symmetric under interchange of indices.

---

[2] This assumes that the Lagrangian does not have any explicit dependence on the coordinates x^μ.

(This symmetry is also required if we wish to define a conserved angular momentum in terms of the energy-momentum tensor.) However, except in the case of particular forms of $\mathcal{L}$, the expression given in (1.24) (after lowering the index ν with the Minkowski metric $\eta_{\mu\nu}$) is not a symmetric tensor. A general manifestly symmetric expression for $T_{\mu\nu}$ will be given later, when we deal with curved spacetime. (Since both of these expressions for $T^{\mu}{}_{\nu}$ will satisfy (1.23) for *any* system with no explicit time or space dependence, we expect on physical grounds that they must each yield the same conserved energy and momentum P^{μ} to within a constant.) Furthermore, a modification of the canonical $T_{\mu\nu}$ that makes it symmetric, and yields the same P_{μ} and angular momentum as the original canonical $T_{\mu\nu}$, has been given by Belinfante (1939, 1940).

From (1.23) we have

$$\int dv_x \, \partial_{\mu} T^{\mu}{}_{\nu} = 0,$$

where dv_x denotes the *spacetime* volume element, and the integration is over a spacetime volume bounded by spatial infinity and any two constant-time hypersurfaces. Assuming that matrix elements of physical interest will be between states in which the physical field configuration is of finite spatial extent, we obtain by the Gauss divergence theorem the conservation law

$$\frac{d}{dt} \int dV_x \, T^{0}{}_{\nu} = 0,$$

where dV_x denotes the *spatial* volume element and the integration is over any constant-time hypersurface. Hence,

$$P_{\nu} = \int dV_x T^{0}{}_{\nu} \tag{1.25}$$

is the conserved energy-momentum vector. The sign in this definition is chosen so that $P_0 = H$, as can be verified by comparing (1.15) with (1.24).

As a special case of the Heisenberg field equation (1.22), suppose that the functional F is an ordinary function $f(\phi(x), \partial_i \phi(x), \pi(x))$ with no explicit time dependence. Then, (1.22) can be written as

$$i\partial_0 f = [f, P_0], \tag{1.26}$$

where the partial derivative symbol is used here in the conventional manner to indicate that the x^i are held fixed. In (1.22), the partial derivative symbol denoted derivation only with respect to explicit t dependence not coming from ϕ and π. The partial derivative in (1.26) includes *all* t dependence. The result in (1.26) is the 0-component of the more general relation

$$i\partial_{\mu} f = [f, P_{\mu}], \tag{1.27}$$

The $\mu = 0$ component, as noted above, follows from (1.22). For $\mu = i$, we easily verify (1.27) for powers of ϕ and π and thus for functions which can be expanded in power series in ϕ and π. For example, suppressing the t-dependence, which is the same in all arguments, we have

$$\begin{aligned}[\pi(\vec{x})^n, P_i] &= \int dV'_x\,\pi(\vec{x}')[\pi(\vec{x})^n, \partial'_i\phi(\vec{x}')] \\ &= -i\int dV'_x\,\pi(\vec{x}')n\pi(\vec{x})^{n-1}\partial'_i\delta(\vec{x}-\vec{x}') \\ &= i\partial_i(\pi(\vec{x})^n).\end{aligned}$$

Equation (1.27) also follows from a powerful generalization of the action principle and of Noether's theorem, known as the Schwinger operator action principle (Schwinger 1951b, 1953). (For textbook treatments see Roman (1969) or Toms (2007).) The action of (1.12) is integrated over a spacetime volume v bounded by two constant-time hypersurfaces at t_1 and t_2. (As originally stated, the principle deals with arbitrary spacelike hypersurfaces, but we work with constant-time hypersurfaces for simplicity at this stage. See Section 6.2 for a discussion.) Consider arbitrary infinitesimal variations, δx^μ and $\delta_0\phi(x)$, of the coordinates and field operators,

$$x^\mu \to x'^\mu = x^\mu + \delta x^\mu, \tag{1.28}$$

$$\phi(x) \to \phi'(x) = \phi(x) + \delta_0\phi(x), \tag{1.29}$$

where $\delta_0\phi(x)$ vanishes on the spatial boundary of integration at each time (i.e., it vanishes everywhere on the boundary of v, except on the interior of the constant-time hypersurfaces that bound v at t_1 and t_2). Then, the Schwinger action principle states that the variation of the action S of (1.12) has the form

$$\delta S = G(t_2) - G(t_1), \tag{1.30}$$

where the operator $G(t)$ is the generator of the above variation of the coordinates and fields at time t.

To say that G generates the variation means the following. For an operator functional $F[\phi, \pi]$, we have

$$i\delta_0 F = [F, G], \tag{1.31}$$

where all quantities are evaluated at the same time, and $\delta_0 F$ is the infinitesimal variation of F produced by (1.28) and (1.29). That is,

$$\delta_0 F = F[\phi + \delta_0\phi, \partial(\phi + \delta_0\phi)] - F[\phi, \partial\phi].$$

One can show from (1.30) that the generator has the form

$$G(t) = \int dV_x\left[\pi_a\delta\phi_a - T^0{}_\nu\delta x^\nu\right], \tag{1.32}$$

where $T^\mu{}_\nu$ is the energy-momentum tensor of (1.24), and

$$\delta\phi(x) \equiv \phi'(x') - \phi(x) \tag{1.33}$$

is the change of the field at a given physical point in spacetime (i.e., the local variation).

The derivation is as follows. The variation δS above is defined by

$$\delta S = S' - S,$$

where

$$S' = \int dv'_x \, \mathcal{L}(\phi'(x'), \partial' \phi'(x'))$$

and

$$S = \int dv_x \, \mathcal{L}(\phi(x), \partial\phi(x)).$$

Here, both integrals are taken over the same physical volume v, with x and x' denoting the same physical point of the system in spacetime, and thus related by (1.28). This way of viewing the transformation is the so-called passive viewpoint, in which the coordinates undergo a transformation from x to x', but the physical system does not change.

Alternatively, it is possible to adopt the active viewpoint taken by Messiah (1961), in which x and x' are regarded as describing a change of the physical system relative to a single coordinate system, such that the event at x is dragged to x'. In the active viewpoint, the volume v is infinitesimally displaced to a new physical volume v', related to v by (1.28). We can write

$$\begin{aligned} S' &= \int_{v'} dv_x \, \mathcal{L}(\phi'(x), \partial\phi'(x)) \\ &= \int_{v'} dv_x \, \mathcal{L}(\phi(x) + \delta_0\phi(x), \partial\phi(x) + \partial\delta_0\phi(x)) \\ &= \int_{v'} dv_x \mathcal{L}(\phi, \partial\phi) + \int_v dv_x \left\{ \frac{\partial \mathcal{L}}{\partial \phi} \delta_0 \phi + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \partial_\mu \delta_0 \phi \right\}. \end{aligned}$$

The volume of integration in the second integral has been changed to v because the integrand is already of first order.

Corresponding events on the boundaries of v and v' are related by the infinitesimal displacement δx^μ. Let $d\sigma^\mu$ denote $n^\mu d\sigma$, where n is an outward normal to the boundary of v at a point x, and $d\sigma$ is an element of surface area (i.e., hypersurface volume) on the boundary of v at x. Then, the scalar product $d\sigma_\mu \delta x^\mu$ is the volume of the cylindrical four-volume element capped at x by the surface area $d\sigma$ and extending along δx^μ from the boundary of v to that of v'. Then, denoting the boundary of v by ∂v, the surface integral,

$$\int_{\partial v} d\sigma_\mu \delta x^\mu \mathcal{L}(\phi, \partial\phi),$$

is equal to the following difference of volume integrals over v and v':

$$\int_{v'} dv_x \mathcal{L}(\phi, \partial\phi) - \int_v dv_x \mathcal{L}(\phi, \partial\phi),$$

because the difference is just the integral of $\mathcal{L}$ over the infinitesimal volume lying between the boundaries of v and v'.

Hence,

$$\begin{aligned}\delta S &= S' - S \\ &= \int_{\partial v} d\sigma_\mu \delta x^\mu \mathcal{L}(\phi, \partial\phi) + \int_v dv_x \left\{ \frac{\partial \mathcal{L}}{\partial \phi} \delta_0 \phi + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \partial_\mu \delta_0 \phi \right\}.\end{aligned}$$

Converting the surface integral to a volume integral by the Gauss divergence theorem, and using the identity,

$$\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \partial_\mu \delta_0 \phi = \partial_\mu \left\{ \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \delta_0 \phi \right\} - \partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \right) \delta_0 \phi$$

in the second term, we are left with the result

$$\delta S = \int_v dv_x \, \partial_\mu \left\{ \delta x^\mu \mathcal{L} + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \delta_0 \phi \right\}.$$

Here, the Euler–Lagrange equations (1.16) have been used.[3] It is convenient to express our result in terms of the local variation $\delta\phi$ defined in (1.33). One has

$$\phi'(x) = \phi'(x' - \delta x) = \phi'(x') - \partial_\mu \phi(x) \delta x^\mu$$

to first order. Consequently, (1.29) gives

$$\delta_0 \phi = \delta \phi - (\partial_\mu \phi) \delta x^\mu.$$

Hence,

$$\delta S = \int_v dv_x \, \partial_\mu \left\{ \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \delta \phi - T^\mu{}_\nu \delta x^\nu \right\}, \tag{1.34}$$

where $T^\mu{}_\nu$ is the energy-momentum tensor of (1.24). It follows that $\delta S = G(t_2) - G(t_1)$, with $G(t)$ given by (1.32), which completes the derivation.

Under an infinitesimal translation, we have $\phi'(x') = \phi(x)$, so that $\delta\phi$ vanishes. Therefore,

$$\delta_0 \phi = -(\partial_\mu \phi) \delta x^\mu.$$

Using the fact that for a translation δx^μ is constant, we now find that the generator is

$$G = -P_\mu \delta x^\mu,$$

where P_ν is the momentum operator of (1.25). One then has (1.31) for the commutator of G with an operator functional $F[\phi, \pi]$. Let us write (1.31) for the case when F is a function f formed from ϕ and the $\partial_\mu \phi$. Then,

$$\delta_0 f = \frac{\partial f}{\partial \phi} \delta_0 \phi + \frac{\partial f}{\partial(\partial_\mu \phi)} \partial_\mu \delta_0 \phi.$$

---

[3] The Euler–Lagrange equations follow, as usual, by demanding that δS is zero for the subset of variations such that $\delta_0 \phi$ vanishes on the boundary, ∂v.

Upon using the form of $\delta_0\phi$ for a translation, we find

$$\delta_0 f = -(\partial_\mu f)\delta x^\mu.$$

Using these results in (1.31), we obtain immediately (1.27).

The transformations of (1.28) and (1.29) are said to be a symmetry or invariance of the Lagrangian density $\mathcal{L}$ if

$$\mathcal{L}(\phi'(x'), \partial'\phi'(x')) = \mathcal{L}(\phi(x), \partial\phi(x)). \tag{1.35}$$

Recall that in S and S', the integrals are taken over the same *physical* volume (x and x' refer to the same physical point in spacetime). Therefore, the action is invariant when (1.35) holds, and we have $\delta S = 0$. In that case, (1.30) implies that G is a constant of the motion. Furthermore, (1.34) implies that

$$\partial_\mu J^\mu = 0, \tag{1.36}$$

with the conserved current

$$J^\mu = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\delta\phi_a - T^\mu{}_\nu \delta x^\nu. \tag{1.37}$$

It follows that when a translation in the x^μ direction is a symmetry of the Lagrangian density, then the operator P_μ is a constant of the motion. In Minkowski spacetime, the Lagrangian density of a free field is symmetric under space and time translations, which implies that energy and momentum are conserved. In curved spacetime, because of the presence in the Lagrangian density of the metric, we will find that for a free field (i.e., one influenced by gravitation alone), only the component of P_μ along the direction of an isometry of the spacetime is conserved.

1.2 Particles

The Schrödinger representation based on the eigenvectors of the field operator ϕ emphasizes the field aspect of the quantized field theory. Let us now turn to a representation which emphasizes the dual particle aspect of the quantum field. One expects that since the particle and wave properties of a system are known to be complementary, rather than simultaneously measurable, the observable corresponding to particle number, for example, will be constructed from both the field ϕ and its non-commuting conjugate momentum π. Furthermore, as the concept of free particle is well understood, we must first understand how to describe a system of free particles. Then, mutually interacting particles can be described through a perturbative description in which the free particles appear at early times and emerge again at late times. Therefore, we consider for now a single Hermitian free-scalar (or pseudo-scalar) field described by the Lagrangian density

$$\mathcal{L} = \frac{1}{2}(\eta^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - m^2\phi^2). \tag{1.38}$$

2

Basics of quantum fields in curved spacetimes

The successful predictions of general relativity are convincing evidence that gravitational phenomena are most clearly understood by regarding spacetime as curved. In general relativity matter exerts its gravitational influence by curving spacetime, and we study the propagation of particles and waves on this curved background. It is then natural to study the propagation of quantum fields in curved spacetimes in order to search for new effects of gravitation. At this level, the gravitational field itself is not quantized, and the methods of Minkowski spacetime quantum field theory are carried over as much as possible. As we shall see, this modest extension of quantum field theory has turned out to be richer in consequences than we could have anticipated.

Among other things, it gives rise to the physically important processes of particle creation in cosmological and black hole spacetimes. The same amplification process that creates particles in an expanding universe is responsible for creating, in the context of an early inflationary expansion, the primordial fluctuations that are now observed with astonishing accuracy in the cosmic microwave background (CMB) radiation. These same primordial fluctuations also appear responsible for the large-scale structure of the universe. The creation of particles by black holes is necessary for maintaining the second law of thermodynamics in their presence. This process of radiation and evaporation of black holes is an important facet in the fundamental search for a microscopic explanation of the entropy of black holes; a search which appears to be leading to new and exciting physics connecting gravitation and quantum theory. Quantum field theory in curved spacetime also provides a new dynamical explanation of the connection between spin and statistics, and brings out some new features of Minkowski spacetime physics, such as the excitation of accelerated detectors. This partial listing is sufficient motivation to turn now to the basis of the theory of quantized fields in curved spacetime.

2.1 Canonical quantization and conservation laws

Consider a set of fields $\phi_a(x)$ propagating in a curved spacetime with invariant line element

$$ds^2 = g_{\mu\nu}(x)dx^\mu dx^\nu. \tag{2.1}$$

The metric $g_{\mu\nu}(x)$ will be treated as a given unquantized external field. We will assume that the spacetime has a well-defined causal structure and set of Cauchy hypersurfaces. The set of fields $\phi_a(x)$ to be quantized may include linearized gravitational wave perturbations propagating on the background $g_{\mu\nu}(x)$. Let n denote the dimension of spacetime, with x^0 being the time coordinate and $x^1, \ldots, x^{n-1}$ being the spatial coordinates.

The action S is constructed from the field ϕ_a, so that it is invariant under general coordinate transformations (diffeomorphisms):

$$S[\phi'(x'), \nabla'\phi'(x'), {g'}_{\mu\nu}(x')] = S[\phi(x), \nabla\phi(x), g_{\mu\nu}(x)]. \tag{2.2}$$

The simplest way to construct such an action is to start with the Minkowski spacetime action and replace ordinary derivatives ∂_μ by covariant derivatives $\nabla_\mu, \eta^{\mu\nu}$ by $g^{\mu\nu}$, and d^nx by the invariant volume element $d^nx|g|^{1/2}$, where $g = \det(g_{\mu\nu})$. This is called the minimal coupling prescription, and is consistent with the Einstein principle of equivalence, according to which local gravitational effects are not present in a neighborhood of the spacetime origin of a locally inertial frame of reference. Occasionally, we can further increase the symmetry by the addition to the Lagrangian of a term which does not vanish at the origin of a locally inertial frame, and such a possibility will also be considered. (The action already involves $\partial_\lambda g_{\mu\nu}$ through $\nabla_\mu\phi_a$; when additional terms are included, it may also involve higher derivatives of $g_{\mu\nu}$.)

The requirement that variations of the action

$$S = \int d^nx\mathcal{L}(\phi, \nabla\phi, g_{\mu\nu}) \tag{2.3}$$

vanish with respect to variations of the fields ϕ_a, which are zero on the boundary of integration, then yields the Euler–Lagrange equations

$$\partial_\mu\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\right) - \frac{\partial\mathcal{L}}{\partial\phi_a} = 0. \tag{2.4}$$

The general covariance of (2.4) is insured by the invariance of the action S. Note that $\mathcal{L}$ is a scalar density, transforming like $|g|^{1/2}$.

Variation of the action with respect to the external field $g_{\mu\nu}$ does not in general vanish because we have not included an additional term proportional to the scalar curvature R in (2.3). (Such a term gives rise to the geometric part of the Einstein gravitational field equations. See Misner *et al.* (1973) or Weinberg (1972) for example.) However, because of the invariance of S under general coordinate transformation, δS will be zero under the change in $g_{\mu\nu}$ induced by an infinitesimal coordinate transformation

$$x^\mu \to x'^\mu = x^\mu - \epsilon^\mu(x), \tag{2.5}$$

where x and x' refer to the same event in spacetime. Under this transformation we have

$$g_{\mu\nu}(x) \to g'_{\mu\nu}(x') = \frac{\partial x^\lambda}{\partial x'^\mu}\frac{\partial x^\sigma}{\partial x'^\nu} g_{\lambda\sigma}(x),$$

which yields the variation

$$\delta_o g_{\mu\nu}(x) \equiv g'_{\mu\nu}(x) - g_{\mu\nu}(x) = \mathcal{L}_\epsilon g_{\mu\nu}, \tag{2.6}$$

where $\mathcal{L}_\epsilon$ denotes the Lie derivative,

$$\mathcal{L}_\epsilon g_{\mu\nu} = \nabla_\mu \epsilon_\nu + \nabla_\nu \epsilon_\mu. \tag{2.7}$$

Let us assume that $\epsilon^\mu(x)$ and $\partial_\lambda \epsilon^\mu(x)$ are zero on the boundary of the region of integration defining the action S of (2.3). Then, under the above infinitesimal coordinate transformation, we have

$$\delta S = \int d^n x \frac{\delta S}{\delta g_{\mu\nu}(x)} \delta_0 g_{\mu\nu}(x),$$

because variations in S produced by the changes in the dynamical fields ϕ_a vanish as a consequence of (2.4) and the boundary conditions on ϵ_μ. With $\delta_o g_{\mu\nu}$ given by (2.6) and (2.7), the invariance of S under coordinate transformations requires that $\delta S = 0$. Hence, with $dv_x \equiv d^n x |g|^{1/2}$,

$$\delta S = -\int dv_x T^{\mu\nu} \nabla_\mu \epsilon_\nu = 0, \tag{2.8}$$

where we have defined the tensor

$$T^{\mu\nu} \equiv -2|g|^{-1/2} \frac{\delta S}{\delta g_{\mu\nu}(x)}, \tag{2.9}$$

and have used its symmetry under interchange of indices. Then from (2.8) and

$$\begin{aligned}\nabla_\mu (T^{\mu\nu}\epsilon_\nu) &= |g|^{-1/2}\partial_\mu (|g|^{1/2} T^{\mu\nu}\epsilon_\nu) \\ &= (\nabla_\mu T^{\mu\nu})\epsilon_\nu + T^{\mu\nu}\nabla_\mu \epsilon_\nu,\end{aligned}$$

it follows that

$$\int dv_x (\nabla_\mu T^{\mu\nu})\epsilon_\nu = 0,$$

and because ϵ_ν is arbitrary, we must have

$$\nabla_\mu T^{\mu\nu} = 0. \tag{2.10}$$

This is the generally covariant generalization of (1.23). Furthermore, $T^{\mu\nu}$ as defined by (2.9) is symmetric, which is not true in general for the canonical energy-momentum tensor $\Theta^{\mu\nu}$ of (1.24). (In Chapter 1, the symbol $T^{\mu\nu}$ was used for the canonical energy-momentum tensor, $\Theta^{\mu\nu}$, but from now on $T^{\mu\nu}$ will refer to the symmetric energy-momentum tensor.) From $\delta(g^{\mu\nu}g_{\mu\lambda}) = 0$, it follows that $g_{\mu\lambda}g_{\nu\sigma}\frac{\delta}{\delta g_{\lambda\sigma}} = -\frac{\delta}{\delta g^{\mu\nu}}$, so

$$T_{\mu\nu} = +\frac{2}{|g|^{1/2}}\frac{\delta S}{\delta g^{\mu\nu}}. \tag{2.11}$$

The sign convention in our definition of $T^{\mu\nu}$ in (2.9) is chosen so that T_{00} will be positive for the classical electromagnetic field. If we were to use the opposite metric signature, then the signs on the right-hand sides of (2.9) and (2.11) would also be opposite.

We can calculate the symmetric energy-momentum tensor $T^{\mu\nu}$ in curved spacetime and then go to the flat spacetime limit, thereby obtaining a symmetric energy-momentum tensor satisfying $\partial_\mu T^{\mu\nu} = 0$ in Minkowski spacetime. For any isolated system in Minkowski spacetime, both $\Theta^{\mu\nu}$ and $T^{\mu\nu}$ yield a conserved energy-momentum vector p_μ (which, as noted earlier, is unique). In curved spacetime it is the symmetric energy-momentum tensor $T^{\mu\nu}$ defined in (2.9) which describes the matter and radiation and couples to the gravitational field through the Einstein field equations. (In a general curved spacetime, the tensor density $\Theta^{\mu\nu}$ of weight $1/2$ defined by (1.24) does not satisfy $\partial_\mu \Theta^\mu{}_\nu = 0$ as it does in Minkowski spacetime, nor any simple generalization of that equation.)

The Schwinger operator action principle continues to hold in curved spacetime for an arbitrary infinitesimal transformation of the form given in (1.28) and (1.29), provided that under the transformation $\delta_0 g_{\mu\nu}(x) = 0$, or

$$g'_{\mu\nu}(x) = g_{\mu\nu}(x). \tag{2.12}$$

In that case, the derivation leading to (1.34) goes through as before (with the canonical stress tensor now called $\Theta^\mu{}_\nu$); because we have $\delta_0 g_{\mu\nu} = 0$, it is not necessary for the Euler–Lagrange equation to hold for the external field $g_{\mu\nu}$. (Note that the metric $g_{\mu\nu}$ is not included here among the fields ϕ_a of (1.34).) Thus, under a transformation of the coordinates and fields given in (1.28) and (1.29), and for which (2.12) holds, we have as in Section 1.1

$$\delta S = G(t_2) - G(t_1), \tag{2.13}$$

with

$$G(t) = \int d^{n-1}x[\pi_a \delta\phi_a - \Theta^o{}_\nu \delta x^\nu], \tag{2.14}$$

where, as noted above, $\Theta^o{}_\nu$ is defined by the right-hand side of (1.24). Here the integration is on a constant time hypersurface, and

$$\pi_a = \frac{\partial \mathcal{L}}{\partial(\partial_0 \phi_a)}. \tag{2.15}$$

As before, with suitable operator ordering and regularization, G acts as the generator of the transformation, satisfying

$$i\delta_0 F = [F, G], \tag{2.16}$$

where F is a functional of the ϕ_a and π_a.

As in Minkowski spacetime, (2.16) will hold with

$$[\phi_a(\vec{x},t), \phi_b(\vec{x}',t)] = 0, \quad [\pi_a(\vec{x},t), \pi_b(\vec{x}',t)] = 0,$$
$$[\phi_a(\vec{x},t), \pi_b(\vec{x}',t)] = i\delta_{a,b}\delta(\vec{x}-\vec{x}'), \tag{2.17}$$

which is appropriate for bosons, or

$$\{\phi_a(\vec{x},t), \phi_b(\vec{x}',t)\} = 0, \quad \{\pi_a(\vec{x},t)\pi_b(\vec{x}',t)\} = 0,$$
$$\{\phi_a(\vec{x},t), \pi_b(\vec{x}',t)\} = i\delta_{a,b}\delta(\vec{x}-\vec{x}'), \tag{2.18}$$

which is appropriate for fermions. Here $\delta(\vec{x}-\vec{x}')$ is the Dirac δ-function satisfying $\int d^{n-1}x\delta(\vec{x}-\vec{x}')f(\vec{x}) = f(\vec{x}')$ with the integral being over the spacelike hypersurface $t =$ constant. The above commutation relations are imposed on independent field components. (They may be modified when gauge conditions are present.) One can show that $\pi(\vec{x}',t)$ and $\delta(\vec{x}-\vec{x}')$ each transform as spatial scalar densities under transformations of the spatial coordinates on the constant-t hypersurface. Hence, (2.17) and (2.18) are covariant under transformations of the spatial coordinates on the hypersurface, and are therefore the spatially covariant generalization of the corresponding relations that hold in flat spacetime. One can also show that they are consistent with the equations of motion of the fields, in the sense that if they hold on one constant-t spatial hypersurface, then they also will hold on the other constant-t spatial hypersurfaces.

Furthermore, for bosons we can define a complete set of commuting Hermitian fields, and define a basis $|\phi' >$ for the Hilbert space of state vectors, as in Minkowski spacetime, through (1.19). This gives a field or Schrödinger representation. For a system of fermions, we can define a set of Hermitian commuting quantities which are bilinear in the fields and build a Hilbert space of state vectors spanned by the simultaneous eigenvectors of these bilinear operators.

There are several cases of interest when G is conserved. The simplest is when $\delta x^\mu = 0$ and $\delta_0\phi_a$ is a symmetry of $\mathcal{L}$. Then (2.12) is trivially satisfied, and the symmetry of $\mathcal{L}$ implies that $\delta S = 0$ so that G is independent of time. One also has, in that case, $\partial_\mu J^\mu = 0$, with

$$J^\mu = \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\delta\phi_a. \tag{2.19}$$

(Note that J^μ is a vector density of weight $1/2$, so that we have $\nabla_\mu(|g|^{-1/2}J^\mu) = 0$.) Thus, in curved spacetime the electric charge and the generators of internal symmetries continue to be conserved.

The generator G is also conserved when $\delta x^\mu \neq 0$, but is such that (2.12) holds, and the fields ϕ_a are components of a spacetime tensor. Then, invariance under coordinate transformations implies that $\delta S = 0$, and (2.13) implies that G is constant. For example, if it is possible to choose a coordinate system in which a particular coordinate, say x^λ, does not appear in $g_{\mu\nu}(x)$, then under a translation in the x^λ direction (2.12) holds, and furthermore we have $\delta\phi(x) = 0$. Then, as in Section 1.1, it follows that

$$p_\lambda = \int d^{n-1}x \Theta^0{}_\lambda \tag{2.20}$$

is constant. (Since $g^{\lambda\mu}$ and the other components of p_μ may not be constants, it does not follow that $p^\lambda = g^{\lambda\mu}p_\mu$ is constant.) A similar expression involving the symmetric energy-momentum tensor $T_{\mu\nu}$ also holds. In deriving that result, we will also work in a more covariant language.

A coordinate transformation for which (2.12) holds is called an isometry of the spacetime. For an infinitesimal isometry of the form

$$x^\mu \to x'^\mu = x^\mu - \epsilon\xi^\mu(x), \tag{2.21}$$

with $\epsilon << 1$, it follows from (2.6) and (2.12) that

$$\mathcal{L}_\xi g_{\mu\nu} \equiv \nabla_\mu\xi_\nu + \nabla_\nu\xi_\mu = 0. \tag{2.22}$$

A vector field satisfying (2.22) is called a Killing vector of the spacetime. As a consequence of the symmetry of $T^{\mu\nu}$ and (2.10) we have

$$\nabla_\mu(T^{\mu\nu}\xi_\nu) = 0. \tag{2.23}$$

But since $T^{\mu\nu}\xi_\nu$ is a vector, we have $\nabla_\mu(T^{\mu\nu}\xi_\nu) = |g|^{-1/2}\partial_\mu(|g|^{1/2}T^{\mu\nu}\xi_\nu)$, and it follows that

$$\partial_\mu(|g|^{1/2}T^{\mu\nu}\xi_\nu) = 0. \tag{2.24}$$

Hence

$$P_\xi \equiv \int dV_x T^0{}_\nu(x)\xi^\nu(x) \tag{2.25}$$

is constant, where $dV_x = d^{n-1}x|g|^{1/2}$. In the case when the coordinates are such that $g_{\mu\nu}(x)$ is independent of a particular coordinate, say x^λ, then $\xi^\nu = \delta^\nu{}_\lambda$ is a Killing vector field, and (2.25) reduces to $P_\lambda = \int dV_x T^0{}_\lambda$ being constant. In such a case, (2.20) should yield the same p_λ to within possibly an additive constant independent of the field configuration.

Thus, in a general curved spacetime, we have shown that $\nabla_\mu T^{\mu\nu} = 0$, and in a spacetime having special symmetries or isometries as implied by the existence of one or more Killing vector fields ξ^μ, we have $\partial_\mu(|g|^{1/2}T^\mu{}_\nu\xi^\nu) = 0$ and $P_\xi \equiv \int dV_x T^0{}_\nu\xi^\nu$ is constant.

Let us now consider again a general curved spacetime without special isometries. An invariance of the action which is of interest is curved spacetime conformal invariance. Certain fields, such as the electromagnetic and massless Dirac fields in curved spacetime, exhibit an invariance of the action under conformal transformations of the metric and field, as defined below. An action $S[\phi, g_{\mu\nu}]$ (suppressing derivatives for brevity) is conformally invariant if

$$S[\phi, g_{\mu\nu}] = S[\tilde{\phi}, \tilde{g}_{\mu\nu}] + \text{surface integral}, \tag{2.26}$$

where

$$\tilde{g}_{\mu\nu}(x) = \Omega^2(x) g_{\mu\nu}(x), \tag{2.27}$$

$$\tilde{\phi}(x) = \Omega^{2p}(x)\phi(x). \tag{2.28}$$

Here $\Omega(x)$ is an arbitrary function and p is a dimensionless constant. Consider an infinitesimal conformal transformation with

$$\Omega^2(x) = 1 + \lambda(x), \quad |\lambda(x)| << 1. \tag{2.29}$$

Then $\delta x^\mu = 0$, and from (2.27) and (2.28),

$$\delta_0 g_{\mu\nu}(x) = \tilde{g}_{\mu\nu}(x) - g_{\mu\nu}(x) = \lambda(x) g_{\mu\nu}(x), \tag{2.30}$$

$$\delta_0 \phi(x) = \tilde{\phi}(x) - \phi(x) = p\lambda(x)\phi(x). \tag{2.31}$$

From (2.26), if $\lambda(x)$ vanishes sufficiently rapidly on the boundary of the region of integration,

$$0 = \delta S = \int d^n x \left\{ \frac{\delta S}{\delta \phi} \delta_0 \phi + \frac{\delta S}{\delta g_{\mu\nu}} \delta_0 g_{\mu\nu} \right\}.$$

If we assume that ϕ satisfies the Euler–Lagrange equation, $\delta S/\delta\phi = 0$, then it follows that

$$0 = \int d^n x \frac{\delta S}{\delta g_{\mu\nu}(x)} g_{\mu\nu}(x)\lambda(x),$$

and because $\lambda(x)$ is arbitrary,

$$\frac{\delta S}{\delta g_{\mu\nu}(x)} g_{\mu\nu}(x) = 0,$$

from which we have

$$g_{\mu\nu} T^{\mu\nu} = 0. \tag{2.32}$$

Thus, conformal invariance of the action implies that the trace of the energy-momentum tensor is zero. We will find later that a theory based on a classical or "bare" action which is conformally invariant will in general lose its conformal invariance in the quantum theory as a result of renormalization. The energy-momentum tensor thus acquires a non-vanishing trace, known as the trace or conformal anomaly.

In this section, we have discussed the action, field equations, symmetric energy-momentum tensor, generators of field transformations, commutation or anticommutation relations, Hilbert space of state vectors in the field representation, isometries and conservation laws, and conformal invariance. Having built a foundation for our discussion, let us consider next the curved spacetime generalization of the free neutral scalar field.

2.2 Scalar field

Following the minimal coupling prescription based on the principle of equivalence and described in Section 2.1, the action of the free neutral scalar field based on the Lagrangian density of (1.38) becomes in curved spacetime

$$S = \int d^n x \mathcal{L} \tag{2.33}$$

with

$$\mathcal{L} = \frac{1}{2}|g|^{1/2}(g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - m^2\phi^2). \tag{2.34}$$

(For the scalar field we have $\nabla_\mu\phi = \partial_\mu\phi$.) This is a special case of the more general Lagrangian density

$$\mathcal{L} = \frac{1}{2}|g|^{1/2}(g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - m^2\phi^2 - \xi R\phi^2), \tag{2.35}$$

where ξ is a dimensionless constant and R is the scalar curvature of the spacetime, $R \equiv g^{\mu\nu}R_{\mu\nu}$. (As noted in the section on notation, we use the following conventions: metric signature -2, $R^\mu{}_{\nu\lambda\sigma} = \partial_\sigma\Gamma^\mu{}_{\nu\lambda} - \partial_\lambda\Gamma^\mu{}_{\nu\sigma} + \Gamma^\tau{}_{\nu\lambda}\Gamma^\mu{}_{\sigma\tau} - \Gamma^\tau{}_{\nu\sigma}\Gamma^\mu{}_{\lambda\tau}$, and $R_{\mu\nu} = R^\lambda{}_{\mu\lambda\nu}$, in agreement with Birrell and Davies (1982), or $(-,-,-)$ in the notation of Misner *et al.* (1973).) We will carry out our discussion for this more general Lagrangian. One reason is that when we include an interaction term such as $|g|^{1/2}\lambda\phi^4$, with λ a constant (dimensionless in four-dimensional spacetime), then a term of the form $|g|^{1/2}\xi R\phi^2$ is needed for renormalization. (This will be shown in Section 6.7.) Another reason is that when $m = 0$ and $\xi = 1/6$ (in four dimensions), the action is invariant under the curved spacetime conformal transformations. The case $\xi = 0$ is referred to as minimal coupling. The magnitude of ξ cannot be very large, because if ξ has a non-zero value, then the term in the Lagrangian that is proportional to $R\phi^2$ can cause the effective gravitational constant to vary with time and position as a result of such variations in ϕ.

Consider an infinitesimal conformal transformation of the form of (2.29)–(2.31) with $p = -1/2$:

$$g_{\mu\nu}(x) \to \tilde{g}_{\mu\nu}(x) = (1 + \lambda(x))g_{\mu\nu}(x), \tag{2.36}$$

$$\phi(x) \to \tilde{\phi}(x) = \left(1 - \frac{1}{2}\lambda(x)\right)\phi(x). \tag{2.37}$$

16 μs. Hence, the average distance travelled by a muon is 4,700 m and these are able to reach the surface of earth. Thus, the results of time dilation are in agreement with the experimental results.

CERN in Geneva conducted an experiment in 1976, in which muons were injected into large storage rings reaching speeds of about 0.9994*c*. Electrons were produced by decaying of muons. The decay lifetime of muons was measured. The lifetime of moving muons was found to be 30 times higher than that of stationary muons, in perfect agreement with the theory of relativity.

1.7 Lorentz Contraction (Length Contraction)

In the previous sections, we have discussed that time is not absolute. In other words, we can say that the time interval between two events depend on the reference frame. In the same way, the measured distance also depends on the reference frame.

If we consider Galilean transformations, then the measured size for an object remains unaffected by the relative motion of observers. But for Lorentz transformation, length varies as time interval varies. To understand this concept, we consider a stick AB at rest w.r.t. frame S and moving w.r.t. frame S′ as shown in Figure 1.7.

The rod is parallel to *X*-axis and difference between AB gives actual length, L_0.

According to reference frame S

$$L_0 = x_2 - x_1 \tag{35}$$

and from reference frame S′

$$L_o' = x_2' - x_1' \tag{36}$$

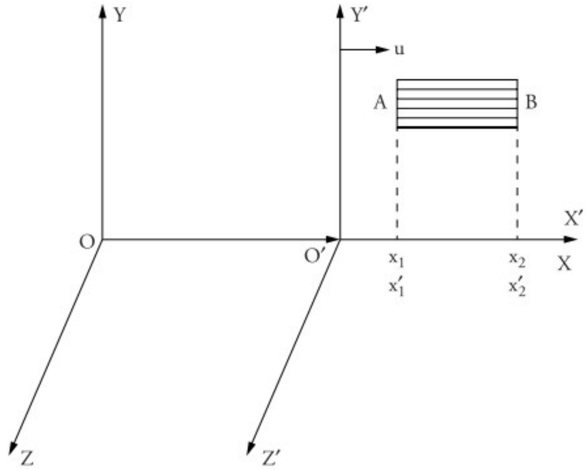

Figure 1.7 The length of rod for S = $x_2 - x_1$ and for S′ = $x_2' - x_1'$.

Substitute $x_2' = \gamma(x_2 - ut)$

$$\left.\begin{aligned} \text{or} \quad x_2 &= \gamma\left(x_2' + ut'\right) \\ \text{and} \quad x_1 &= \gamma\left(x_1' + ut'\right) \end{aligned}\right] \text{in Eqn. (35)}$$

$$L_o = \gamma\left[x_2' + \cancel{u}t' - x_1' - \cancel{u}t'\right]$$

$$L_o = \gamma\left(x_2' - x_1'\right) \tag{37}$$

$$\begin{aligned} L_o &= \gamma L_o' \\ As \quad \gamma > 1 \quad & L_o \geq L_o' \end{aligned} \tag{38}$$

The dimensions of the rod are same in *y* and *z* directions because there is no motion along these directions. L_0 is the proper length of the object. The proper length (like proper time) of an object is always measured by someone who is at rest w.r.t. the object. Hence, if the length of an object is measured from some moving reference frame, then the length appears to be small. This phenomena is called length contraction.

> Although muons are formed at a proper height of 6,000 m, the muons move towards earth at U = 0.998c, and hence the length appears to be contracted for them as $L'_o \frac{L_o}{\gamma}$ with a value of γ = 15.82. The height becomes $L_o' = \frac{6{,}000}{15.82} = 379.2$ m.

1.8 Concept of Space–time (Minkowski Space)

Einstein proposed the special theory of relativity, but the modern approach to the theory depends on the concept of four-dimensional universe as proposed by Hermann Minkowski in 1908. He proposed that if things could be arranged in time, then universe becomes four dimensional. He also emphasized that Einstein's discovery is a consequence of a four-dimensional universe. He used Pythagoras' theorem to relate space and time in four-dimensional space i.e.

$$S^2 = x^2 + y^2 + z^2 + (ict)^2 \tag{39}$$

where *x*, *y* and *z* are displacements, *c* is constant and *t* is time spanned by space–time interval S. If we do a dimensional analysis, then it becomes

Meters = (Conversion constant) × Time

c has a value of 3×10^8 m/s. This transforms Eqn. (39) as

$$S^2 = x^2 + y^2 + z^2 - (ct)^2 \tag{40}$$

If universe is four dimensional, then the space–time interval will be invariant. The constancy of velocity is also its consequence, as explained:

(i) If an object is travellling at velocity c, then the space–time interval is 0.

$$S^2 = x^2 + y^2 + z^2 - (ct)^2 \tag{41a}$$

(ii) If an object moves along x-direction for t seconds with velocity v, then

$$S^2 = (vt)^2 - (ct)^2 \tag{41b}$$

If $v = c$, then

$$S^2 = 0 \tag{42}$$

Hence, we can say that if an object is traveling at c m/s, then all observers will measure the same velocity for it, no matter how fast the observers are moving. This universal constant "c" is the velocity of light. The second consequence of space–time demonstrates that clocks will appear to go slower on objects moving relative to observer.

To illustrate this, we can take the example of Jack and Jill. Let us assume that Jack and Jill are on separate planets moving away from each other. Jack draws a graph for Jill's motion through space and time as demonstrated below (Figure 1.8): Jack and Jill are on planets and they think they are stationary and moving through time only. Both think the same way for each other.

Jack calculates Jill's space–time as

$$S^2 = (vt)^2 - (ct)^2 \tag{43}$$

whereas Jill calculates his space–time as

$$S^2 = (0t)^2 - (cT)^2 \tag{44}$$

But as the space–time interval is invariant, that is,

$$-(cT)^2 = (vt)^2 - (ct)^2$$

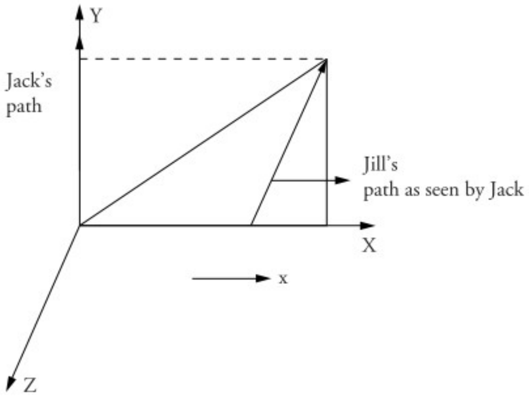

Figure 1.8 Jill thinks he is moving through time only, but Jack thinks he is moving through both space and time.

$$t = \frac{T}{\sqrt{1 - \frac{v^2}{c^2}}} \tag{45}$$

Hence, $T = 1$ between two ticks of clocks that are in rest in Jill's reference frame.

Great care must be taken while interpreting space–time diagrams. The general space–time diagram is shown in Figure 1.9. Time is plotted on a vertical axis and space coordinates on a horizontal axis. World line represents the plot of position of an object w.r.t. time. Hence, an event is a point in space–time and world line indicates a line of space–time. Line of simultaneity is the line parallel to x-axis, and it makes a difference in Galilean relativity and special relativity. In Galilean relativity, all events occur simultaneously on line of simultaneity.

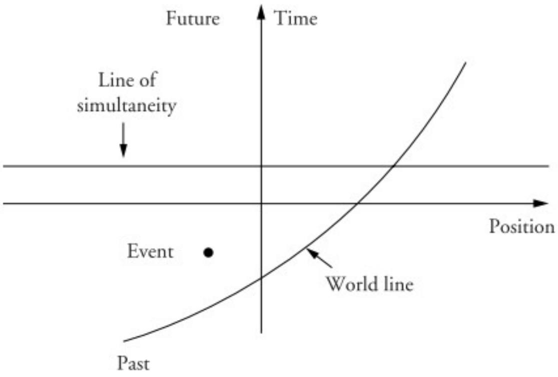

Figure 1.9 Space–time diagram.

The slope of world line has significant meaning.

$$\text{Velocity} = \frac{1}{\text{Slope of world line}} \tag{46}$$

This is valid for "+ve" and "–ve" slopes. If an object changes its velocity, then the world line is curved and velocity is represented by tangent to curve.

In conclusion, the space time as interpreted by minkowski is:

> The views of space and time which I wish to lay before you have spring from the soil of experimental physics, and therein lies their strength. They are radical. Henceforth time by itself and space by itself are doomed to fade away in mere shadows and only a union of two will preserve an independent reality. (Herman Minkowski, 1908, Assembly of German Natural Scientists and Physicians)

The motion of objects was provided by earth itself: from astronomical calculations, it was predicted to be 30,000 m/s. As this speed is 4 orders smaller than the velocity of light, the maximum difference expected in terrestrial measurements was 0.0002c.

Mechanical Curves

In this chapter we shall describe mechanical curves from the Lagrangian and Hamiltonian point of view. In this way, many geometric properties of these curves will be derived from the variational formalism.

A mechanical curve is a curve described by a particle on which acts an exterior force. For instance the circle, cycloid, hypocycloid, astroid, etc are models of particle trajectories under some exterior forces. A particle on which acts a central force of constant magnitude describes a circle. A point on a circle which rolls on a line, without slipping, describes a cycloid. A point on a circle tangent interior to another circle, which rotates without slipping in the interior of the large circle, describes a hypocycloid.

12.1 The areal velocity

Suppose an object moves in the plane from the point A to point B along a continuous arc $\widehat{AB}$. Let $\mathcal{A}$ be the area swept by the vectorial radius $\overrightarrow{OX}$ with $X \in \widehat{AB}$. We shall consider positive the orientation given by the clock-wise rotation of $\overrightarrow{OX}$. An elementary calculus formula in polar coordinates yields

$$\mathcal{A} = \frac{1}{2}\int_0^{\phi} r^2\,d\phi, \tag{12.1.1}$$

where $r = r(\phi)$ is the length of the vectorial radius and the argument angle $\phi = \angle AOX$.

Written in differential form, we have $d\mathcal{A} = \dfrac{1}{2}r^2\,d\phi$. Let t be the time parameter. Then

$$\frac{d\mathcal{A}}{dt} = \frac{1}{2}r^2\frac{d\phi}{dt} = \frac{1}{2}r^2\dot{\phi}. \tag{12.1.2}$$

The derivative $d\mathcal{A}/dt$ is called *areal velocity*.

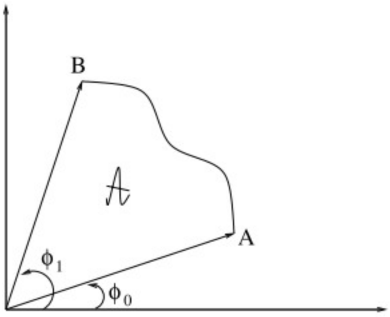

Figure 12.1: The area swept by the vectorial radius between two points.

12.1.0.1 Areal velocity as an angular momentum

Using polar coordinates $x = r\ \cos\phi,\ y = r\ \sin\phi$, the areal velocity becomes

$$\begin{aligned}\frac{d\mathcal{A}}{dt} &= \frac{1}{2}r^2\dot{\phi} = \frac{1}{2}\big(r\cos\phi\, r\cos\phi\,\dot{\phi} - r\sin\phi\,(-r\cos\phi)\,\dot{\phi}\big)\\ &= \frac{1}{2}(x\dot{y} - y\dot{x}).\end{aligned}$$

The expression $x\dot{y} - y\dot{x} = \langle (x, y), (\dot{x}, -\dot{y})\rangle$ is called *angular momentum*.

If $x\dot{y} - y\dot{x}$ is constant, the particle moves such that equal areas are described in equal amounts of time *i.e.*, the vectorial radius sweeps out equal areas in equal time. This happens for instance, in the case of a particle in uniform motion on a circle or in the case of a planet in the revolution motion around the sun (Kepler's second law).

12.2 The circular motion

Consider a particle in the (x, y)-plane which is described by the Lagrangian

$$L(x, y, \dot{x}, \dot{y}) = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + (x\dot{y} - y\dot{x}) \tag{12.2.3}$$

i.e., the particle moves on a trajectory which is an extremizer for the action

$$S = \int L(x, y, \dot{x}, \dot{y}). \tag{12.2.4}$$

The Lagrangian L is the sum of the kinetic energy and the angular momentum.

Theorem 12.1. *The Euler–Lagrange system associated with the Lagrangian* (12.2.3) *is*

$$\begin{cases}\ddot{x} - 2\dot{y} &= 0,\\ \ddot{y} + 2\dot{x} &= 0.\end{cases} \tag{12.2.5}$$

The solutions of the system (12.2.5) *with the boundary conditions*

$$x(0) = \mathbf{x}_0, \qquad x(\tau) = \mathbf{x}, \qquad y(0) = \mathbf{y}_0, \qquad y(\tau) = \mathbf{y}, \tag{12.2.6}$$

with $0 < \tau < \pi$, *are*

$$\begin{aligned} x(s) &= \pm C \sin s\, \sin(s + \alpha_0) + \mathbf{x}_0, \\ y(s) &= \pm C \sin s\, \cos(s + \alpha_0) + \mathbf{y}_0, \end{aligned}$$

with $C = \sqrt{\frac{E}{2}}$ *and the energy* E *given by*

$$E = \frac{(\mathbf{x} - \mathbf{x}_0)^2 + (\mathbf{y} - \mathbf{y}_0)^2}{2\sin^2 \tau}. \tag{12.2.7}$$

Proof. Using

$$\begin{aligned} &\frac{\partial L}{\partial \dot{x}} = \dot{x} - y, \qquad \frac{d}{dt}\frac{\partial L}{\partial \dot{x}} = \ddot{x} - \dot{y}, \qquad \frac{\partial L}{\partial x} = \dot{y}, \\ &\frac{\partial L}{\partial \dot{y}} = \dot{y} + x, \qquad \frac{d}{dt}\frac{\partial L}{\partial \dot{y}} = \ddot{y} + \dot{x}, \qquad \frac{\partial L}{\partial \dot{y}} = -\dot{x}, \end{aligned}$$

it is easy to see that the Euler–Lagrange system becomes (12.2.5).

Multiplying the first equation of (12.2.5) by $\dot{x}$ and the second by $\dot{y}$ and adding yields $\dot{x}\ddot{x} + \dot{y}\ddot{y} = 0$, therefore

$$\frac{d}{dt}(\dot{x}^2 + \dot{y}^2) = 0 \Longrightarrow \dot{x}^2 + \dot{y}^2 = C^2 \tag{12.2.8}$$

where C is a constant along the trajectory. Let $E = \frac{1}{2}(\dot{x}^2 + \dot{y}^2)$ denote the first integral of energy. Using (12.2.8) there is a smooth function $\alpha = \alpha(s)$ such that

$$\begin{aligned} \dot{x}(s) &= \pm C \sin \alpha(s) \Longrightarrow \ddot{x}(s) = \pm C \cos \alpha(s)\, \dot{\alpha}(s), \\ \dot{y}(s) &= \pm C \cos \alpha(s) \Longrightarrow \ddot{y}(s) = \mp C \sin \alpha(s)\, \dot{\alpha}(s). \end{aligned}$$

Substituting back in the system (12.2.5) yields

$$\begin{aligned} \pm \cos^2 \alpha(s)\, \dot{\alpha}(s) &= \pm 2 \cos^2 \alpha(s), \\ \mp \sin^2 \alpha(s)\, \dot{\alpha}(s) &= \mp 2 \sin^2 \alpha(s). \end{aligned}$$

Subtracting we get

$$\dot{\alpha}(s) = 2 \Longrightarrow \alpha(s) = 2s + \alpha_0, \tag{12.2.9}$$

with α_0 constant. Hence

$$\begin{aligned}\dot{x}(s) &= \pm C\sin(2s+\alpha_0) \Longrightarrow x(s) = \pm C\int_0^s \sin(2u+\alpha_0)\,du + \mathbf{x}_0\\ &= \pm C\frac{1}{2}(-\cos w)\Big|_{\alpha_0}^{2s+\alpha_0} + \mathbf{x}_0 = \pm\frac{C}{2}\Big(\cos\alpha_0 - \cos(2s+\alpha_0)\Big) + \mathbf{x}_0\\ &= \pm C\sin s\sin(s+\alpha_0) + \mathbf{x}_0,\end{aligned}$$

where we used

$$\begin{aligned}\cos\alpha_0 - \cos(2s+\alpha_0) &= -2\sin\frac{\alpha_0+2s+\alpha_0}{2}\sin\frac{\alpha_0-2s-\alpha_0}{2}\\ &= 2\sin(s+\alpha_0)\sin s.\end{aligned}$$

Substituting $\alpha(s)$ in the formula for $\dot{y}(s)$ yields

$$\begin{aligned}\dot{y}(s) &= \pm C\cos\alpha(s) = \pm C\cos(2s+\alpha_0)\\ \Longrightarrow y(s) &= \pm C\int_0^s \cos(2u+\alpha_0)\,du + \mathbf{y}_0\\ &= \pm\frac{1}{2}C\sin w\Big|_{\alpha_0}^{2s+\alpha_0} + \mathbf{y}_0\\ &= \pm\frac{1}{2}C\Big(\sin(2s+\alpha_0) - \sin\alpha_0\Big) + \mathbf{y}_0\\ &= \pm C\sin s\cos(s+\alpha_0) + \mathbf{y}_0,\end{aligned}$$

where we used

$$\begin{aligned}\sin(2s+\alpha_0) - \sin\alpha_0 &= 2\sin\frac{2s+\alpha_0-\alpha_0}{2}\cos\frac{2s+\alpha_0+\alpha_0}{2}\\ &= 2\sin s\cos(s+\alpha_0).\end{aligned}$$

Hence we have arrived at

$$x(s) = \pm C\sin s\ \sin(s+\alpha_0) + \mathbf{x}_0, \tag{12.2.10}$$

$$y(s) = \pm C\sin s\ \cos(s+\alpha_0) + \mathbf{y}_0, \tag{12.2.11}$$

where α_0 is a constant. We shall show that energy $E = C^2/2$ does not depend on α_0. Making $s = \tau$ in (12.2.10), (12.2.11) yields

$$\mathbf{x} = \pm C\sin\tau\ \sin(\tau+\alpha_0) + \mathbf{x}_0, \tag{12.2.12}$$

$$\mathbf{y} = \pm C\sin\tau\ \cos(\tau+\alpha_0) + \mathbf{y}_0, \tag{12.2.13}$$

hence it follows that

$$\Big(\frac{\mathbf{x}-\mathbf{x}_0}{\sin\tau}\Big)^2 = C^2\sin^2(\tau+\alpha_0), \tag{12.2.14}$$

$$\Big(\frac{\mathbf{y}-\mathbf{y}_0}{\sin\tau}\Big)^2 = C^2\cos^2(\tau+\alpha_0). \tag{12.2.15}$$

Adding yields

$$2E = C^2 = \frac{(\mathbf{x}-\mathbf{x}_0)^2 + (\mathbf{y}-\mathbf{y}_0)^2}{\sin^2 \tau},$$

which is (12.2.7). ■

Remark 12.2 *Let* $d = \sqrt{(\mathbf{x}-\mathbf{x}_0)^2 + (\mathbf{y}-\mathbf{y}_0)^2}$ *denote the Euclidean distance between* $(\mathbf{x}_0, \mathbf{y}_0)$ *and* $(\mathbf{x}, \mathbf{y})$. *We note the fact that the energy* $E = \dfrac{d^2}{2\sin^2 \tau}$ *is not Euclidean. Replacing* $\sin^2 \tau$ *by* τ^2 *we obtain the Euclidean energy.*
Let δ *be the Riemannian distance in which the solutions of the Euler–Lagrange equations become geodesics. Then* $E = \dfrac{\delta^2}{2\tau^2}$. *Then* $\delta^2 = \Big(\dfrac{\tau}{\sin \tau}\Big)^2 d^2$, *and hence* d *and* δ *are homothetic.*

The action

The action $S = S(\mathbf{x}_0, \mathbf{y}_0, \mathbf{x}, \mathbf{y}, \tau)$ satisfies the Hamilton–Jacobi equation

$$\begin{aligned} \frac{\partial S}{\partial \tau} &= -E = -\frac{d^2}{2\sin^2 \tau} = \frac{d^2}{2}\frac{\partial}{\partial \tau}(\cot \tau) \\ \Longrightarrow 0 &= \frac{\partial}{\partial \tau}\Big(S - \frac{d^2}{2}\cot \tau\Big) \Longrightarrow S = S_0 + \frac{d^2}{2}\cot \tau. \end{aligned} \tag{12.2.16}$$

Proposition 12.3 *The Hamiltonian associated with the Lagrangian* (12.2.3) *is*

$$H(x, y, p_1, p_2) = \frac{1}{2}\big(p_1 + y\big)^2 + \frac{1}{2}\big(p_2 - x\big)^2. \tag{12.2.17}$$

Proof. The Hamiltonian system for the Hamiltonian (12.2.17) yields

$$\begin{aligned} \dot{x} &= H_{p_1} = p_1 + y \Longrightarrow p_1 = \dot{x} - y, \\ \dot{y} &= H_{p_2} = p_2 - x \Longrightarrow p_2 = \dot{y} + x. \end{aligned}$$

Using the Legendre transform we have

$$\begin{aligned} L &= p_1\dot{x} + p_2\dot{y} - H \\ &= (\dot{x} - y)\dot{x} + (\dot{y} + x)\dot{y} - \frac{1}{2}\big(p_1 + y\big)^2 - \frac{1}{2}\big(p_2 - x\big)^2 \\ &= (\dot{x} - y)\dot{x} + (\dot{y} + x)\dot{y} - \frac{1}{2}\dot{x}^2 - \frac{1}{2}\dot{y}^2 \\ &= \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + x\dot{y} - y\dot{x}. \end{aligned}$$

■

We note that the Hamiltonian (12.2.17) is the principal symbol of the operator

$$\begin{aligned} P &= \frac{1}{2}\big(\partial_x + y\big)^2 + \frac{1}{2}\big(\partial_y - x\big)^2 \\ &= \frac{1}{2}(\partial_x^2 + \partial_y^2) + y\partial_x - x\partial_y + \frac{1}{2}(x^2 + y^2), \end{aligned}$$

which describes the circular motion.

12.3 The astroid

The trajectory of a point P on the unit circle which rolls without slipping in the interior of a circle of radius 4 is a hypocycloid with four cuspidal points. This curve is called *astroid*. The equation of the astroid is

$$x^{2/3} + y^{2/3} = 1. \tag{12.3.18}$$

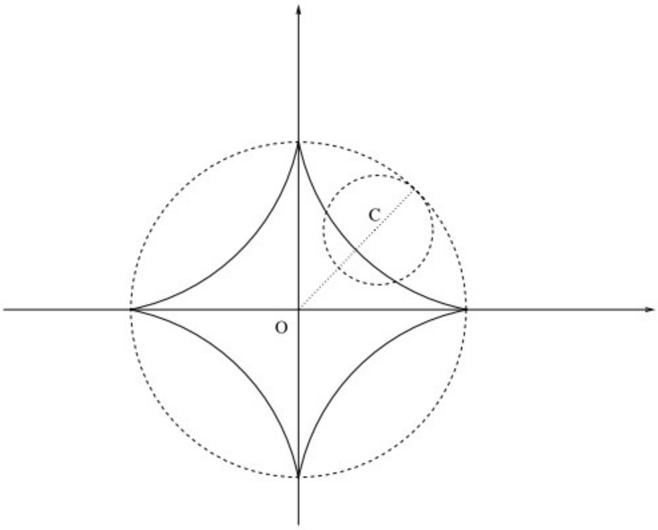

Figure 12.2: The astroid.

If P starts at the cuspidal point $(4, 0)$ and s denotes the angle argument of the center C, we have

$$x(s) = \cos^3 s, \qquad y(s) = \sin^3 s, \tag{12.3.19}$$

which are equivalent with

$$x(s) = 3\cos s + \cos\, 3s, \qquad y(s) = 3\sin s - \sin\, 3s. \tag{12.3.20}$$

A simple computation shows that (12.3.20) is the solution of the system

$$\begin{cases} \ddot{x} - 2\dot{y} + 3x = 0, \\ \ddot{y} + 2\dot{x} + 3y = 0, \end{cases} \tag{12.3.21}$$

-2 7 * " . ; A)*+,)))
." (

with initial conditions

$$x(0) = 4, \quad \dot{x}(0) = \dot{y}(0) = y(0) = 0. \tag{12.3.22}$$

Standard ODE techniques show that the solution (12.3.20) is unique.

Proposition 12.4 *The system* (12.3.21) *is the Euler–Lagrange system associated with the Lagrangian*

$$L(x, y, \dot{x}, \dot{y}) = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + x\dot{y} - \dot{x}y - \frac{3}{2}(x^2 + y^2). \tag{12.3.23}$$

Proof. We have

$$\frac{\partial L}{\partial \dot{x}} = \dot{x} - y, \quad \frac{d}{dt}\frac{\partial L}{\partial \dot{x}} = \ddot{x} - \dot{y}, \quad \frac{\partial L}{\partial x} = \dot{y} - 3x,$$

$$\frac{\partial L}{\partial \dot{y}} = \dot{y} + x, \quad \frac{d}{dt}\frac{\partial L}{\partial \dot{y}} = \ddot{y} + \dot{x}, \quad \frac{\partial L}{\partial y} = -\dot{x} - 3y.$$

Then

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{x}} = \frac{\partial L}{\partial x}, \quad \frac{d}{dt}\frac{\partial L}{\partial \dot{y}} = \frac{\partial L}{\partial y}$$

yields the system (12.3.21). ∎

12.3.0.2 Noether's Theorem

The Lagrangian (12.3.23) is invariant under rotations centered at the origin. The vector field associated with this rotation at the point (x, y) is $(-y, x)$. Noether's theorem yields a first integral of motion given by

$$\begin{aligned} I &= \left\langle \left(\frac{\partial L}{\partial \dot{x}}, \frac{\partial L}{\partial \dot{y}}\right), (-y, x) \right\rangle = (\dot{x} - y)(-y) + (\dot{y} + x)x \\ &= -\dot{x}y + y^2 + \dot{y}x + x^2 = x^2 + y^2 + x\dot{y} - \dot{x}y \\ &= r^2 + 2\frac{d\mathcal{A}}{ds}, \end{aligned}$$

where $x = r\cos\phi$, $y = r\sin\phi$. We have arrived at the following result.

Proposition 12.5 *For any solution of the system* (12.3.21) *there is a constant C such that*

(*i*)
$$r^2 + 2\frac{d\mathcal{A}}{ds} = C,$$

(*ii*)
$$\phi(s) = C\int_0^s \frac{du}{r^2(u)} - s$$

along the solution.

Proof. (i) It clearly follows from the fact that the first integral is constant along the solutions.
(ii) We have

$$\begin{aligned} C &= r^2 + x\dot{y} - \dot{x}y \\ &= r^2 + r^2\dot{\phi} \\ &= r^2(1+\dot{\phi}) \\ \Longrightarrow \frac{d\phi}{ds} &= \frac{C}{r^2} - 1. \end{aligned}$$

Integrating yields the desired result. ∎

We can get the same result if we write the Euler–Lagrange system in polar coordinates. See Exercise 2.

As the astroid is a solution of the system (12.3.21), the above proposition applies to it. In this case the constant C is obtained by taking the value at $s = 0$,

$$\begin{aligned} C &= x^2(0) + y^2(0) + x(0)\dot{y}(0) - \dot{x}(0)y(0) \\ &= 16. \end{aligned}$$

Proposition 12.6 *The Hamiltonian associated with the Lagrangian* (12.3.23) *is*

$$H(p_1, p_2, x, y) = \frac{1}{2}[(p_1 + y)^2 + (p_2 - x)^2] + \frac{3}{2}(x^2 + y^2). \tag{12.3.24}$$

Proof. The momenta are $p_1 = \dfrac{\partial L}{\partial \dot{x}} = \dot{x} - y, \quad p_2 = \dfrac{\partial L}{\partial \dot{y}} = \dot{y} + x$, and then

$$\dot{x} = p_1 + y, \quad \dot{y} = p_2 - x. \tag{12.3.25}$$

Using (12.3.25), the Legendre transform yields

$$\begin{aligned} H(p_1, p_2, x, y) &= p_1\dot{x} + p_2\dot{y} - \frac{1}{2}(\dot{x}^2 + \dot{y}^2) - x\dot{y} + \dot{x}y + \frac{3}{2}(x^2 + y^2) \\ &= p_1(p_1 + y) + p_2(p_2 - x) - \frac{1}{2}\Big((p_1 + y)^2 + (p_2 - x)^2\Big) \\ &\quad - x(p_2 - x) + (p_1 + y)y + \frac{3}{2}(x^2 + y^2) \\ &= \frac{1}{2}(p_1^2 + p_2^2) + p_1 y - p_2 x + 2(x^2 + y^2) \\ &= \frac{1}{2}\Big[(p_1 + y)^2 + (p_2 - x)^2\Big] + \frac{3}{2}(x^2 + y^2). \end{aligned}$$

∎

12.3.0.3 The first integral of energy

As

$$\frac{\partial H}{\partial t} = 0 \quad \text{and} \quad \frac{\partial H}{\partial t} = \frac{dH}{dt},$$

it follows that H is preserved along the trajectory. The value of H along the trajectory is called *the total energy*. In x, y, $\dot{x}$, $\dot{y}$ coordinates the energy takes the form

$$E = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + \frac{3}{2}(x^2 + y^2). \tag{12.3.26}$$

Note that E does not depend on the angular momentum as the Lagrangian does. It depends only on the magnitude of the velocity and the distance to the origin.

12.3.0.4 Physical interpretation

The speed of a particle described by a solution of the Euler–Lagrange system is

$$v = \sqrt{\dot{x}^2 + \dot{y}^2}.$$

If $r = \sqrt{x^2 + y^2}$ denotes the distance from the origin to the point (x, y), formula (12.3.26) yields

$$v^2 = 2E - 3r^2.$$

In the case of the astroid with the initial conditions (12.3.26) we have $E = 24$. Thus $v = \sqrt{3(16 - r^2)}$ with $r \in [0, 4]$. The speed on the astroid is zero iff $r = 4$, which occurs only at the cuspidal points.

12.4 The cycloid

Consider a particle described by a Lagrangian, which is the sum of the kinetic, angular momentum and potential energy in the x-direction

$$L(x, y, \dot{x}, \dot{y}) = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + \frac{1}{2}(x\dot{y} - \dot{x}y) + x. \tag{12.4.27}$$

The Euler–Lagrange system of equations associated with the Lagrangian (12.4.27) is

$$\begin{cases} \ddot{x} - \dot{y} = 1, \\ \ddot{y} + \dot{x} = 0. \end{cases} \tag{12.4.28}$$

If we consider the initial conditions

$$x(0) = 0, \quad \dot{x}(0) = 0, \quad y(0) = 0, \quad \dot{y}(0) = 0$$

Chapter 3

Basic Topology of R

3.1 Discussion: The Cantor Set

What follows is a fascinating mathematical construction, due to Georg Cantor, which is extremely useful for extending the horizons of our intuition about the nature of subsets of the real line. Cantor's name has already appeared in the first chapter in our discussion of uncountable sets. Indeed, Cantor's proof that **R** is uncountable occupies another spot on the short list of the most significant contributions toward understanding the mathematical infinite. In the words of the mathematician David Hilbert, "No one shall expel us from the paradise that Cantor has created for us."

Let C_0 be the closed interval $[0, 1]$, and define C_1 to be the set that results when the open middle third is removed; that is,

$$C_1 = C_0 \setminus \left(\frac{1}{3}, \frac{2}{3}\right) = \left[0, \frac{1}{3}\right] \cup \left[\frac{2}{3}, 1\right].$$

Now, construct C_2 in a similar way by removing the open middle third of each of the two components of C_1:

$$C_2 = \left(\left[0, \frac{1}{9}\right] \cup \left[\frac{2}{9}, \frac{1}{3}\right]\right) \cup \left(\left[\frac{2}{3}, \frac{7}{9}\right] \cup \left[\frac{8}{9}, 1\right]\right).$$

If we continue this process inductively, then for each $n = 0, 1, 2, \dots$ we get a set C_n consisting of 2^n closed intervals each having length $1/3^n$. Finally, we define the *Cantor set* C (Fig. 3.1) to be the intersection

$$C = \bigcap_{n=0}^{\infty} C_n.$$

© Springer Science+Business Media New York 2015
S. Abbott, *Understanding Analysis*, Undergraduate Texts
in Mathematics, DOI 10.1007/978-1-4939-2712-8_3

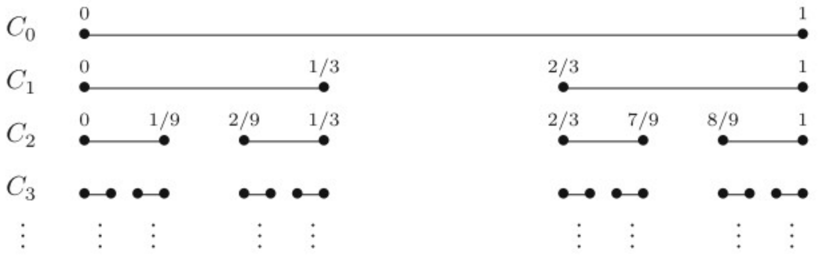

Figure 3.1: Defining the Cantor set; $C = \bigcap_{n=0}^{\infty} C_n$.

It may be useful to understand C as the remainder of the interval $[0, 1]$ after the iterative process of removing open middle thirds is taken to infinity:

$$C = [0,1] \backslash \left[\left(\frac{1}{3}, \frac{2}{3} \right) \cup \left(\frac{1}{9}, \frac{2}{9} \right) \cup \left(\frac{7}{9}, \frac{8}{9} \right) \cup \cdots \right].$$

There is some initial doubt whether anything remains at all, but notice that because we are always removing open middle thirds, then for every $n \in \mathbf{N}$, $0 \in C_n$ and hence $0 \in C$. The same argument shows $1 \in C$. In fact, if y is the endpoint of some closed interval of some particular set C_n, then it is also an endpoint of one of the intervals of C_{n+1}. Because, at each stage, endpoints are never removed, it follows that $y \in C_n$ for all n. Thus, C at least contains the endpoints of all of the intervals that make up each of the sets C_n.

Is there anything else? Is C countable? Does C contain any intervals? Any irrational numbers? These are difficult questions at the moment. All of the endpoints mentioned earlier are rational numbers (they have the form $m/3^n$), which means that if it is true that C consists of only these endpoints, then C would be a subset of $\mathbf{Q}$ and hence countable. We shall see about this. There is some strong evidence that not much is left in C if we consider the total length of the intervals removed. To form C_1, an open interval of length $1/3$ was taken out. In the second step, we removed two intervals of length $1/9$, and to construct C_n we removed 2^{n-1} middle thirds of length $1/3^n$. There is some logic, then, to defining the "length" of C to be 1 minus the total

$$\frac{1}{3} + 2\left(\frac{1}{9}\right) + 4\left(\frac{1}{27}\right) + \cdots + 2^{n-1}\left(\frac{1}{3^n}\right) + \cdots = \frac{\frac{1}{3}}{1 - \frac{2}{3}} = 1.$$

The Cantor set has *zero length.*

To this point, the information we have collected suggests a mental picture of C as a relatively small, thin set. For these reasons, the set C is often referred to as Cantor "dust." But there are some strong counterarguments that imply a very different picture. First, C is actually *uncountable*, with cardinality equal to the cardinality of $\mathbf{R}$. One slightly intuitive but convincing way to see this is to create a 1–1 correspondence between C and sequences of the form $(a_n)_{n=1}^{\infty}$, where $a_n = 0$ or 1. For each $c \in C$, set $a_1 = 0$ if c falls in the left-hand component

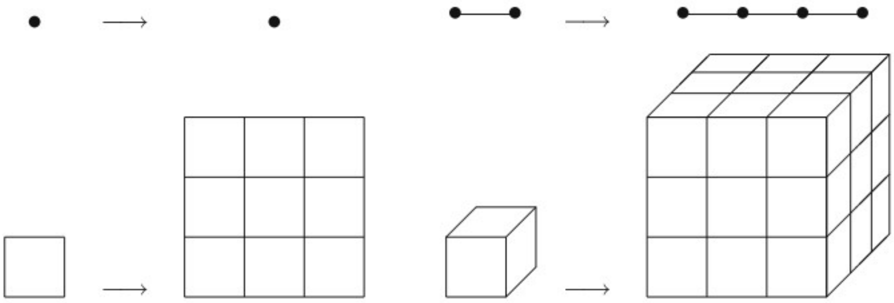

Figure 3.2: Magnifying sets by a factor of 3.

of C_1 and set $a_1 = 1$ if c falls in the right-hand component. Having established where in C_1 the point c is located, there are now two possible components of C_2 that might contain c. This time, we set $a_2 = 0$ or 1 depending on whether c falls in the left or right half of these two components of C_2. Continuing in this way, we come to see that every element $c \in C$ yields a sequence $(a_1, a_2, a_3, \ldots)$ of zeros and ones that acts as a set of directions for how to locate c within C. Likewise, every such sequence corresponds to a point in the Cantor set. Because the set of sequences of zeros and ones is uncountable (Exercise 1.6.4), we must conclude that C is uncountable as well.

What does this imply? In the first place, because the endpoints of the approximating sets C_n form a countable set, we are forced to accept the fact that not only are there other points in C but there are uncountably many of them. From the point of view of *cardinality*, C is quite large—as large as $\mathbf{R}$, in fact. This should be contrasted with the fact that from the point of view of *length*, C measures the same size as a single point. We conclude this discussion with a demonstration that from the point of view of *dimension*, C strangely falls somewhere in between.

There is a sensible agreement that a point has dimension zero, a line segment has dimension one, a square has dimension two, and a cube has dimension three. Without attempting a formal definition of dimension (of which there are several), we can nevertheless get a sense of how one might be defined by observing how the dimension affects the result of magnifying each particular set by a factor of 3 (Fig. 3.2). (The reason for the choice of 3 will become clear when we turn our attention back to the Cantor set). A single point undergoes no change at all, whereas a line segment triples in length. For the square, magnifying each length by a factor of 3 results in a larger square that contains 9 copies of the original square. Finally, the magnified cube yields a cube that contains 27 copies of the original cube within its volume. Notice that, in each case, to compute the "size" of the new set, the dimension appears as the exponent of the magnification factor.

	dim	$\times 3$	new copies
point	0	$\to$	$1 = 3^0$
segment	1	$\to$	$3 = 3^1$
square	2	$\to$	$9 = 3^2$
cube	3	$\to$	$27 = 3^3$
C	x	$\to$	$2 = 3^x$

Figure 3.3: DIMENSION OF C; $2 = 3^x \Rightarrow x = \log 2/\log 3$.

Now, apply this transformation to the Cantor set. The set $C_0 = [0, 1]$ becomes the interval $[0, 3]$. Deleting the middle third leaves $[0, 1] \cup [2, 3]$, which is where we started in the original construction except that we now stand to produce an additional copy of C in the interval $[2, 3]$. Magnifying the Cantor set by a factor of 3 yields *two* copies of the original set. Thus, if x is the dimension of C, then x should satisfy $2 = 3^x$, or $x = \log 2/\log 3 \approx .631$ (Fig. 3.3).

The notion of a noninteger or fractional dimension is the impetus behind the term "fractal," coined in 1975 by Benoit Mandlebrot to describe a class of sets whose intricate structures have much in common with the Cantor set. Cantor's construction, however, is over a hundred years old and for us represents an invaluable testing ground for the upcoming theorems and conjectures about the often elusive nature of subsets of the real line.

3.2 Open and Closed Sets

Given $a \in \mathbf{R}$ and $\epsilon > 0$, recall that the *ϵ-neighborhood* of a is the set

$$V_\epsilon(a) = \{x \in \mathbf{R} : |x - a| < \epsilon\}.$$

In other words, $V_\epsilon(a)$ is the open interval $(a - \epsilon, a + \epsilon)$, centered at a with radius ϵ.

Definition 3.2.1. A set $O \subseteq \mathbf{R}$ is *open* if for all points $a \in O$ there exists an ϵ-neighborhood $V_\epsilon(a) \subseteq O$.

Example 3.2.2. (i) Perhaps the simplest example of an open set is $\mathbf{R}$ itself. Given an arbitrary element $a \in \mathbf{R}$, we are free to pick any ϵ-neighborhood we like and it will always be true that $V_\epsilon(a) \subseteq \mathbf{R}$. It is also the case that the logical structure of Definition 3.2.1 requires us to classify the empty set $\emptyset$ as an open subset of the real line.

(ii) For a more useful collection of examples, consider the open interval

$$(c, d) = \{x \in \mathbf{R} : c < x < d\}.$$

Chapter 7

The Riemann Integral

7.1 Discussion: How Should Integration be Defined?

The Fundamental Theorem of Calculus is a statement about the inverse relationship between differentiation and integration. It comes in two parts, depending on whether we are differentiating an integral or integrating a derivative. Under suitable hypotheses on the functions f and F, the Fundamental Theorem of Calculus states that

(i) $\displaystyle\int_a^b F'(x)\,dx = F(b) - F(a)$ and

(ii) if $\displaystyle G(x) = \int_a^x f(t)\,dt$, then $G'(x) = f(x)$.

Before we can undertake any type of rigorous investigation of these statements, we need to settle on a definition for $\int_a^b f$. Historically, the concept of integration was defined as the inverse process of differentiation. In other words, the integral of a function f was understood to be a function F that satisfied $F' = f$. Newton, Leibniz, Fermat, and the other founders of calculus then went on to explore the relationship between antiderivatives and the problem of computing areas. This approach is ultimately unsatisfying from the point of view of analysis because it results in a very limited number of functions that can be integrated. Recall that every derivative satisfies the intermediate value property (Darboux's Theorem, Theorem 5.2.7). This means that any function with a jump discontinuity cannot be a derivative. If we want to define integration via antidifferentiation, then we must accept the consequence that a function as simple as

S. Abbott, *Understanding Analysis*, Undergraduate Texts in Mathematics, DOI 10.1007/978-1-4939-2712-8_7

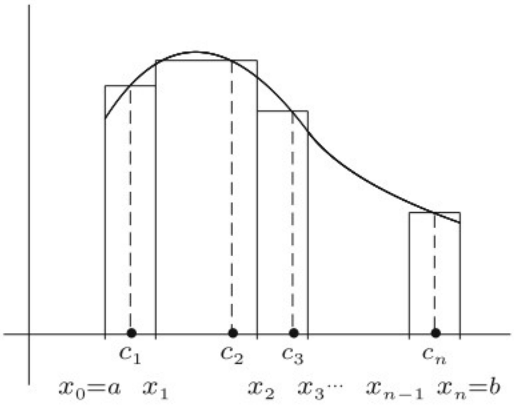

Figure 7.1: A RIEMANN SUM.

$$h(x) = \begin{cases} 1 & \text{for } 0 \le x < 1 \\ 2 & \text{for } 1 \le x \le 2 \end{cases}$$

is not integrable on the interval $[0, 2]$.

A very interesting shift in emphasis occurred around 1850 in the work of Cauchy, and soon after in the work of Bernhard Riemann. The idea was to completely divorce integration from the derivative and instead use the notion of "area under the curve" as a starting point for building a rigorous definition of the integral. The reasons for this were complicated. As we have mentioned earlier (Section 1.2), the concept of *function* was undergoing a transformation. The traditional understanding of a function as a holistic formula such as $f(x) = x^2$ was being replaced with a more liberal interpretation, which included such bizarre constructions as Dirichlet's function discussed in Section 4.1. Serving as a catalyst to this evolution was the budding theory of Fourier series (discussed in Section 8.5), which required, among other things, the need to be able to integrate these more unruly objects.

The Riemann integral, as it is called today, is the one usually discussed in introductory calculus. Starting with a function f on $[a, b]$, we partition the domain into small subintervals. On each subinterval $[x_{k-1}, x_k]$, we pick some point $c_k \in [x_{k-1}, x_k]$ and use the y-value $f(c_k)$ as an approximation for f on $[x_{k-1}, x_k]$. Graphically speaking, the result is a row of thin rectangles constructed to approximate the area between f and the x-axis. The area of each rectangle is $f(c_k)(x_k - x_{k-1})$, and so the total area of all of the rectangles is given by the *Riemann sum* (Fig. 7.1)

$$\sum_{k=1}^{n} f(c_k)(x_k - x_{k-1}).$$

Note that "area" here comes with the understanding that areas below the x-axis are assigned a negative value.

What should be evident from the graph is that the accuracy of the Riemann-sum approximation seems to improve as the rectangles get thinner. In some sense, we take the *limit* of these approximating Riemann sums as the width of the individual subintervals of the partitions tends to zero. This limit, if it exists, is Riemann's definition of $\int_a^b f$.

This brings us to a handful of questions. Creating a rigorous meaning for the limit just referred to is not too difficult. What will be of most interest to us—and was also to Riemann—is deciding what types of functions can be integrated using this procedure. Specifically, what conditions on f guarantee that this limit exists?

The theory of the Riemann integral turns on the observation that smaller subintervals produce better approximations to the function f. On each subinterval $[x_{k-1}, x_k]$, the function f is approximated by its value at some point $c_k \in [x_{k-1}, x_k]$. The quality of the approximation is directly related to the difference

$$|f(x) - f(c_k)|$$

as x ranges over the subinterval. Because the subintervals can be chosen to have arbitrarily small width, this means that we want $f(x)$ to be close to $f(c_k)$ whenever x is close to c_k. But this sounds like a discussion of continuity! We will soon see that the continuity of f is intimately related to the existence of the Riemann integral $\int_a^b f$.

Is continuity sufficient to prove that the Riemann sums converge to a well-defined limit? Is it necessary, or can the Riemann integral handle a discontinuous function such as $h(x)$ mentioned earlier? Relying on the intuitive notion of area, it would seem that $\int_0^2 h = 3$, but does the Riemann integral reach this conclusion? If so, how discontinuous can a function be before it fails to be integrable? Can the Riemann integral make sense out of something as pathological as Dirichlet's function on the interval $[0, 1]$?

A function such as

$$g(x) = \begin{cases} x^2 \ \sin(\frac{1}{x}) & \text{for } x \neq 0 \\ 0 & \text{for } x = 0 \end{cases}$$

raises another interesting question. Here is an example of a differentiable function, studied in Section 5.1, where the derivative $g'(x)$ is *not* continuous. As we explore the class of integrable functions, some attempt must be made to reunite the integral with the derivative. Having defined integration independently of differentiation, we would like to come back and investigate the conditions under which equations (i) and (ii) from the Fundamental Theorem of Calculus stated earlier hold. If we are making a wish list for the types of functions that we want to be integrable, then in light of equation (i) it seems desirable to expect this set to at least contain the set of derivatives. The fact that derivatives are not always continuous is further motivation not to content ourselves with an integral that cannot handle some discontinuities.

7.2 The Definition of the Riemann Integral

Although it has the benefit of some polish due to Darboux, the development of the integral presented in this chapter is closely related to the procedure just discussed. In place of Riemann sums, we will construct *upper sums* and *lower sums* (Fig. 7.2), and in place of a limit we will use a supremum and an infimum.

Throughout this section, it is assumed that we are working with a *bounded* function f on a closed interval $[a, b]$, meaning that there exists an $M > 0$ such that $|f(x)| \leq M$ for all $x \in [a, b]$.

Partitions, Upper Sums, and Lower Sums

Definition 7.2.1. A *partition* P of $[a, b]$ is a finite set of points from $[a, b]$ that includes both a and b. The notational convention is to always list the points of a partition $P = \{x_0, x_1, x_2, \ldots, x_n\}$ in increasing order; thus,

$$a = x_0 < x_1 < x_2 < \cdots < x_n = b.$$

For each subinterval $[x_{k-1}, x_k]$ of P, let

$$m_k = \inf\{f(x) : x \in [x_{k-1}, x_k]\} \quad \text{and} \quad M_k = \sup\{f(x) : x \in [x_{k-1}, x_k]\}.$$

The *lower sum* of f with respect to P is given by

$$L(f, P) = \sum_{k=1}^{n} m_k(x_k - x_{k-1}).$$

Likewise, we define the *upper sum* of f with respect to P by

$$U(f, P) = \sum_{k=1}^{n} M_k(x_k - x_{k-1}).$$

For a particular partition P, it is clear that $U(f, P) \geq L(f, P)$. The fact that this same inequality holds if the upper and lower sums are computed with respect to different partitions is the content of the next two lemmas.

Definition 7.2.2. A partition Q is a *refinement* of a partition P if Q contains all of the points of P; that is, if $P \subseteq Q$.

Lemma 7.2.3. *If $P \subseteq Q$, then $L(f, P) \leq L(f, Q)$, and $U(f, P) \geq U(f, Q)$.*

Proof. Consider what happens when we refine P by adding a single point z to some subinterval $[x_{k-1}, x_k]$ of P.

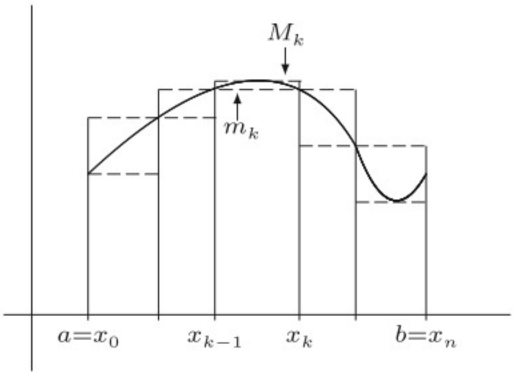

Figure 7.2: Upper and Lower Sums.

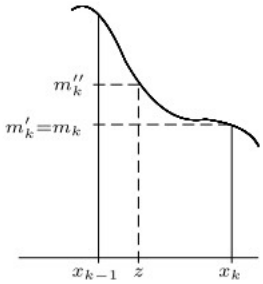


Focusing on the lower sum for a moment, we have

$$\begin{aligned} m_k(x_k - x_{k-1}) &= m_k(x_k - z) + m_k(z - x_{k-1}) \\ &\leq m_k'(x_k - z) + m_k''(z - x_{k-1}), \end{aligned}$$

where

$$m_k' = \inf\{f(x) : x \in [z, x_k]\} \quad \text{and} \quad m_k'' = \inf\{f(x) : x \in [x_{k-1}, z]\}$$

are each necessarily as large or larger than m_k.

By induction, we have $L(f,P) \leq L(f,Q)$, and an analogous argument holds for the upper sums. ☐

Lemma 7.2.4. *If P_1 and P_2 are any two partitions of $[a,b]$, then $L(f,P_1) \leq U(f,P_2)$.*

Proof. Let $Q = P_1 \cup P_2$ be the so-called *common refinement* of P_1 and P_2. Because $P_1 \subseteq Q$ and $P_2 \subseteq Q$, it follows that

$$L(f,P_1) \leq L(f,Q) \leq U(f,Q) \leq U(f,P_2).$$ ☐

Integrability

Intuitively, it helps to visualize a particular upper sum as an overestimate for the value of the integral and a lower sum as an underestimate. As the partitions get more refined, the upper sums get potentially smaller while the lower sums get potentially larger. A function is *integrable* if the upper and lower sums "meet" at some common value in the middle.

Rather than taking a limit of these sums, we will instead make use of the Axiom of Completeness and consider the *infimum* of the upper sums and the *supremum* of the lower sums.

Definition 7.2.5. Let $\mathcal{P}$ be the collection of all possible partitions of the interval $[a, b]$. The *upper integral* of f is defined to be

$$U(f) = \inf\{U(f, P) : P \in \mathcal{P}\}.$$

In a similar way, define the *lower integral* of f by

$$L(f) = \sup\{L(f, P) : P \in \mathcal{P}\}.$$

The following fact is not surprising.

Lemma 7.2.6. *For any bounded function f on $[a, b]$, it is always the case that $U(f) \geq L(f)$.*

Proof. Exercise 7.2.1. □

Definition 7.2.7 (Riemann Integrability). A bounded function f defined on the interval $[a, b]$ is *Riemann-integrable* if $U(f) = L(f)$. In this case, we define $\int_a^b f$ or $\int_a^b f(x)\,dx$ to be this common value; namely,

$$\int_a^b f = U(f) = L(f).$$

The modifier "Riemann" in front of "integrable" accurately suggests that there are other ways to define the integral. In fact, our work in this chapter will expose the need for a different approach, one of which is discussed in Section 8.1. In this chapter, the Riemann integral is the only method under consideration, so it will usually be convenient to drop the modifier "Riemann" and simply refer to a function as being "integrable."

Criteria for Integrability

To summarize the situation thus far, it is always the case for a bounded function f on $[a, b]$ that

$$\sup\{L(f, P) : P \in \mathcal{P}\} = L(f) \leq U(f) = \inf\{U(f, P) : P \in \mathcal{P}\}.$$

The function f is integrable if the inequality is an equality. The major thrust of our investigation of the integral is to describe, as best we can, the class of integrable functions. The preceding inequality reveals that integrability is really equivalent to the existence of partitions whose upper and lower sums are arbitrarily close together.

Theorem 7.2.8 (Integrability Criterion). *A bounded function f is integrable on $[a, b]$ if and only if, for every $\epsilon > 0$, there exists a partition P_ϵ of $[a, b]$ such that*

$$U(f, P_\epsilon) - L(f, P_\epsilon) < \epsilon.$$

Proof. Let $\epsilon > 0$. If such a partition P_ϵ exists, then

$$U(f) - L(f) \leq U(f, P_\epsilon) - L(f, P_\epsilon) < \epsilon.$$

Because ϵ is arbitrary, it must be that $U(f) = L(f)$, so f is integrable. (To be absolutely precise here, we could throw in a reference to Theorem 1.2.6.)

The proof of the converse statement is a familiar triangle inequality argument with parentheses in place of absolute value bars because, in each case, we know which quantity is larger. Because $U(f)$ is the greatest lower bound of the upper sums, we know that, given some $\epsilon > 0$, there must exist a partition P_1 such that

$$U(f, P_1) < U(f) + \frac{\epsilon}{2}.$$

Likewise, there exists a partition P_2 satisfying

$$L(f, P_2) > L(f) - \frac{\epsilon}{2}.$$

Now, let $P_\epsilon = P_1 \cup P_2$ be the common refinement. Keeping in mind that the integrability of f means $U(f) = L(f)$, we can write

$$\begin{aligned} U(f, P_\epsilon) - L(f, P_\epsilon) &\leq U(f, P_1) - L(f, P_2) \\ &< \left(U(f) + \frac{\epsilon}{2}\right) - \left(L(f) - \frac{\epsilon}{2}\right) \\ &= \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon. \end{aligned}$$

□

In the discussion at the beginning of this chapter, it became clear that integrability is closely tied to the concept of continuity. To make this observation more precise, let $P = \{x_0, x_1, x_2, \ldots, x_n\}$ be an arbitrary partition of $[a, b]$, and define $\Delta x_k = x_k - x_{k-1}$. Then,

$$U(f, P) - L(f, P) = \sum_{k=1}^{n} (M_k - m_k)\Delta x_k,$$

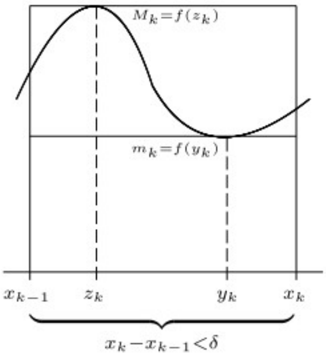
where M_k and m_k are the supremum and infimum of the function on the interval $[x_{k-1}, x_k]$, respectively. Our ability to control the size of $U(f, P) - L(f, P)$ hinges on the differences $M_k - m_k$, which we can interpret as the variation in the range of the function over the interval $[x_{k-1}, x_k]$. Restricting the variation of f over arbitrarily small intervals in $[a, b]$ is *precisely* what it means to say that f is uniformly continuous on this set.

Theorem 7.2.9. *If f is continuous on $[a, b]$, then it is integrable.*

Proof. Because f is continuous on a compact set, it must be bounded. It is also uniformly continuous for the same reason. This means that, given $\epsilon > 0$, there exists a $\delta > 0$ so that $|x - y| < \delta$ guarantees

$$|f(x) - f(y)| < \frac{\epsilon}{b-a}.$$

Now, let P be a partition of $[a, b]$ where $\Delta x_k = x_k - x_{k-1}$ is less than δ for every subinterval of P.



Given a particular subinterval $[x_{k-1}, x_k]$ of P, we know from the Extreme Value Theorem (Theorem 4.4.2) that the supremum $M_k = f(z_k)$ for some $z_k \in [x_{k-1}, x_k]$. In addition, the infimum m_k is attained at some point y_k also in the interval $[x_{k-1}, x_k]$. But this means $|z_k - y_k| < \delta$, so

$$M_k - m_k = f(z_k) - f(y_k) < \frac{\epsilon}{b-a}.$$

Finally,

$$U(f, P) - L(f, P) = \sum_{k=1}^{n} (M_k - m_k)\Delta x_k < \frac{\epsilon}{b-a} \sum_{k=1}^{n} \Delta x_k = \epsilon,$$

and f is integrable by the criterion given in Theorem 7.2.8. □

Exercises

Exercise 7.2.1. Let f be a bounded function on $[a, b]$, and let P be an arbitrary partition of $[a, b]$. First, explain why $U(f) \geq L(f, P)$. Now, prove Lemma 7.2.6.

Exercise 7.2.2. Consider $f(x) = 1/x$ over the interval $[1, 4]$. Let P be the partition consisting of the points $\{1, 3/2, 2, 4\}$.

(a) Compute $L(f,P)$, $U(f,P)$, and $U(f,P)-L(f,P)$.

(b) What happens to the value of $U(f,P)-L(f,P)$ when we add the point 3 to the partition?

(c) Find a partition P' of $[1,4]$ for which $U(f,P')-L(f,P')<2/5$.

Exercise 7.2.3 (Sequential Criterion for Integrability). (a) Prove that a bounded function f is integrable on $[a,b]$ if and only if there exists a sequence of partitions $(P_n)_{n=1}^{\infty}$ satisfying

$$\lim_{n\to\infty}\left[U(f,P_n)-L(f,P_n)\right]=0,$$

and in this case $\int_a^b f=\lim_{n\to\infty}U(f,P_n)=\lim_{n\to\infty}L(f,P_n)$.

(b) For each n, let P_n be the partition of $[0,1]$ into n equal subintervals. Find formulas for $U(f,P_n)$ and $L(f,P_n)$ if $f(x)=x$. The formula $1+2+3+\cdots+n=n(n+1)/2$ will be useful.

(c) Use the sequential criterion for integrability from (a) to show directly that $f(x)=x$ is integrable on $[0,1]$ and compute $\int_0^1 f$.

Exercise 7.2.4. Let g be bounded on $[a,b]$ and assume there exists a partition P with $L(g,P)=U(g,P)$. Describe g. Is g necessarily continuous? Is it integrable? If so, what is the value of $\int_a^b g$?

Exercise 7.2.5. Assume that, for each n, f_n is an integrable function on $[a,b]$. If $(f_n)\to f$ uniformly on $[a,b]$, prove that f is also integrable on this set. (We will see that this conclusion does not necessarily follow if the convergence is pointwise.)

Exercise 7.2.6. A *tagged partition* $(P,\{c_k\})$ is one where in addition to a partition P we choose a sampling point c_k in each of the subintervals $[x_{k-1},x_k]$. The corresponding *Riemann sum*,

$$R(f,P)=\sum_{k=1}^{n}f(c_k)\Delta x_k,$$

is discussed in Section 7.1, where the following definition is alluded to.

Riemann's Original Definition of the Integral: A bounded function f is *integrable* on $[a,b]$ with $\int_a^b f=A$ if for all $\epsilon>0$ there exists a $\delta>0$ such that for any tagged partition $(P,\{c_k\})$ satisfying $\Delta x_k<\delta$ for all k, it follows that

$$|R(f,P)-A|<\epsilon.$$

Show that if f satisfies Riemann's definition above, then f is integrable in the sense of Definition 7.2.7. (The full equivalence of these two characterizations of integrability is proved in Section 8.1.)

Exercise 7.2.7. Let $f:[a,b]\to\mathbf{R}$ be increasing on the set $[a,b]$ (i.e., $f(x)\leq f(y)$ whenever $x<y$). Show that f is integrable on $[a,b]$.

2 Fuzzy Controller Design

In this chapter we describe the basic definitions of fuzzy sets and operators on fuzzy sets. As they are used throughout the book it is necessary to start by introducing basic definitions of terms such as linguistic variables, fuzzy propositions, relations, implications, and inference engines. An emphasis is given to the description of the fuzzy controller structure that is most commonly used in practice, as well as to the several ways of defuzzification, that is, calculation of the crisp controller output value.

2.1 FUZZY SETS

We will use the following example to help us define a fuzzy set. Let A be a set of all integers *greater* than 10. We write

$$A = \{x\colon x \in \mathbb{N}, x > 10\} \tag{2.1}$$

Let B be a set of all integers *much greater* than 10. Mathematically, this statement can be written as

$$B = \{x\colon x \in \mathbb{N}, x \gg 10\} \tag{2.2}$$

The main difference between these two sets is that relation (2.1) completely defines set A, while relation (2.2) is not sufficient for a complete definition of set B. The reason is the vagueness of the term *much greater*. It is clear that 11, 12, 1178, and 2,075 are elements of set A. Most of the people will agree that 11,234 and 23^{10} undoubtedly belong to set B, but it is doubtful whether 15 or 50 are elements of B. The problem is how to determine the lowest integer which is *much greater* than 10.

This problem can be solved if one uses an alternative way of describing a set. According to traditional set theory, a set can be defined by its *characteristic function*. In other words, instead of individually declaring each element of a set we define a function that can take on values 1 or 0 depending on full membership or no membership of a particular element, respectively.

Definition 2.1 (Characteristic function, crisp set) Let S be a set from the domain X. A *characteristic function* of the set S attains value $\mu_S(x) = 1$ if $x \in S$, and $\mu_S(x) = 0$ if $x \notin S$, $\mu\colon X \to \{0, 1\}$. Set S with its characteristic function is called a *crisp set*.

Defined as it is, the characteristic function cannot describe set B, that is, it cannot cope with the vagueness in determining the lowest integer which would

© 2006 by Taylor & Francis Group, LLC

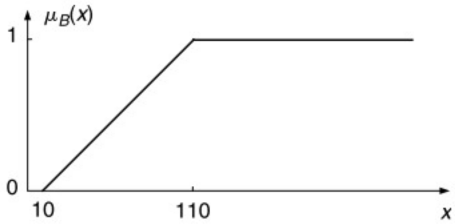

FIGURE 2.1 A graphical representation of a fuzzy set.

belong to set B. However, broadening the notion of a characteristic function offers an elegant way to define set B. Instead of determining the lowest integer belonging to set B, we may say that *all* integers greater than 10 belong to set B but with a different *membership degree*. The characteristic function, obtaining partial, or graded, values from the interval [0, 1], now becomes a *membership function*.

Definition 2.2 (Membership function and fuzzy set) Let F be a set from the domain X. A membership function $\mu_F(x)$ of set F is a function that assigns value, or *membership degree*, to every $x \in F$, $\mu\colon X \to [0,1]$. Then set F is called a *fuzzy set*.

Apparently, crisp sets may be treated as a special case of fuzzy sets since the characteristic function can assume only margin values from the interval [0, 1] on which membership function is defined.

Now we can completely define fuzzy set B as a set of pairs:

$$B = \{(\mu_B(x), x)\colon x \in \aleph\}$$

$$\mu_B(x) = \begin{cases} 0, & \text{for } x < 10 \\ \dfrac{x-10}{100}, & \text{for } 10 \le x \le 110 \\ 1, & \text{for } x > 110 \end{cases} \tag{2.3}$$

From the above definition we can see that numbers with membership degree 0 do not belong to fuzzy set B. Number 11 is an element of B with membership degree $\mu_B(11) = 0.01$, while membership degree of number 100 is $\mu_B(100) = 0.9$. Fuzzy set B is pictured in Figure 2.1.

From fuzzy set Definition 2.2, it follows that two fuzzy sets having the same elements will be equal only if their membership functions are equal. This means that each element belonging to one fuzzy set must belong to the other fuzzy set with the same membership degree.

Definition 2.3 (Fuzzy subset) Fuzzy set C is a *fuzzy subset* of fuzzy set B if

$$\forall x \in X\colon \mu_C(x) \le \mu_B(x) \tag{2.4}$$

© 2006 by Taylor & Francis Group, LLC

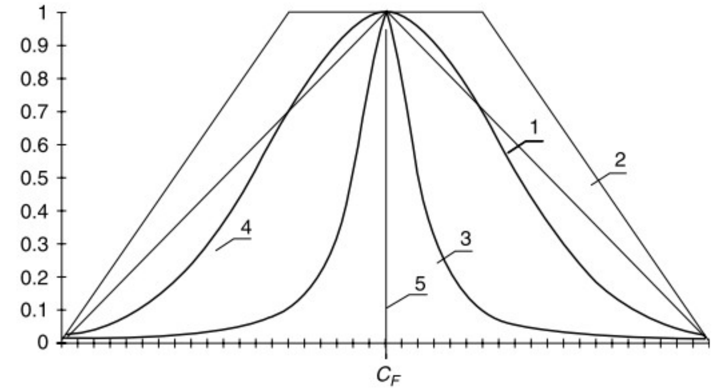

FIGURE 2.2 Typical shapes of membership functions: 1 — triangular, 2 — trapezoidal, 3 — Gaussian, 4 — bell-shaped, 5 — singleton.

In fuzzy sets theory, the range of possible quantitative values considered for fuzzy set members is called *universe of discourse*. Universe of discourse can be continuous or discrete. Discrete universe of discourse is normally bounded and contains a finite number of elements. A fuzzy set with discrete universe of discourse is called *a discrete fuzzy set*. The measure of fuzziness of each element is determined using a membership function spread either over a part or over the entire universe of discourse. As we have stated, the membership function converts the degree of fuzziness into the normalized interval [0, 1] where the boundary values 0 and 1 resemble the membership degrees of crisp set members. Membership functions can attain different forms. However, triangular, trapezoidal, Gaussian, and bell-shaped forms, shown in Figure 2.2, are used more than others:

$$\mu_F(x) = \begin{cases} 0, & \text{for } x < a \\ \dfrac{x-a}{b-a}, & \text{for } a \leq x < b \\ \dfrac{c-x}{c-b}, & \text{for } b \leq x \leq c \\ 0, & \text{for } x > c \end{cases} \quad \text{triangular}$$

$$\mu_F(x) = \begin{cases} 0, & \text{for } x < a \\ \dfrac{x-a}{b-a}, & \text{for } a \leq x < b \\ 1, & \text{for } b \leq x < c \\ \dfrac{d-x}{d-c}, & \text{for } c \leq x \leq d \\ 0, & \text{for } x > d \end{cases} \quad \text{trapezoidal}$$

$$\mu_F(x) = \mathrm{e}^{-(x-c_F)^2/w} \quad \text{Gaussian}, \qquad \mu_F(x) = \frac{1}{1+(x-c_F)^2} \quad \text{bell-shaped}$$

© 2006 by Taylor & Francis Group, LLC

These fuzzy sets are defined for variable x. Anticipating that different variables, for example, x and y, may have fuzzy sets with identical names (indices), it is convenient to introduce modified membership function notation $\mu_F^x = \mu_F(x)$. Such notation can, for example, discern notation for $\mu_F^y = \mu_F(y)$. This allows further generalizations, such as $\mu_i^x = \mu_i(x), i = 1, \ldots, l$.

Definition 2.4 (Center and nucleus of fuzzy set) A singular value $x = c_F = c_F^x \in F$ with the maximum degree of membership, $\mu_F(c_F) = 1$, is called the *center* of fuzzy set F. If there exists a set of values with the maximum degree of membership,

$$\mathrm{nuc}(F) = \{x \in X \colon \mu_F(x) = 1\} \tag{2.5}$$

then $\mathrm{nuc}(F)$ is called the *nucleus* of fuzzy set F.

The center of fuzzy set F with a nucleus is defined as $c_F^x = (x_a + x_b)/2$; where x_a and x_b are the boundaries of the nucleus. Fuzzy set F, having the center c_F^x as its only element, is a *fuzzy singleton* (Figure 2.2). In case we would like to replace a typical fuzzy set with a singleton (which is often done in the case of output fuzzy sets of fuzzy controllers), we must decide which value is representative and unique for different shapes of fuzzy sets, in order to be able to make such a replacement. Due to the fact that fuzzy sets can be either uniform or not, symmetrical or not, bounded or not — a good measure of their geometrical shape is the *centroid*, the point within a fuzzy set designating its center of gravity (COG). For example, the centroid of a triangular fuzzy set is the concurrence point of its three medians.

For a symmetrical fuzzy set the projection of its centroid on universe of discourse is equal to the center of the fuzzy set. That is why the center c_F^x is often referred to as the centroid. Fuzzy singletons are frequently used in fuzzy controller design since they reduce calculation efforts and provide shorter control intervals, which are desirable features in real-time control applications. We shall return to this issue in the chapters that follow.

Definition 2.5 (Adjacent fuzzy sets) Let two fuzzy sets, F and T, with centers c_F^x and c_T^x, $c_F^x < c_T^x$, be defined from the same universe of discourse X. If there does not exist a fuzzy set S, defined from X, with the center c_S^x, such that $c_F^x < c_S^x < c_T^x$, then F and T are called *adjacent fuzzy sets*.

The importance of adjacency will become apparent in the next paragraph where we describe properties of a set of rules formed by fuzzy sets.

Operations *union*, *intersection*, and *complement* are strictly defined on crisp sets. They are unambiguous because statements in traditional set theory are formed by *and*, *or*, and *not* operators which have well-defined semantics. In traditional set theory statement "$x \in B$ and $x \in C$" is true only if both declarations are true. In other words, a new set can be formed from sets B and C and x will belong to this new set only in case it is an element of both set B and set C. In fuzzy set theory the interpretation of statement "($x \in B$: $\mu_B(x) = 0.1$) and ($x \in C$: $\mu_C(x) = 0.3$)"

© 2006 by Taylor & Francis Group, LLC

is not that simple. Namely, it is not apparent how to determine the membership degree of x in the new fuzzy set formed by fuzzy sets B and C.

There are many different suggestions for determining the membership function of a fuzzy set that is the result of union, intersection, and complement of other fuzzy sets. Zadeh proposed the following definitions of these operations:

$$\begin{aligned}
&\mu_{B\cap C}(x) = \min(\mu_B(x), \mu_C(x)) \\
&\mu_{B\cup C}(x) = \max(\mu_B(x), \mu_C(x)) \\
&\mu_{\bar{B}}(x) = 1 - \mu_B(x)
\end{aligned} \tag{2.6}$$

According to (2.6), statement "($x \in B$: $\mu_B(x) = 0.1$) and ($x \in C$: $\mu_C(x) = 0.3$)" form a new fuzzy set $D = B \cap C$ with $\mu_D(x) = 0.1$.

It should be noted that the above definitions are also valid for crisp sets. If a membership function is replaced with a characteristic function that obtains only two values, 0 and 1, then Zadeh's operators will give the same results as standard *and*, *or*, and *not* operators.

In general, operators on fuzzy sets use *triangular norms* — a class of binary functions, which may be divided into *T-norms* (AND operators) and *S-norms* (OR operators) [1,2]. T-norms perform an *intersection* operation on fuzzy sets and have a particular importance in fuzzy logic control. T-norm is usually denoted as $T(a, b)$. S-norms represent a *union* operation denoted as $S(a, b)$.

Almost all T-norms used in fuzzy control applications can be derived from four basic T-norms listed below:

$$\begin{aligned}
&1.\quad T(\mu_B, \mu_C) = \min(\mu_B, \mu_C) \\
&2.\quad T(\mu_B, \mu_C) = \mu_B \cdot \mu_C \\
&3.\quad T(\mu_B, \mu_C) = \max(0, \mu_B + \mu_C - 1) \\
&4.\quad T(\mu_B, \mu_C) = \begin{cases} \mu_B, & \text{if } \mu_C = 1 \\ \mu_C, & \text{if } \mu_B = 1 \\ 0, & \text{if } \mu_B, \mu_C < 1 \end{cases}
\end{aligned} \tag{2.7}$$

The differences between these four T-norms are shown in the following example.

Example 2.1 Four basic T-norms.

We will now consider two fuzzy sets, B and C, which are defined as:

$$B = \{(\mu_B(x), x) \colon x \in \aleph\}, \qquad \mu_B(x) = \begin{cases} 0.1 \cdot x, & \text{for } x < 10 \\ \dfrac{20 - x}{10}, & \text{for } 10 \le x \le 19 \\ 0, & \text{for } x > 19 \end{cases}$$

© 2006 by Taylor & Francis Group, LLC

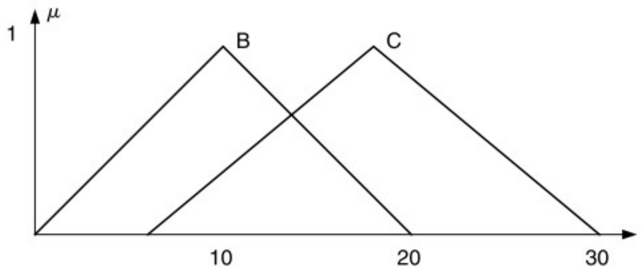

FIGURE 2.3 Fuzzy sets *B* and *C* considered in Example 2.1.

$$C = \{(\mu_C(x), x) \colon x \in \aleph\} \qquad \mu_C(x) = \begin{cases} 0, & \text{for } x < 7 \\ \dfrac{x-6}{12}, & \text{for } 7 \le x \le 18 \\ \dfrac{30-x}{12}, & \text{for } 19 \le x \le 29 \\ 0, & \text{for } x > 29 \end{cases}$$

Fuzzy sets *B* and *C* are pictured in Figure 2.3. Numerical values of the corresponding membership functions and results obtained after the application of four basic *T*-norms are given in Table 2.1.

Membership functions calculated in Table 2.1 for four different *T*-norms are represented graphically in Figure 2.4.

2.2 LINGUISTIC VARIABLES

In everyday communication we often use short sentences, which carry the same amount of information as their longer counterparts. When we say that "the car is far away" we actually mean that "the car's distance belongs to the *far away* (*very long*) category." Even if we knew that the distance was exactly 350 m, in everyday communication we would prefer saying that "the car is far away," as we would assume that there is a common understanding what a *very long distance* in traffic terms is. The term *distance* may attain two different values: numerical (350 m) and linguistic (far away). Variables, for which values are words or sentences, rather than numbers, are called *linguistic variables*. Continuing with our car analogy — the driver makes decisions about her/his actions based on imprecise linguistic qualifications of input information. Therefore, the strategy of driving a car is expressed in the form of IF–THEN rules, which contain linguistic variables: usually the names of inputs and outputs, rather than their concrete values (numbers). As Zadeh has stated, linguistic variables may assume different linguistic values over a specified universe of discourse. This means that linguistic values defined by an appropriate

Let OP be drawn through the origin parallel to the given line so that l, m, n are the cosines of the angles which OP makes with OX, OY, OZ respectively. (*Refer Fig. 6*)

Let (x, y, z) be the co-ordinates of any point P on this line.

Let $\qquad OP=r.$

$\therefore \qquad x=lr,\ y=mr,\ z=nr.$

Squaring and adding, we obtain

$$x^2+y^2+z^2=(l^2+m^2+n^2)r^2.$$

But $\qquad x^2+y^2+z^2=OP^2=r^2.$

$$\therefore \qquad \mathbf{l^2+m^2+n^2=1.}$$

Cor. If a, b, c be three numbers *proportional* to the *actual* direction cosines l, m, n of a line, we have

$$\frac{l}{a}=\frac{m}{b}=\frac{n}{c}=\pm\frac{\sqrt{(l^2+m^2+n^2)}}{\sqrt{(a^2+b^2+c^2)}}=\pm\frac{1}{\sqrt{(a^2+b^2+c^2)}}.$$

$$\therefore \qquad l=\pm\frac{a}{\sqrt{(a^2+b^2+c^2)}},\quad m=\pm\frac{b}{\sqrt{(a^2+b^2+c^2)}},$$

$$n=\pm\frac{c}{\sqrt{(a^2+b^2+c^2)}},$$

where the same sign, positive or negative, is to be chosen throughout.

✓ **Direction Ratios.** From above, we see that a set of three numbers which are proportional to the actual direction cosines are sufficient to specify the direction of a line. Such numbers are called the **direction ratios.** Thus if a, b, c be the direction ratios of a line, its direction cosines are

$$\pm a/\sqrt{\Sigma a^2},\ \pm b/\sqrt{\Sigma a^2},\ \pm c/\Sigma a^2$$

Note. It is easy to see that if a line OP through the origin O makes angles α, β, γ with OX, OY, OZ, then the line OP obtained by producing OP backwards through O will make angles $\pi-\alpha$, $\pi-\beta$, $\pi-\gamma$ with OX, OY, OZ. Thus if

$$\cos\alpha=l,\ \cos\beta=m,\ \cos\gamma=n$$

are the direction cosines of OP, then

$$\cos(\pi-\alpha)=-l,\ \cos(\pi-\beta)=-m,\ \cos(\pi-\gamma)=-n$$

are the direction cosines of OP', *i.e.*, the line OP produced backwards.

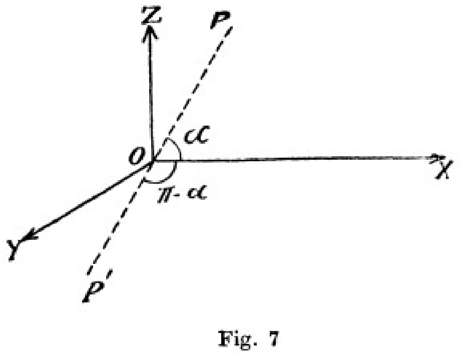

Fig. 7

Thus if we ignore the two senses of a line, we can think of the direction cosines l, m, n or $-l, -m, -n$ determining the direction of one and the same line. This explains the ambiguity in sign obtained above.

Note. The student should always make a distinction between direction cosines and direction ratios. It is only when l, m, n are direction cosines, that we have the relation

$$l^2+m^2+n^2=1.$$

Exercises

1. 6, 2, 3 are proportional to the direction cosines of a line. What are their actual values? [*Ans.* (6/7, 2/7, 3/7).

2. What are the direction cosines of lines equally inclined to the axes? How many such lines are there? [*Ans.* $(1/\sqrt{3}, \pm 1/\sqrt{3}, \pm 1/\sqrt{3})$; 4.

3. The co-ordinates of a point P are (3, 12, 4). Find the direction cosines of the line OP. [*Ans.* (3/13, 12/13, 4/13).

4. *The direction cosines l, m, n, of two lines are connected by the relations*

$$l+m+n=0 \qquad \ldots(i)$$

$$2lm+2ln-mn=0. \qquad \ldots(ii)$$

Find them?

Eliminating n between (i) and (ii); we get

$$2l^2-lm-m^2=0$$

or

$$2\left(\frac{l}{m}\right)^2-\frac{l}{m}-1=0. \qquad \ldots(iii)$$

This equation gives two values of l/m and hence there are two lines. The two roots of (iii) are 1 and $-\frac{1}{2}$.

If l_1, m_1, n_1 and l_2, m_2, n_2 be the direction cosines of two lines, we have

$$\frac{l_1}{m_1}=1 \text{ and } \frac{l_2}{m_2}=-\frac{1}{2}.$$

Also $\because l_1+m_1+n_1=0$ or $\dfrac{l_1}{m_1}+1+\dfrac{n_1}{m_1}=0$, $\quad\therefore \dfrac{n_1}{m_1}=-2,$

and $\because l_2+m_2+n_2=0$ or $\dfrac{l_2}{m_2}+1+\dfrac{n_2}{m_2}=0$, $\quad\therefore \dfrac{n_2}{m_2}=-\dfrac{1}{2}.$

$$\therefore \quad \frac{l_1}{1}=\frac{m_1}{1}=\frac{n_1}{-2}=\frac{1}{\sqrt{6}}, \text{ or } l_1=\frac{1}{\sqrt{6}}, \quad m_1=\frac{1}{\sqrt{6}}, \; n_1=-\frac{2}{\sqrt{6}}.$$

$$\text{and } \frac{l_2}{1}=\frac{m_2}{-2}=\frac{n_2}{1}=\frac{1}{\sqrt{6}}, \text{ or } l_2=\frac{1}{\sqrt{6}}, \; m_2=-\frac{2}{\sqrt{6}}, \; n_2=\frac{1}{\sqrt{6}}.$$

5. The direction cosines of two lines are determined by the relations

(i) $l-5m+3n=0, \; 7l^2+5m^2-3n^2=0$;

(ii) $l+m-n=0, \quad mn+6ln-12lm=0$;

find them?

[*Ans.* (i) $\dfrac{1}{\sqrt{14}}, \dfrac{2}{\sqrt{14}}, \dfrac{3}{\sqrt{14}}$; $-\dfrac{1}{\sqrt{6}}, \dfrac{1}{\sqrt{6}}, \dfrac{2}{\sqrt{6}}$

(ii) $\dfrac{1}{\sqrt{26}}, \dfrac{3}{\sqrt{26}}, \dfrac{4}{\sqrt{26}}$; $\dfrac{1}{\sqrt{14}}, \dfrac{2}{\sqrt{14}}, \dfrac{3}{\sqrt{14}}$.

1·8. Projection on a Straight line.

1·81. Projection of a point on a line. The foot of the perpendicular P from a given point A on a given straight line BC is called the *orthogonal projection* (or simply projection for the purpose of this book) of the point on the line and is the same point where the plane through the given point and perpendicular to the given line meets the line.

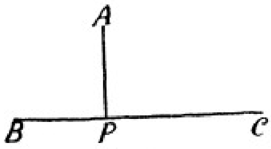

Fig. 8.

Thus in Fig. 1, page 1, A is the projection of P on X-axis ; also B and C are the projections of P on Y-axis and Z-axis respectively.

1·82. Projection of a segment of a line on another line. The projection of a segment AB of a line on any line CD is the segment $A'B'$ of CD where A', B' are the projections of A, B respectively on the line CD.

Clearly $A'B'$ is the intercept made on CD by planes through A, B each perpendicular to CD.

Ex. The co-ordinates of a point P are (x, y, z). What are the projections of OP on the co-ordinate axes ? [*Ans.* x, y, z.

Theorem. *The projection of a given segment AB of a line on any line CD is $AB \cos \theta$, where θ is the angle between AB and CD.*

Let the planes through A and B perpendicular to the line CD meet it in A', B' respectively so that $A'B'$ is the projection of AB.

Through A draw a line $AP \parallel CD$ to meet the plane through B at P.

Now, $AP \parallel CD$.

$\therefore$ $\angle PAB = \theta$.

Also BP lies in the plane which is $\perp AP$.

$\therefore$ $\angle APB = 90°$

Hence $AP = AB \cos \theta$

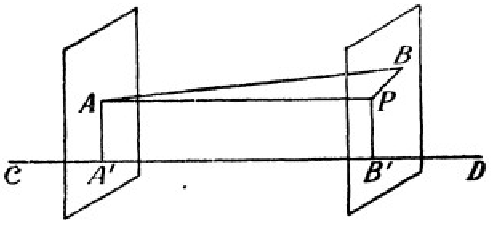

Fig. 9

Clearly $A'B'PA$ is a rectangle so that we have

$$AP = A'B'.$$

Hence $A'B' = AB \cos \theta$.

Cor. Direction cosines of the join of two points.

To find the direction cosines of the line joining the two points

$$P(x_1, y_1, z_1) \text{ and } Q(x_2, y_2, z_2).$$

Let L, M be the feet of the perpendiculars drawn from P, Q to the X-axis respectively so that

$$OL = x_1,\ OM = x_2.$$

Projection of PQ on X-axis $= LM$

$$= OM - OL$$

$$= x_2 - x_1.$$

Also if l, m, n be the direction cosines of PQ, the projection of PQ on X-axis $= l.PQ$.

$$\therefore \qquad l.PQ = x_2 - x_1.$$

Similarly projecting PQ on Y-axis and Z-axis, we get

$$m.PQ = y_2 - y_1,$$

$$n.PQ = z_2 - z_1.$$

PQ $= \sqrt{(x_2-x_1)^2+(y_2-}$

$$\therefore \qquad \frac{x_2 - x_1}{l} = \frac{y_2 - y_1}{m} = \frac{z_2 - z_1}{n} = PQ. \checkmark$$

Thus the direction cosines of the line joining the two points

(x_1, y_1, z_1) *and* (x_2, y_2, z_2)

are proportional to

$$x_2 - x_1,\ y_2 - y_1,\ z_2 - z_1.$$

Exercises

1. Find the direction cosines of the lines joining the points
   (*i*) (4, 3, −5) and (−2, 1, −8). [*Ans.* (6/7, 2/7, 3/7)
   (*ii*) (7, −5, 9) and (5, −3, 8). [*Ans.* (2/3, −2/3, 1/3)
2. Show that the points (1, −2, 3), (2, 3, −4), (0, −7, 10) are collinear.
3. The projections of a line on the axes are 12, 4, 3. Find the length and the direction cosines of the line. [*Ans.* 13 ; (12/13, 4/13, 3/13)

1·83. Projection of a broken line (*consisting of several continuous segments*). *If* $P_1, P_2, P_3, \ldots\ldots, P_n$ *be any number of points in space, then the sum of the projections of*

$$P_1P_2,\ P_2P_3, \ldots\ldots, P_{n-1}P_n$$

on any line is equal to the projection of P_1P_n *on the same line.*

Let $Q_1, Q_2, Q_3, \ldots\ldots, Q_n$ be the projections of the points

$$P_1, P_2, P_3, \ldots\ldots, P_n$$

on the given line. Then

$$Q_1Q_2 = \text{projection of } P_1P_2,$$

$$Q_2Q_3 = \quad ,, \quad ,, \ P_2P_3,$$

and so on.

Donated by
Mr. N. Sreeka
M.Sc.(Maths)

Also $\qquad Q_1Q_n = \text{projection of } P_1P_n.$

As $Q_1, Q_2, Q_3 \ldots\ldots, Q_n$ lie on the same line we have, for all relative positions of these points on the line, the relation

$$Q_1Q_2 + Q_2Q_3 + \ldots\ldots + Q_{n-1}Q_n = Q_1Q_n$$

Hence the theorem.

✓ **1·84. Projection of the join of two points on a line.** *To show that the projection of the line joining*

$$P(x_1, y_1, z_1) \text{ and } Q(x_2, y_2, z_2)$$

on a line with direction cosines l, m, n is

$$(x_2-x_1)l+(y_2-y_1)m+(z_2-z_1)n.$$

Through P, Q draw planes parallel to the co-ordinate planes to form a rectangular parallelopiped whose one diagonal is PQ. (*See Fig. 3, Page 3*).

Now

$$PA=x_2-x_1,\ AN=y_2-y_1,\ NQ=z_2-z_1.$$

The lines PA, AN, NQ are respectively parallel to x-axis, y-axis, z-axis. Therefore, their respective projections on the line with direction cosines l, m, n are

$$(x_2-x_1)l,\ (y_2-y_1)m,\ (z_2-z_1)n.$$

As the projection of PQ on any line is equal to the sum of the projections of PA, AN, NQ on that line, therefore the required projection is

$$(\mathbf{x_2}-\mathbf{x_1})\mathbf{l}+(\mathbf{y_2}-\mathbf{y_1})\mathbf{m}+(\mathbf{z_2}-\mathbf{z_1})\mathbf{n}.$$

Exercises

1. $A(6, 3, 2)$, $B(5, 1, 4)$, $C(3, -4, 7)$, $D(0, 2, 5)$ are four points. Find the projections of AB on CD and of CD on AB. [*Ans.* $-13/7$; $-13/3$.

2. Show by projection that if P, Q, R, S are the points $(6, -6, 0)$, $(-1, -7, 6)$, $(3, -4, 4,)$ $(2, -9, 2)$ respectively then $PQ \perp RS$.

✓ **1·9. Angle between two lines.** *To find the angle between lines whose direction cosines are (l_1, m_1, n_1) and (l_2, m_2, n_2).*

Let OP_1, OP_2, be lines through the origin parallel to the given lines so that the cosines of the angles which OP_1 and OP_2 make with the axes are l_1, m_1, n_1 and l_2, m_2, n_2, respectively and the angle between the given lines is the angle between OP_1 and OP_2. Let this angle be θ.

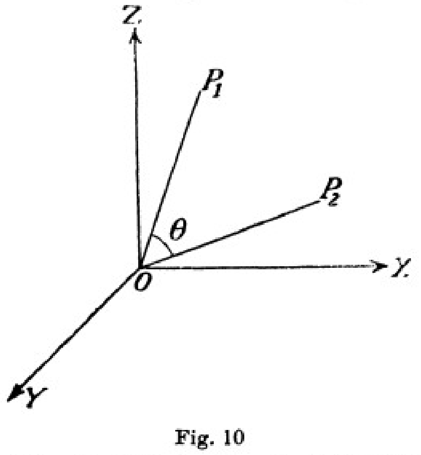

Fig. 10

Let the co-ordinates of P_2 be (x_2, y_2, z_2).

The projection of the line OP_2 joining

$$O(0, 0, 0) \text{ and } P_2(x_2, y_2, z_2)$$

on the line OP_1 whose direction cosines are

$$l_1, m_1, n_1,$$

is $$(x_2-0)l_1+(y_2-0)m_1+(z_2-0)n_1=l_1x_2+m_1y_2+n_1z_2$$

Also this projection is $OP_2 \cos\theta$.

$\therefore$ $$OP_2 \cos\theta=l_1x_2+m_1y_2+n_1z_2.$$

But $$x_2=l_2.OP_2,\ y_2=m_2.OP_2,\ z_2=n_2.OP_2. \qquad (\S 1{\cdot}61)$$

$\therefore$ $$OP_2 \cos\theta=(l_1l_2+m_1m_2+n_1n_2)OP_2$$

or $$\cos\theta=\mathbf{l_1l_2+m_1m_2+n_1n_2}.$$

Second Method. Suppose $OP_1=r_1$, $OP_2=r_2$.

Let the co-ordinates of P_1, P_2, be (x_1, y_1, z_1) and (x_2, y_2, z_2) respectively.

Then $$x_1=r_1l_1,\quad y_1=r_1m_1,\quad z_1=r_1n_1, \qquad (\S 1{\cdot}61)$$

and $$x_2=r_2l_2,\quad y_2=r_2m_2,\quad z_2=r_2n_2.$$

We have

$$\begin{aligned}P_1P_2^2&=(x_2-x_1)^2+(y_2-y_1)^2+(z_2-z_1)^2\\&=(x_2^2+y_2^2+z_2^2)+(x_1^2+y_1^2+z_1^2)-2(x_1x_2+y_1y_2+z_1z_2)\\&=r_2^2+r_1^2-2r_2r_1(l_1l_2+m_1m_2+n_1n_2). \qquad \ldots(i)\end{aligned}$$

Also from Trigonometry, we have

$$P_1P_2^2=r_1^2+r_2^2-2r_1r_2\cos\theta \qquad \ldots(ii)$$

Therefore, from (i) and (ii), we obtain

$$\begin{aligned}r_1^2+r_2^2-2r_1r_2\cos\theta&=P_1P_2^2\\&=r_1^2+r_2^2-2r_1r_2(l_1l_2+m_1m_2+n_1n_2)\end{aligned}$$

i.e., $$\cos\theta=l_1l_2+m_1m_2+n_1n_2.$$

Cor. 1. Sin θ and **tan θ**. The expressions for sin θ and tan θ in a convenient form are obtained as follows :—

$$\begin{aligned}\sin^2\theta&=1-\cos^2\theta\\&=1-(l_1l_2+m_1m_2+n_1n_2)^2\\&=(l_1^2+m_1^2+n_1^2)(l_2^2+m_2^2+n_2^2)-(l_1l_2+m_1m_2+n_1n_2)^2\\&=(l_1m_2-l_2m_1)^2+(m_1n_2-m_2n_1)^2+(n_1l_2-n_2l_1)^2.\end{aligned}$$

$\therefore$ $$\sin\theta=\pm\sqrt{[\Sigma(l_1m_2-l_2m_1)^2]}$$

and $$\tan\theta=\frac{\sin\theta}{\cos\theta}=\pm\frac{\sqrt{[\Sigma(l_1m_2-l_2m_1)^2]}}{\Sigma l_1l_2}.$$

Cor. 2. If the direction cosines of two lines be proportional to a_1, b_1, c_1, and a_2, b_2, c_2, then their actual values are

$$\pm\frac{a_1}{\sqrt{(a_1^2+b_1^2+c_1^2)}},\ \pm\frac{b_1}{\sqrt{(a_1^2+b_1^2+c_1^2)}},\ \pm\frac{c_1}{\sqrt{(a_1^2+b_1^2+c_1^2)}}\ ;$$

$$\pm\frac{a_2}{\sqrt{(a_2^2+b_2^2+c_2^2)}},\ \pm\frac{b_2}{\sqrt{(a_2^2+b_2^2+c_2^2)}},\ \pm\frac{c_2}{\sqrt{(a_2^2+b_2^2+c_2^2)}},$$

so that if θ be the angle between the given lines, we have

$$\cos\theta = \pm\frac{a_1a_2+b_1b_2+c_1c_2}{\sqrt{(a_1^2+b_1^2+c_1^2)}\sqrt{(a_2^2+b_2^2+c_2^2)}},$$

$$\sin\theta = \pm\frac{\sqrt{[(a_1b_2-a_2b_1)^2+(b_1c_2-b_2c_1)^2+(c_1a_2-c_2a_1)^2]}}{\sqrt{(a_1^2+b_1^2+c_1^2)}\sqrt{(a_2^2+b_2^2+c_2^2)}},$$

$$\tan\theta = \pm\frac{\sqrt{[\Sigma(a_1b_2-a_2b_1)^2]}}{\Sigma a_1a_2}.$$

The expression for tan θ is of the same form whether we use direction cosines or direction ratios.

Cor. 3. Conditions for perpendicularity and parallelism.

(*i*) When the given lines are perpendicular,

$$\theta=90° \text{ so that } \cos\theta=0.$$

This gives

$$\mathbf{a_1a_2+b_1b_2+c_1c_2=0}.$$

(*ii*) When the given lines are parallel,

$$\theta=0 \text{ so that } \sin\theta=0.$$

This gives

$$(a_1b_2-a_2b_1)^2+(b_1c_2-b_2c_1)^2+(c_1a_2-c_2a_1)^2=0,$$

which is true only when

$$a_1b_2-a_2b_1=0,\ b_1c_2-b_2c_1=0,\ c_1a_2-c_2a_1=0,$$

or

$$\frac{\mathbf{a_1}}{\mathbf{a_2}}=\frac{\mathbf{b_1}}{\mathbf{b_2}}=\frac{\mathbf{c_1}}{\mathbf{c_2}}.$$

This result is also otherwise evident, for, the lines through the origin drawn parallel to the parallel lines coincide and, therefore, their direction cosines must be the same and hence direction ratios proportional.

Exercises

1. Find the angles between the lines whose direction ratios are

(*i*) 5, −12, 13 ; −3, 4, 5. [*Ans.* $\cos^{-1}(1/65)$.

(*ii*) 1, 1, 2 ; $\sqrt{3}-1, -\sqrt{3}-1, 4$. [*Ans.* $\pi/3$.

2. Show that the angle between the lines whose direction cosines are given by the relations in Ex. 4, P. 9 is $\frac{1}{3}\pi$.

3. *Find the direction cosines of the line which is perpendicular to the lines with direction cosines proportional to (1, −2, −2), (0, 2, 1).*

Sol. If l, m, n be the direction cosines of the line perpendicular to the given lines, we have

$$l.1+m(-2)+n(-2)=0,\ i.e.,\ l-2m-2n=0,$$
$$l(0)+m(2)+n(1)=0,\ i.e.,\ 0l+2m+n=0.$$

These give

$$\frac{l}{2}=\frac{m}{-1}=\frac{n}{2}.$$

$$\therefore\quad l=\frac{2}{\sqrt{[2^2+(-1)^2+2^2]}}=\frac{2}{3},\ m=-\frac{1}{3},\ n=\frac{2}{3}.$$

4. Show that a line can be found perpendicular to the three lines with direction cosines proportional to (2, 1, 5), (4, −2, 2), (−6, 4, −1). Hence show that if these three lines be concurrent, they are also coplanar.

5. *l_1, m_1, n_1 ; l_2, m_2, n_2 are the direction cosines of two mutually perpendicular lines. Show that the direction cosines of the line perpendicular to them both are*

$$m_1n_2-m_2n_1,\ n_1l_2-n_2l_1,\ l_1m_2-l_2m_1.$$

Sol. If l, m, n be the direction cosines of the required line, we have

$$ll_1+mm_1+nn_1=0,$$
$$ll_2+mm_2+nn_2=0.$$

These give

$$\frac{l}{m_1n_2-m_2n_1}=\frac{m}{n_1l_2-n_2l_1}=\frac{n}{l_1m_2-l_2m_1}=\frac{\sqrt{\Sigma l^2}}{\sqrt{[\Sigma(m_1n_2-m_2n_1)^2]}}=\frac{1}{\sin\theta},$$

where θ is the angle between the given lines. As $\theta=90°$, we have $\sin\theta=1$. Hence the result.

6. l_1, m_1, n_1 and l_2, m_2, n_2 are the direction ratios of two intersecting lines. Show that lines through the intersection of these two with direction ratios

$$l_1+kl_2,\ m_1+km_2,\ n_1+kn_2$$

are coplanar with them ; k being any number whatsoever.

(Show that they all have a common perpendicular direction.)

7. Show that three concurrent lines with direction cosines

$$(l_1, m_1, n_1),\ (l_2, m_2, n_2),\ (l_3, m_3, n_3)$$

are coplanar if.

$$\begin{vmatrix} l_1, & m_1, & n_1 \\ l_2, & m_2, & n_2 \\ l_3, & m_3, & n_3 \end{vmatrix}=0.$$

8. Show that the join of points (1, 2, 3), (4, 5, 7) is parallel to the join of the points (−4, 3, −6), (2, 9, 2).

9. Show that the points

(4, 7, 8) ; (2, 3, 4) ; (−1, −2, 1) ; (1, 2, 5)

are the vertices of a parallelogram.

10. Show that the points

(5, −1, 1), (7, −4, 7), (1, −6, 10), (−1, −3, 4)

are the vertices of a rhombus.

11. Show that the points.

(0, 4, 1), (2, 3, −1), (4, 5, 0), (2, 6, 2)

are the vertices of a square.

✓**12.** $A(1, 8, 4)$, $B(0, -11, 4)$, $C(2, -3, 1)$ are three points and D is the foot of the perpendicular from A on BC. Find the co-ordinates of D.

[*Ans.* (4, 5, −2).

13. Find the point in which the join of (−9, 4, 5) and (11, 0, −1) is met by the perpendicular from the origin. [*Ans.* (1, 2, 2).

14. $A(-1, 2, -3)$, $B(5, 0, -6)$, $C(0, 4, -1)$ are three points. Show that the direction cosines of the bisectors of the angle BAC are proportional to (25, 8, 5) and (−11, 20, 23).

[*Hint.*—Find the co-ordinates of the points which divide BC in the ratio $AB : AC$.]

15. Find the angle between the lines whose direction cosines are given by the equations $3l+m+5n=0$ and $6mn-2nl+5lm=0$. [*Ans.* $\cos^{-1}\frac{1}{6}$.

16. Show that the pair of lines whose direction cosines are given by $3lm-4ln+mn=0$, $l+2m+3n=0$ are perpendicular.

17. *Show that the straight lines whose direction cosines are given by the equations*

$$al+bm+cn=0,\ ul^2+vm^2+wn^2=0$$

are perpendicular or parallel according as

$$a^2(v+w)+b^2(w+u)+c^2(u+v)=0 \quad \text{or} \quad a^2/u+b^2/v+c^2/w=0,$$

Sol. Eliminating l, between the given relations, we have

$$\frac{u(bm+cn)^2}{a^2}+vm^2+wn^2=0$$

or
$$(b^2u+a^2v)m^2+2ubcmn+(c^2u+a^2w)n^2=0 \qquad \ldots(i)$$

If the lines be parallel, their direction cosines are equal so that the two values of m/n must be equal. The condition for this is

$$u^2b^2c^2=(b^2u+a^2v)(c^2u+a^2w)$$

or

$$\frac{a^2}{u}+\frac{b^2}{v}+\frac{c^2}{w}=0.$$

Again, if l_1, m_1, n_1 and l_2, m_2, n_2 be the direction cosines of the two lines, then equation (i) gives

$$\frac{m_1}{n_1}\cdot\frac{m_2}{n_2}=\frac{m_1m_2}{n_1n_2}=\frac{c^2u+a^2w}{b^2u+a^2v}$$

or

$$\frac{m_1m_2}{c^2u+a^2w}=\frac{n_1n_2}{b^2u+a^2v}$$

or

Similarly the elimination of n, gives, (or by symmetry)

$$\frac{l_1l_2}{b^2w+c^2v}=\frac{m_1m_2}{a^2w+c^2u}$$

$$\therefore \qquad \frac{l_1l_2}{b^2w+c^2v}=\frac{m_1m_2}{a^2w+c^2u}=\frac{n_1n_2}{b^2u+a^2v}=k, \text{ say}$$

or

$$l_1l_2+m_1m_2+n_1n_2=k(b^2w+c^2v+a^2w+c^2u+b^2u+a^2v).$$

For perpendicular lines

$$l_1l_2+m_1m_2+n_1n_2=0$$

Thus the condition for perpendicularity is

$$a^2(v+w)+b^2(w+u)+c^2(u+v)=0.$$

18. Show that the straight lines whose direction cosines are given by

$$al+bm+cn=0,\ fmn+gnl+hlm=0,$$

are perpendicular if

$$f/a+g/b+h/c=0,$$

and parallel if

$$\sqrt{af}\pm\sqrt{bg}\pm\sqrt{ch}=0.$$

19. *l_1, m_1, n_1 ; l_2, m_2, n_2 are the direction cosines of two concurrent lines. Show that the direction cosines of the lines bisecting the angles between them are proportional to*

$$l_1\pm l_2,\ m_1\pm m_2,\ n_1\pm n_2.$$

Sol. Let the lines concur at the origin O and let OA, OB be the two lines. Take points A, B on the two lines such that $OA=OB=r$, say. Also take a point A' on AO produced such that $AO=OA'$. Let C, C' be the mid-points of AB and $A'B$. Then OC, OC' are the required bisectors. The result, now, follows from the fact that the co-ordinates of A, B, A' respectively are

$$(l_1r,\ m_1r,\ n_1r)\ ;\ (l_2r,\ m_2r,\ n_2r)\ ;\ (-l_1r,\ -m_1r,\ -n_1r),$$

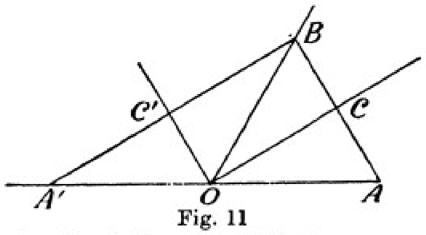

Fig. 11

20. *If the edges of a rectangular parallelopiped are a, b, c show that the angles between the four diagonals are given by*

$$\cos^{-1}[(\pm a^2 \pm b^2 \pm c^2)/(a^2+b^2+c^2)].$$

Sol. Take one of the vertices O of the parallelopiped as origin and the three rectangular faces through it as the three rectangular co-ordinate planes. (*See Fig. 1, Page 1*).

$$\text{Let } OA=a,\ OB=b,\ OC=c$$

The lines OP, AL, BM, CN are the four diagonals.

The co-ordinates of A, B, C are $(a, 0, 0)$; $(0, b, 0)$; $(0, 0, c)$.

" L, M, N are $(0, b, c)$; $(a, 0, c)$; $(a, b, 0)$.

" O, P are $(0, 0, 0)$; (a, b, c).

Direction cosines of OP are $\dfrac{a}{\sqrt{\Sigma a^2}}, \dfrac{b}{\sqrt{\Sigma a^2}}, \dfrac{c}{\sqrt{\Sigma a^2}}$;

Direction cosines of AL are $\dfrac{-a}{\sqrt{\Sigma a^2}}, \dfrac{b}{\sqrt{\Sigma a^2}}, \dfrac{c}{\sqrt{\Sigma a^2}}$;

" " " BM are $\dfrac{a}{\sqrt{\Sigma a^2}}, \dfrac{-b}{\sqrt{\Sigma a^2}}, \dfrac{c}{\sqrt{\Sigma a^2}}$;

" " " CN are $\dfrac{a}{\sqrt{\Sigma a^2}}, \dfrac{b}{\sqrt{\Sigma a^2}}, \dfrac{-c}{\sqrt{\Sigma a^2}}$.

The angle between OP and CN, therefore, is

$$\cos^{-1} \frac{a^2+b^2-c^2}{a^2+b^2+c^2}.$$

Similarly the angle between any one of the six pairs of diagonals can be found.

21. A line makes angles α, β, γ, δ, with the four diagonals of a cube ; prove that $\cos^2\alpha+\cos^2\beta+\cos^2\gamma+\cos^2\delta=4/3$. *(P.U. 1932)*

(Choose axes as in Ex. 20 above and suppose that the direction cosines of the given line are l, m, n.)

22. *O, A, B, C, are four points not lying in the same plane and such that $OA \perp BC$ and $OB \perp CA$. Prove that $OC \perp AB$. What well-known theorem does this become if four points are co-planar ?*

The result of this example may also be stated thus :—

"If two pairs of opposite edges of a tetrahedron be at right angles, then so is the third."

Take O as origin and any three mutually perpendicular lines through O as co-ordinate axes.

Let (x_1, y_1, z_1), (x_2, y_2, z_2), (x_3, y_3, z_3) be the co-ordinates of the points A, B, C respectively.

As $OA \perp BC$, we have

$$x_1(x_2-x_3)+y_1(y_2-y_3)+z_1(z_2-z_3)=0, \qquad \ldots(i)$$

As $OB \perp CA$, we have

$$x_2(x_3-x_1)+y_2(y_3-y_1)+z_2(z_3-z_1)=0. \qquad \ldots(ii)$$

Adding (i) and (ii), we obtain

$$x_3(x_2-x_1)+y_3(y_2-y_1)+z_3(z_2-z_1)=0$$

which shows that $OC \perp AB$.

23. If, in a tetrahedron $OABC$,

$$OA^2+BC^2=OB^2+CA^2=OC^2+AB^2,$$

then its pairs of opposite edges are at right angles.

24. l_1, m_1, n_1 and l_2, m_2, n_2 are two directions inclined at an angle φ, to each other. Show that the direction

$$\frac{l_1+l_2}{2\cos\frac{1}{2}\varphi}, \frac{m_1+m_2}{2\cos\frac{1}{2}\varphi}, \frac{n_1+n_2}{2\cos\frac{1}{2}\varphi}$$

bisects the angle between these two directions.

Show that these direction cosines are the actual values.

25. Show that the direction equally inclined to the three mutually perpendicular directions

$$l_1, m_1, n_1\ ;\ l_2, m_2, n_2\ ;\ l_3, m_3, n_3,$$

is given by the direction cosines

$$\frac{l_1+l_2+l_3}{\sqrt{3}},\ \frac{m_1+m_2+m_3}{\sqrt{3}},\ \frac{n_1+n_2+n_3}{\sqrt{3}}.$$

26. Show that the area of the triangle whose vertices are the origin and the points (x_1, y_1, z_1), and (x_2, y_2, z_2) is

$$\tfrac{1}{2}\sqrt{[(y_1z_2-y_2z_1)^2+(z_1x_2-z_2x_1)^2+(x_1y_2-x_2y_1)^2]}. \qquad \textit{(B.U. 1958)}$$

27. $l_1, m_1, n_1\ ;\ l_2, m_2, n_2\ ;\ l_3, m_3, n_3$

are the direction cosines of three mutually perpendicular lines ; show that

$$l_1, l_2, l_3\ ;\ m_1, m_2, m_3\ ;\ n_1, n_2, n_3$$

are also the direction cosines of three mutually perpendicular lines. Hence show that

$$\begin{aligned}
l_1^2+m_1^2+n_1^2&=1, & l_1^2+l_2^2+l_3^2&=1,\\
l_2^2+m_2^2+n_2^2&=1, & m_1^2+m_2^2+m_3^2&=1,\\
l_3^2+m_3^2+n_3^2&=1, & n_1^2+n_2^2+n_3^2&=1,\\
l_1l_2+m_1m_2+n_1n_2&=0, & l_1m_1+l_2m_2+l_3m_3&=0,\\
l_2l_3+m_2m_3+n_2n_3&=0, & m_1n_1+m_2n_2+m_3n_3&=0,\\
l_3l_1+m_3m_1+n_3n_1&=0, & n_1l_1+n_2l_2+n_3l_3&=0.
\end{aligned}$$

10. The number $\sqrt{3}$ is defined as the positive number c such that $c^2 = 3$. That there *is* such a number may be proved as follows: Let S be the set of all positive numbers x such that $x^2 < 3$. This set is not empty, since $1 \in S$. It is a bounded set, for, if $x \in S$, either $x \leqq 1$ or $x > 1$, and in the latter case $x < x^2 < 3$. By Thoerem II, S has a least upper bound, which we shall denote by c. It remains to prove that $c^2 = 3$. (Why must c be positive?) If $\epsilon > 0$, there is some x in S such that $c - \epsilon < x$. Hence $(c-\epsilon)^2 < 3$, or $c^2 - 2c\epsilon + \epsilon^2 < 3$, since $x^2 < 3$. Now let $\epsilon \to 0$, and by Theorem XI, §1.61, we conclude that $c^2 \leqq 3$. Finally, we show that $c^2 < 3$ is impossible. For, if $c^2 < 3$, the fact that $\lim_{h \to 0} (c^2 + 2ch + h^2) = c^2$ shows that $(c+h)^2 < 3$ if h is sufficiently small. This means that $c + h$ is in S if h is any sufficiently small positive number. Since c is the least upper bound of S, this is a contradiction. Therefore $c^2 = 3$.

Now let the student develop a similar argument to show that if $A > 0$ and n is a positive integer, there is a positive number c such that $c^n = A$.

Euclidean Space

Euclidean space is a mathematical construct that encompasses the line, the plane, and three-dimensional space as special cases. Its elements are called *vectors*. Vectors can be understood in various ways: as arrows, as quantities with magnitude and direction, as displacements, or as points. However, along with a sense of what vectors are, we also need to emphasize how they interact. The axioms in Section 2.1 capture the idea that vectors can be added together and can be multiplied by scalars, with both of these operations obeying familiar laws of algebra. Section 2.2 expresses the geometric ideas of length and angle in Euclidean space in terms of vector algebra. Section 2.3 discusses continuity for functions (also called *mappings*) whose inputs and outputs are vectors rather than scalars. Section 2.4 introduces a special class of sets in Euclidean space, the *compact* sets, and shows that compact sets are preserved under continuous mappings.

2.1 Algebra: Vectors

Let n be a positive integer. The set of all ordered n-tuples of real numbers,

$$\mathbb{R}^n = \{(x_1, \ldots, x_n) : x_i \in \mathbb{R} \text{ for } i = 1, \ldots, n\},$$

constitutes **n-dimensional Euclidean space**. When $n = 1$, the parentheses and subscript in the notation (x_1) are superfluous, so we simply view the elements of $\mathbb{R}^1$ as real numbers x and write $\mathbb{R}$ for $\mathbb{R}^1$. Elements of $\mathbb{R}^2$ and of $\mathbb{R}^3$ are written (x, y) and (x, y, z) to avoid needless subscripts. These first few Euclidean spaces, $\mathbb{R}$, $\mathbb{R}^2$, and $\mathbb{R}^3$, are conveniently visualized as the line, the plane, and space itself. (See Figure 2.1.)

Elements of $\mathbb{R}$ are called **scalars**, of $\mathbb{R}^n$, **vectors**. The **origin** of $\mathbb{R}^n$, denoted $\mathbf{0}$, is defined to be

$$\mathbf{0} = (0, \ldots, 0).$$

© Springer International Publishing AG 2016

J. Shurman, *Calculus and Analysis in Euclidean Space*,
Undergraduate Texts in Mathematics, DOI 10.1007/978-3-319-49314-5_2

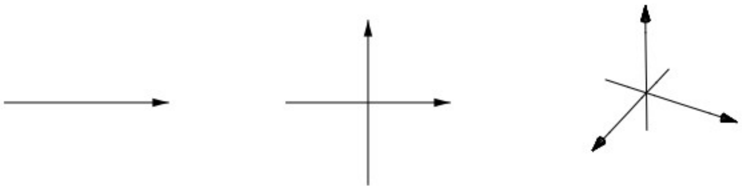

Figure 2.1. The first few Euclidean spaces

Sometimes the origin of $\mathbb{R}^n$ will be denoted $\mathbf{0}_n$ to distinguish it from other *origins* that we will encounter later.

In the first few Euclidean spaces $\mathbb{R}$, $\mathbb{R}^2$, $\mathbb{R}^3$, one can visualize a vector as a point x or as an arrow. The arrow can have its tail at the origin and its head at the point x, or its tail at any point p and its head correspondingly translated to $p+x$. (See Figure 2.2. Most illustrations will depict $\mathbb{R}$ or $\mathbb{R}^2$.)

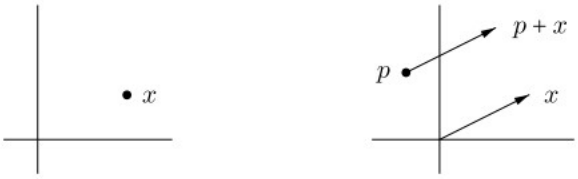

Figure 2.2. Various ways to envision a vector

To a mathematician, the word *space* doesn't connote volume but instead refers to a set endowed with some structure. Indeed, Euclidean space $\mathbb{R}^n$ comes with two algebraic operations. The first is **vector addition**,

$$+ : \mathbb{R}^n \times \mathbb{R}^n \longrightarrow \mathbb{R}^n,$$

defined by adding the scalars at each component of the vectors,

$$(x_1, \dots, x_n) + (y_1, \dots, y_n) = (x_1 + y_1, \dots, x_n + y_n).$$

For example, $(1,2,3) + (4,5,6) = (5,7,9)$. Note that the meaning of the "+" sign is now overloaded: on the left of the displayed equality, it denotes the new operation of vector addition, whereas on the right side it denotes the old addition of real numbers. The multiple meanings of the plus sign shouldn't cause problems, because the meaning of "+" is clear from context, i.e., the meaning of "+" is clear from whether it sits between vectors or scalars. (An expression such as "$(1,2,3)+4$," with the plus sign between a vector and a scalar, makes no sense according to our grammar.)

The interpretation of vectors as arrows gives a geometric description of vector addition, at least in $\mathbb{R}^2$. To add the vectors x and y, draw them as arrows starting at $\mathbf{0}$ and then complete the parallelogram P that has x and y as two of its sides. The diagonal of P starting at $\mathbf{0}$ is then the arrow depicting the vector $x+y$. (See Figure 2.3.) The proof of this is a small argument with similar triangles, left to the reader as Exercise 2.1.2.

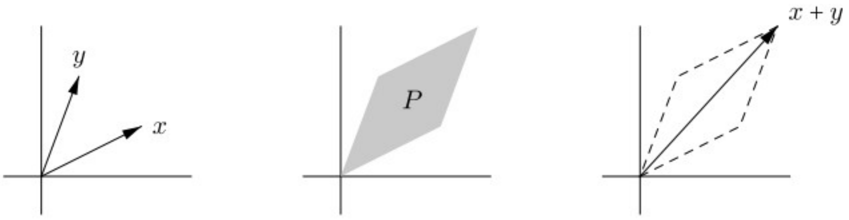

Figure 2.3. The parallelogram law of vector addition

The second operation on Euclidean space is **scalar multiplication**,

$$\cdot : \mathbb{R} \times \mathbb{R}^n \longrightarrow \mathbb{R}^n,$$

defined by

$$a \cdot (x_1, \dots, x_n) = (ax_1, \dots, ax_n).$$

For example, $2\cdot(3,4,5) = (6,8,10)$. We will almost always omit the symbol "$\cdot$" and write ax for $a\cdot x$. With this convention, juxtaposition is overloaded as "+" was overloaded above, but again this shouldn't cause problems.

Scalar multiplication of the vector x (viewed as an arrow) by a also has a geometric interpretation: it simply stretches (i.e., scales) x by a factor of a. When a is negative, ax turns x around and stretches it in the other direction by $|a|$. (See Figure 2.4.)

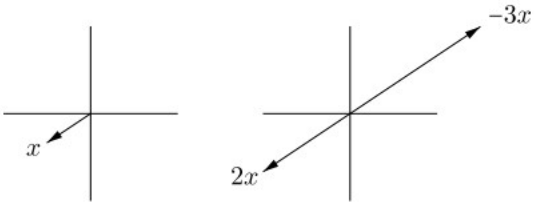

Figure 2.4. Scalar multiplication as stretching

With these two operations and distinguished element $\mathbf{0}$, Euclidean space satisfies the following algebraic laws.

Theorem 2.1.1 (Vector space axioms).

(A1) *Addition is associative:* $(x+y)+z = x+(y+z)$ *for all* $x, y, z \in \mathbb{R}^n$.
(A2) $\mathbf{0}$ *is an additive identity:* $\mathbf{0} + x = x$ *for all* $x \in \mathbb{R}^n$.
(A3) *Existence of additive inverses: for each* $x \in \mathbb{R}^n$ *there exists* $y \in \mathbb{R}^n$ *such that* $y + x = \mathbf{0}$.
(A4) *Addition is commutative:* $x + y = y + x$ *for all* $x, y \in \mathbb{R}^n$.
(M1) *Scalar multiplication is associative:* $a(bx) = (ab)x$ *for all* $a, b \in \mathbb{R}$, $x \in \mathbb{R}^n$.
(M2) 1 *is a multiplicative identity:* $1x = x$ *for all* $x \in \mathbb{R}^n$.
(D1) *Scalar multiplication distributes over scalar addition:* $(a+b)x = ax + bx$ *for all* $a, b \in \mathbb{R}$, $x \in \mathbb{R}^n$.
(D2) *Scalar multiplication distributes over vector addition:* $a(x+y) = ax + ay$ *for all* $a \in \mathbb{R}$, $x, y \in \mathbb{R}^n$.

All of these are consequences of how "+" and "·" and $\mathbf{0}$ are defined for $\mathbb{R}^n$ in conjunction with the fact that the real numbers, in turn endowed with "+" and "·" and containing 0 and 1, satisfy the field axioms (see Section 1.1). For example, to prove that $\mathbb{R}^n$ satisfies (M1), take any scalars $a, b \in \mathbb{R}$ and any vector $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$. Then

$$\begin{aligned}
a(bx) &= a(b(x_1, \ldots, x_n)) && \text{by definition of } x \\
&= a(bx_1, \ldots, bx_n) && \text{by definition of scalar multiplication} \\
&= (a(bx_1), \ldots, a(bx_n)) && \text{by definition of scalar multiplication} \\
&= ((ab)x_1, \ldots, (ab)x_n) && \text{by } n \text{ applications of (m1) in } \mathbb{R} \\
&= (ab)(x_1, \ldots, x_n) && \text{by definition of scalar multiplication} \\
&= (ab)x && \text{by definition of } x.
\end{aligned}$$

The other vector space axioms for $\mathbb{R}^n$ can be shown similarly, by unwinding vectors to their coordinates, quoting field axioms coordinatewise, and then bundling the results back up into vectors (see Exercise 2.1.3). Nonetheless, the vector space axioms do not perfectly parallel the field axioms, and you are encouraged to spend a little time comparing the two axiom sets to get a feel for where they are similar and where they are different (see Exercise 2.1.4). Note in particular that

For $n > 1$, $\mathbb{R}^n$ *is not endowed with vector-by-vector multiplication.*

Although one can define vector multiplication on $\mathbb{R}^n$ componentwise, this multiplication does not combine with vector addition to satisfy the field axioms except when $n = 1$. The multiplication of complex numbers makes $\mathbb{R}^2$ a field, and in Section 3.10 we will see an interesting noncommutative multiplication of vectors for $\mathbb{R}^3$, but these are special cases.

One benefit of the vector space axioms for $\mathbb{R}^n$ is that they are phrased **intrinsically**, meaning that they make no reference to the scalar coordinates of the vectors involved. Thus, once you use coordinates to establish the vector space axioms, your vector algebra can be intrinsic thereafter, making it lighter and more conceptual. Also, in addition to being intrinsic, the vector space axioms are general. While $\mathbb{R}^n$ is the prototypical set satisfying the vector space axioms, it is by no means the only one. In coming sections we will encounter other sets V (whose elements may be, for example, functions) endowed with their own addition, multiplication by elements of a field F, and distinguished element $\mathbf{0}$. If the vector space axioms are satisfied with V and F replacing $\mathbb{R}^n$ and $\mathbb{R}$ then we say that V is a **vector space over** F.

The pedagogical point here is that although the similarity between vector algebra and scalar algebra may initially make vector algebra seem uninspiring, in fact the similarity is exciting. It makes mathematics easier, because familiar algebraic manipulations apply in a wide range of contexts. The same symbol-patterns have more meaning. For example, we use intrinsic vector algebra to prove a result from Euclidean geometry, that the three medians of a triangle intersect. (A median is a segment from a vertex to the midpoint of the opposite edge.) Consider a triangle with vertices x, y, and z, and form the average of the three vertices,

$$p = \frac{x+y+z}{3}.$$

This algebraic average will be the **geometric center** of the triangle, where the medians meet. (See Figure 2.5.) Indeed, rewrite p as

$$p = x + \frac{2}{3}\left(\frac{y+z}{2} - x\right).$$

The displayed expression for p shows that it is two-thirds of the way from x along the line segment from x to the average of y and z, i.e., that p lies on the triangle median from vertex x to side yz. (Again see the figure. The idea is that $(y+z)/2$ is being interpreted as the midpoint of y and z, each of these viewed as a point, while on the other hand, the little mnemonic

head minus tail

helps us to remember quickly that $(y+z)/2 - x$ can be viewed as the arrow-vector from x to $(y+z)/2$.) Since p is defined symmetrically in x, y, and z, and it lies on one median, it therefore lies on the other two medians as well. In fact, the vector algebra has shown that it lies two-thirds of the way along each median. (As for how a person might find this proof, it is a matter of hoping that the geometric center $(x+y+z)/3$ lies on the median by taking the form $x + c((y+z)/2 - x)$ for some c and then seeing that indeed $c = 2/3$ works.)

The **standard basis** of $\mathbb{R}^n$ is the set of vectors

$$\{e_1, e_2, \ldots, e_n\}$$

where

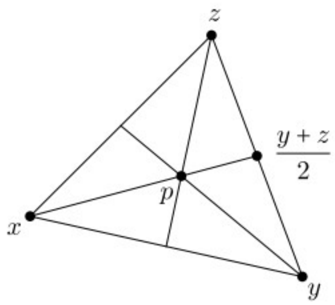

Figure 2.5. Three medians of a triangle

$$e_1 = (1,0,\dots,0), \quad e_2 = (0,1,\dots,0), \quad \dots, \quad e_n = (0,0,\dots,1).$$

(Thus each e_i is itself a vector, not the ith scalar entry of a vector.) Every vector $x = (x_1, x_2, \dots, x_n)$ (where the x_i are scalar entries) decomposes as

$$\begin{aligned} x &= (x_1, x_2, \dots, x_n) \\ &= (x_1, 0, \dots, 0) + (0, x_2, \dots, 0) + \cdots + (0, 0, \dots, x_n) \\ &= x_1(1,0,\dots,0) + x_2(0,1,\dots,0) + \cdots + x_n(0,0,\dots,1) \\ &= x_1e_1 + x_2e_2 + \cdots + x_ne_n, \end{aligned}$$

or more succinctly,

$$x = \sum_{i=1}^{n} x_i e_i. \tag{2.1}$$

Note that in equation (2.1), x and the e_i are vectors, while the x_i are scalars. The equation shows that every $x \in \mathbb{R}^n$ is expressible as a **linear combination** (sum of scalar multiples) of the standard basis vectors. The expression is unique, for if also $x = \sum_{i=1}^n x_i' e_i$ for some scalars $x_1', \dots, x_n'$ then the equality says that $x = (x_1', x_2', \dots, x_n')$, so that $x_i' = x_i$ for $i = 1, \dots, n$.

(The reason that the geometric-sounding word *linear* is used here and elsewhere in this chapter to describe properties having to do with the algebraic operations of addition and scalar multiplication will be explained in Chapter 3.)

The standard basis is handy in that it is a finite set of vectors from which each of the infinitely many vectors of $\mathbb{R}^n$ can be obtained in exactly one way as a linear combination. But it is not the only such set, nor is it always the optimal one.

Definition 2.1.2 (Basis). *A set of vectors* $\{f_i\}$ *is a* **basis** *of* $\mathbb{R}^n$ *if every* $x \in \mathbb{R}^n$ *is uniquely expressible as a linear combination of the* f_i.

For example, the set $\{f_1, f_2\} = \{(1,1),(1,-1)\}$ is a basis of $\mathbb{R}^2$. To see this, consider an arbitrary vector $(x,y) \in \mathbb{R}^2$. This vector is expressible as a linear combination of f_1 and f_2 if and only if there are scalars a and b such that

$$(x,y) = af_1 + bf_2.$$

Since $f_1 = (1,1)$ and $f_2 = (1,-1)$, this vector equation is equivalent to a pair of scalar equations,

$$\begin{aligned} x &= a + b, \\ y &= a - b. \end{aligned}$$

Add these equations and divide by 2 to get $a = (x+y)/2$, and similarly $b = (x-y)/2$. In other words, we have found that

$$(x,y) = \frac{x+y}{2}(1,1) + \frac{x-y}{2}(1,-1),$$

and the coefficients $a = (x+y)/2$ and $b = (x-y)/2$ on the right side of the equation are the only possible coefficients a and b for the equation to hold. That is, scalars a and b exist to express the vector (x,y) as a linear combination of $\{f_1, f_2\}$, and the scalars are uniquely determined by the vector. Thus $\{f_1, f_2\}$ is a basis of $\mathbb{R}^2$, as claimed.

The set $\{g_1, g_2\} = \{(1,3),(2,6)\}$ is not a basis of $\mathbb{R}^2$, because every linear combination $ag_1 + bg_2$ takes the form $(a+2b, 3a+6b)$, with the second entry equal to three times the first. The vector $(1,0)$ is therefore not a linear combination of g_1 and g_2.

Nor is the set $\{h_1, h_2, h_3\} = \{(1,0),(1,1),(1,-1)\}$ a basis of $\mathbb{R}^2$, because $h_3 = 2h_1 - h_2$, so that h_3 is a nonunique linear combination of the h_j.

See Exercises 2.1.9 and 2.1.10 for practice with bases.

Exercises

2.1.1. Write down any three specific nonzero vectors u, v, w from $\mathbb{R}^3$ and any two specific nonzero scalars a, b from $\mathbb{R}$. Compute $u+v$, aw, $b(v+w)$, $(a+b)u$, $u+v+w$, abw, and the additive inverse to u.

2.1.2. Working in $\mathbb{R}^2$, give a geometric proof that if we view the vectors x and y as arrows from $\mathbf{0}$ and form the parallelogram P with these arrows as two of its sides, then the diagonal z starting at $\mathbf{0}$ is the vector sum $x+y$ viewed as an arrow.

2.1.3. Verify that $\mathbb{R}^n$ satisfies vector space axioms (A2), (A3), (D1).

2.1.4. Are all the field axioms used in verifying that Euclidean space satisfies the vector space axioms?

2.1.5. Show that $\mathbf{0}$ is the unique additive identity in $\mathbb{R}^n$. Show that each vector $x \in \mathbb{R}^n$ has a unique additive inverse, which can therefore be denoted $-x$. (And it follows that vector subtraction can now be defined,

$$- : \mathbb{R}^n \times \mathbb{R}^n \longrightarrow \mathbb{R}^n, \qquad x - y = x + (-y) \quad \text{for all } x, y \in \mathbb{R}^n.)$$

Show that $0x = \mathbf{0}$ for all $x \in \mathbb{R}^n$.

2.1.6. Repeat the previous exercise, but with $\mathbb{R}^n$ replaced by an arbitrary vector space V over a field F. (Work with the axioms.)

2.1.7. Show the uniqueness of the additive identity and the additive inverse using only (A1), (A2), (A3). (This is tricky; the opening pages of some books on group theory will help.)

2.1.8. Let x and y be noncollinear vectors in $\mathbb{R}^3$. Give a geometric description of the set of all linear combinations of x and y.

2.1.9. Which of the following sets are bases of $\mathbb{R}^3$?

$$\begin{aligned} S_1 &= \{(1,0,0),(1,1,0),(1,1,1)\}, \\ S_2 &= \{(1,0,0),(0,1,0),(0,0,1),(1,1,1)\}, \\ S_3 &= \{(1,1,0),(0,1,1)\}, \\ S_4 &= \{(1,1,0),(0,1,1),(1,0,-1)\}. \end{aligned}$$

How many elements do you think a basis for $\mathbb{R}^n$ must have? Give (without proof) geometric descriptions of all bases of $\mathbb{R}^2$, of $\mathbb{R}^3$.

2.1.10. Recall the field $\mathbb{C}$ of complex numbers. Define **complex n-space** $\mathbb{C}^n$ analogously to $\mathbb{R}^n$:

$$\mathbb{C}^n = \{(z_1, \dots, z_n) : z_i \in \mathbb{C} \text{ for } i = 1, \dots, n\},$$

and endow it with addition and scalar multiplication defined by the same formulas as for $\mathbb{R}^n$. You may take for granted that under these definitions, $\mathbb{C}^n$ satisfies the vector space axioms with scalar multiplication by scalars from $\mathbb{R}$, and also $\mathbb{C}^n$ satisfies the vector space axioms with scalar multiplication by scalars from $\mathbb{C}$. That is, using language that was introduced briefly in this section, $\mathbb{C}^n$ can be viewed as a vector space over $\mathbb{R}$ and also, separately, as a vector space over $\mathbb{C}$. Give a basis for each of these vector spaces.

Brief Pedagogical Interlude

Before continuing, a few comments about how to work with these notes may be helpful.

The subject-matter of Chapters 2 through 5 is largely cumulative, with the main theorem of Chapter 5 being proved with main results of Chapters 2, 3, and 4. Each chapter is largely cumulative internally as well. To acquire detailed command of so much material and also a large-scale view of how it fits together, the trick is to focus on each section's techniques while studying that section and working its exercises, but thereafter to use the section's ideas freely by reference. Specifically, after the scrutiny of vector algebra in the previous section, one's vector manipulations should be fluent from now on, freeing one to concentrate on vector geometry in the next section, after which the geometry should also be light while one is concentrating on the analytical ideas of the following section, and so forth.

Admittedly, the model that one has internalized all the prior material before moving on is idealized. For that matter, so is the model that a body of interplaying ideas is linearly cumulative. In practice, focusing entirely on the details of whichever topics are currently active while using previous ideas by reference isn't always optimal. One might engage with the details of previous ideas because one is coming to understand them better, or because the current ideas showcase the older ones in a new way. Still, the paradigm of technical emphasis on the current ideas and fluent use of the earlier material does help a person who is navigating a large body of mathematics to conserve energy and synthesize a larger picture.

2.2 Geometry: Length and Angle

The geometric notions of length and angle in $\mathbb{R}^n$ are readily described in terms of the algebraic notion of inner product.

Definition 2.2.1 (Inner product). *The* **inner product** *is a function from pairs of vectors to scalars,*

$$\langle\ ,\ \rangle : \mathbb{R}^n \times \mathbb{R}^n \longrightarrow \mathbb{R},$$

defined by the formula

$$\langle (x_1, \dots, x_n), (y_1, \dots, y_n) \rangle = \sum_{i=1}^{n} x_i y_i.$$

For example,

$$\begin{aligned} &\langle (1,1,\dots,1), (1,2,\dots,n) \rangle = \frac{n(n+1)}{2}, \\ &\langle x, e_j \rangle = x_j \quad \text{where } x = (x_1, \dots, x_n) \text{ and } j \in \{1, \dots, n\}, \\ &\langle e_i, e_j \rangle = \delta_{ij} \text{ (this means 1 if } i = j \text{, 0 otherwise).} \end{aligned}$$

Proposition 2.2.2 (Inner product properties).

(IP1) *The inner product is positive definite:* $\langle x, x\rangle \geq 0$ *for all* $x \in \mathbb{R}^n$*, with equality if and only if* $x = \mathbf{0}$.
(IP2) *The inner product is symmetric:* $\langle x, y\rangle = \langle y, x\rangle$ *for all* $x, y \in \mathbb{R}^n$.
(IP3) *The inner product is bilinear:*

$$\begin{aligned}\langle x + x', y\rangle &= \langle x, y\rangle + \langle x', y\rangle, \quad \langle ax, y\rangle = a\langle x, y\rangle,\\ \langle x, y + y'\rangle &= \langle x, y\rangle + \langle x, y'\rangle, \quad \langle x, by\rangle = b\langle x, y\rangle\end{aligned}$$

for all $a, b \in \mathbb{R}$*,* $x, x', y, y' \in \mathbb{R}^n$.

Proof. Exercise 2.2.4. □

The reader should be aware that:

> *In general,* $\langle x + x', y + y'\rangle$ *does not equal* $\langle x, y\rangle + \langle x', y'\rangle$.

Indeed, expanding $\langle x + x', y + y'\rangle$ carefully with the inner product properties shows that the cross-terms $\langle x, y'\rangle$ and $\langle x', y\rangle$ are present in addition to $\langle x, y\rangle$ and $\langle x', y'\rangle$.

Like the vector space axioms, the inner product properties are phrased intrinsically, although they need to be proved using coordinates. As mentioned in the previous section, intrinsic methods are neater and more conceptual than using coordinates. More importantly:

> *The rest of the results of this section are proved by reference to the inner product properties, with no further reference to the inner product formula.*

The notion of an inner product generalizes beyond Euclidean space—this will be demonstrated in Exercise 2.3.4, for example—and thanks to the displayed sentence, once the properties (IP1) through (IP3) are established for any inner product, all of the pending results in the section will follow automatically with no further work. (But here a slight disclaimer is necessary. In the displayed sentence, the word *results* does not refer to the pending graphic figures. The fact that the length and angle to be defined in this section will agree with prior notions of length and angle in the plane, or in three-dimensional space, does depend on the specific inner product formula. In Euclidean space, the inner product properties do not determine the inner product formula uniquely. This point will be addressed in Exercise 3.5.1.)

Definition 2.2.3 (Modulus). *The* **modulus** (*or* **absolute value**) *of a vector* $x \in \mathbb{R}^n$ *is defined as*

$$|x| = \sqrt{\langle x, x\rangle}.$$

Thus the modulus is defined in terms of the inner product, rather than by its own formula. The inner product formula shows that the modulus formula is

$$|(x_1, \dots, x_n)| = \sqrt{x_1^2 + \cdots + x_n^2},$$

so that some particular examples are

$$|(1,2,\dots,n)| = \sqrt{\frac{n(n+1)(2n+1)}{6}},$$
$$|e_i| = 1.$$

However, the definition of the modulus in terms of inner product combines with the inner product properties to show, with no reference to the inner product formula or the modulus formula, that the modulus satisfies the following properties (Exercise 2.2.5).

Proposition 2.2.4 (Modulus properties).

(Mod1) *The modulus is positive:* $|x| \geq 0$ *for all* $x \in \mathbb{R}^n$*, with equality if and only if* $x = \mathbf{0}$.

(Mod2) *The modulus is absolute-homogeneous:* $|ax| = |a||x|$ *for all* $a \in \mathbb{R}$ *and* $x \in \mathbb{R}^n$.

Like other symbols, the absolute value signs are now overloaded, but their meaning can be inferred from context, as in property (Mod2). When n is 1, 2, or 3, the modulus $|x|$ gives the distance from $\mathbf{0}$ to the point x, or the length of x viewed as an arrow. (See Figure 2.6.)

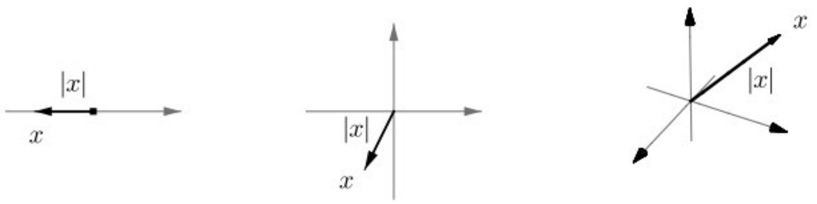

Figure 2.6. Modulus as length

The following relation between inner product and modulus will help to show that distance in $\mathbb{R}^n$ behaves as it should, and that angle in $\mathbb{R}^n$ makes sense. Since the relation is not obvious, its proof is a little subtle.

Theorem 2.2.5 (Cauchy–Schwarz inequality). *For all* $x, y \in \mathbb{R}^n$,

$$|\langle x, y\rangle| \leq |x|\,|y|,$$

with equality if and only if one of x, y *is a scalar multiple of the other.*

Note that the absolute value signs mean different things on each side of the Cauchy–Schwarz inequality. On the left side, the quantities x and y are vectors, their inner product $\langle x, y\rangle$ is a scalar, and $|\langle x, y\rangle|$ is its scalar absolute value, while on the right side, $|x|$ and $|y|$ are the scalar absolute values of vectors, and $|x|\,|y|$ is their product. That is, the Cauchy–Schwarz inequality says:

The size of the product is at most the product of the sizes.

The Cauchy–Schwarz inequality can be written out in coordinates if we temporarily abandon the principle that we should avoid reference to formulas,

$$(x_1y_1 + \cdots + x_ny_n)^2 \le (x_1^2 + \cdots + x_n^2)(y_1^2 + \cdots + y_n^2).$$

And this inequality can be proved unconceptually as follows (the reader is encouraged only to skim the following computation). Rewrite the desired inequality as

$$\Big(\sum_i x_iy_i\Big)^2 \le \sum_i x_i^2 \cdot \sum_j y_j^2,$$

where the indices of summation run from 1 to n. Expand the square to get

$$\sum_i x_i^2y_i^2 + \sum_{\substack{i,j\\ i\ne j}} x_iy_ix_jy_j \le \sum_{i,j} x_i^2y_j^2,$$

and canceling the terms common to both sides reduces it to

$$\sum_{i\ne j} x_iy_ix_jy_j \le \sum_{i\ne j} x_i^2y_j^2,$$

or

$$\sum_{i\ne j}(x_i^2y_j^2 - x_iy_ix_jy_j) \ge 0.$$

Rather than sum over all pairs (i,j) with $i \ne j$, sum over the pairs with $i < j$, collecting the (i,j)-term and the (j,i)-term for each such pair, and the previous inequality becomes

$$\sum_{i<j}(x_i^2y_j^2 + x_j^2y_i^2 - 2x_iy_jx_jy_i) \ge 0.$$

Thus the desired inequality has reduced to a true inequality,

$$\sum_{i<j}(x_iy_j - x_jy_i)^2 \ge 0.$$

So the main proof is done, although there is still the question of when equality holds.

But surely the previous paragraph is not the graceful way to argue. The computation draws on the minutiae of the formulas for the inner product and the modulus, rather than using their properties. It is uninformative, making the Cauchy–Schwarz inequality look like a low-level accident. It suggests that larger-scale mathematics is just a matter of bigger and bigger formulas. To prove the inequality in a way that is enlightening and general, we should work intrinsically, keeping the scalars $\langle x, y\rangle$ and $|x|$ and $|y|$ notated in their concise forms, and we should use properties, not formulas. The idea is that the calculation in coordinates reduces to the fact that squares are nonnegative. That is, the Cauchy–Schwarz inequality is somehow *quadratically hard*, and its verification amounted to completing many squares. The argument to be given here is guided by this insight to prove the inequality by citing facts about quadratic polynomials, facts established by completing one square back in high-school algebra at the moment that doing so was called for. Thus we eliminate redundancy and clutter. So the argument to follow will involve an auxiliary object, a judiciously chosen quadratic polynomial, but in return it will become coherent.

Proof. The result is clear when $x = \mathbf{0}$, so assume $x \neq \mathbf{0}$. For every $a \in \mathbb{R}$,

$$\begin{aligned} 0 &\le \langle ax - y, ax - y\rangle && \text{by positive definiteness} \\ &= a\langle x, ax - y\rangle - \langle y, ax - y\rangle && \text{by linearity in the first variable} \\ &= a^2\langle x, x\rangle - a\langle x, y\rangle - a\langle y, x\rangle + \langle y, y\rangle && \text{by linearity in the second variable} \\ &= a^2|x|^2 - 2a\langle x, y\rangle + |y|^2 && \text{by symmetry, definition of modulus.} \end{aligned}$$

View the right side as a quadratic polynomial in the scalar variable a, where the scalar coefficients of the polynomial depend on the generic but fixed vectors x and y,

$$f(a) = |x|^2a^2 - 2\langle x, y\rangle a + |y|^2.$$

We have shown that $f(a)$ is always nonnegative, so f has at most one root. Thus by the quadratic formula its discriminant is nonpositive,

$$4\langle x, y\rangle^2 - 4|x|^2|y|^2 \le 0,$$

and the Cauchy–Schwarz inequality $|\langle x, y\rangle| \le |x|\,|y|$ follows. Equality holds exactly when the quadratic polynomial $f(a) = |ax - y|^2$ has a root a, i.e., exactly when $y = ax$ for some $a \in \mathbb{R}$. □

Geometrically, the condition for equality in Cauchy–Schwarz is that the vectors x and y, viewed as arrows at the origin, are parallel, though perhaps pointing in opposite directions. A geometrically conceived proof of Cauchy–Schwarz is given in Exercise 2.2.15 to complement the algebraic argument that has been given here.

The Cauchy–Schwarz inequality shows that the modulus function satisfies the *triangle inequality*.

Theorem 2.2.6 (Triangle inequality). *For all* $x, y \in \mathbb{R}^n$,

$$|x + y| \le |x| + |y|,$$

with equality if and only if one of x, y is a nonnegative scalar multiple of the other.

Proof. To show this, compute

$$\begin{aligned} |x+y|^2 &= \langle x+y, x+y\rangle \\ &= |x|^2 + 2\langle x,y\rangle + |y|^2 && \text{by bilinearity} \\ &\le |x|^2 + 2|x||y| + |y|^2 && \text{by Cauchy–Schwarz} \\ &= (|x|+|y|)^2, \end{aligned}$$

proving the inequality. Equality holds exactly when $\langle x,y\rangle = |x||y|$, or equivalently when $|\langle x,y\rangle| = |x||y|$ and $\langle x,y\rangle \ge 0$. These hold when one of x, y is a scalar multiple of the other and the scalar is nonnegative. □

While the Cauchy–Schwarz inequality says that the size of the product is at most the product of the sizes, the triangle inequality says:

The size of the sum is at most the sum of the sizes.

The triangle inequality's name is explained by its geometric interpretation in $\mathbb{R}^2$. View x as an arrow at the origin, y as an arrow with tail at the head of x, and $x+y$ as an arrow at the origin. These three arrows form a triangle, and the assertion is that the lengths of two sides sum to at least the length of the third. (See Figure 2.7.)

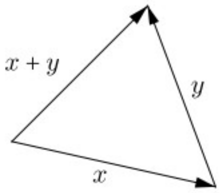

Figure 2.7. Sides of a triangle

The **full triangle inequality** says that for all $x, y \in \mathbb{R}^n$,

$$\big|\,|x| - |y|\,\big| \le |x \pm y| \le |x| + |y|.$$

The proof is Exercise 2.2.7.

A small argument, which can be formalized as induction if one is painstaking, shows that the basic triangle inequality extends from two vectors to any finite number of vectors. For example,

$$|x+y+z| \le |x+y| + |z| \le |x| + |y| + |z|.$$

The only obstacle to generalizing the basic triangle inequality in this fashion is notation. The argument can't use the symbol n to denote the number of vectors, because n already denotes the dimension of the Euclidean space where we are working; and furthermore, the vectors can't be denoted with subscripts since a subscript denotes a component of an individual vector. Thus, for now we are stuck writing something like

$$|x^{(1)} + \cdots + x^{(k)}| \le |x^{(1)}| + \cdots + |x^{(k)}| \quad \text{for all } x^{(1)}, \dots, x^{(k)} \in \mathbb{R}^n,$$

or

$$\left|\sum_{i=1}^{k} x^{(i)}\right| \le \sum_{i=1}^{k} |x^{(i)}|, \quad x^{(1)}, \dots, x^{(k)} \in \mathbb{R}^n.$$

As our work with vectors becomes more intrinsic, vector entries will demand less of our attention, and we will be able to denote vectors by subscripts. The notation-change will be implemented in the next section.

For every vector $x = (x_1, \dots, x_n) \in \mathbb{R}^n$, useful bounds on the modulus $|x|$ in terms of the scalar absolute values $|x_i|$ are as follows.

Proposition 2.2.7 (Size bounds). *For every* $j \in \{1, \dots, n\}$,

$$|x_j| \le |x| \le \sum_{i=1}^{n} |x_i|.$$

The proof (by quick applications of the Cauchy–Schwarz inequality and the triangle inequality) is Exercise 2.2.8.

The modulus gives rise to a distance function on $\mathbb{R}^n$ that behaves as distance should. Define

$$d : \mathbb{R}^n \times \mathbb{R}^n \longrightarrow \mathbb{R}$$

by

$$d(x,y) = |y - x|.$$

For example, $d(e_i, e_j) = \sqrt{2}(1 - \delta_{ij})$.

Theorem 2.2.8 (Distance properties).

(D1) *Distance is positive:* $d(x,y) \ge 0$ *for all* $x, y \in \mathbb{R}^n$, *and* $d(x,y) = 0$ *if and only if* $x = y$.
(D2) *Distance is symmetric:* $d(x,y) = d(y,x)$ *for all* $x, y \in \mathbb{R}^n$.
(D3) *Triangle inequality:* $d(x,z) \le d(x,y) + d(y,z)$ *for all* $x, y, z \in \mathbb{R}^n$.

(D1) and (D2) are clearly desirable as properties of a distance function. Property (D3) says that you can't shorten your trip from x to z by making a stop at y.

Proof. Exercise 2.2.9. □

The Cauchy–Schwarz inequality also lets us define the angle between two nonzero vectors in terms of the inner product. If x and y are nonzero vectors in $\mathbb{R}^n$, define their angle $\theta_{x,y}$ by the condition

$$\cos\theta_{x,y} = \frac{\langle x, y\rangle}{|x||y|}, \quad 0 \le \theta_{x,y} \le \pi. \tag{2.2}$$

The condition is sensible because $-1 \le \frac{\langle x,y\rangle}{|x||y|} \le 1$ by the Cauchy–Schwarz inequality. For example, $\cos\theta_{(1,0),(1,1)} = 1/\sqrt{2}$, and so $\theta_{(1,0),(1,1)} = \pi/4$. In particular, two nonzero vectors x and y are **orthogonal** when $\langle x, y\rangle = 0$. Naturally, we would like $\theta_{x,y}$ to correspond to the usual notion of angle, at least in $\mathbb{R}^2$, and indeed it does—see Exercise 2.2.10. For convenience, define *any* two vectors x and y to be orthogonal if $\langle x, y\rangle = 0$, thus making $\mathbf{0}$ orthogonal to all vectors.

Rephrasing geometry in terms of intrinsic vector algebra not only extends the geometric notions of length and angle uniformly to any dimension, it also makes some low-dimensional geometry easier. For example, vectors show in a natural way that the three altitudes of every triangle must meet. Let x and y denote two sides of the triangle, making the third side $x-y$ by the *head minus tail* mnemonic. Let q be the point where the altitudes to x and y meet. (See Figure 2.8, which also shows the third altitude.) Thus

$$q - y \perp x \quad \text{and} \quad q - x \perp y.$$

We want to show that q also lies on the third altitude, i.e., that

$$q \perp x - y.$$

To rephrase matters in terms of inner products, we want to show that

$$\begin{Bmatrix} \langle q - y, x\rangle = 0 \\ \langle q - x, y\rangle = 0 \end{Bmatrix} \implies \langle q, x - y\rangle = 0.$$

Since the inner product is linear in each of its arguments, a further rephrasing is that we want to show that

$$\begin{Bmatrix} \langle q, x\rangle = \langle y, x\rangle \\ \langle q, y\rangle = \langle x, y\rangle \end{Bmatrix} \implies \langle q, x\rangle = \langle q, y\rangle.$$

And this is immediate because the inner product is symmetric: $\langle q, x\rangle$ and $\langle q, y\rangle$ both equal $\langle x, y\rangle$, and so they equal each other as desired. The point q where the three altitudes meet is called the **orthocenter** of the triangle. In general, the orthocenter of a triangle is not the geometric center that we considered in the previous section.

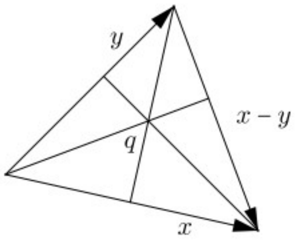

Figure 2.8. Three altitudes of a triangle

Exercises

2.2.1. Let $x = (\frac{\sqrt{3}}{2}, -\frac{1}{2}, 0)$, $y = (\frac{1}{2}, \frac{\sqrt{3}}{2}, 1)$, $z = (1,1,1)$. Compute $\langle x, x\rangle$, $\langle x, y\rangle$, $\langle y, z\rangle$, $|x|$, $|y|$, $|z|$, $\theta_{x,y}$, θ_{y,e_1}, θ_{z,e_2}.

2.2.2. Show that the points $x = (2,-1,3,1)$, $y = (4,2,1,4)$, $z = (1,3,6,1)$ form the vertices of a triangle in $\mathbb{R}^4$ with two equal angles.

2.2.3. Explain why for all $x \in \mathbb{R}^n$, $x = \sum_{j=1}^n \langle x, e_j\rangle e_j$.

2.2.4. Prove the inner product properties.

2.2.5. Use the inner product properties and the definition of the modulus in terms of the inner product to prove the modulus properties.

2.2.6. In the text, the modulus is defined in terms of the inner product. Prove that this can be turned around by showing that for every $x, y \in \mathbb{R}^n$,

$$\langle x, y\rangle = \frac{|x+y|^2 - |x-y|^2}{4}.$$

2.2.7. Prove the full triangle inequality: for every $x, y \in \mathbb{R}^n$,

$$\big|\,|x| - |y|\,\big| \le |x \pm y| \le |x| + |y|.$$

Do not do this by writing three more variants of the proof of the triangle inequality, but by substituting suitably into the basic triangle inequality, which is already proved.

2.2.8. Let $x = (x_1, \dots, x_n) \in \mathbb{R}^n$. Prove the size bounds: for every $j \in \{1, \dots, n\}$,

$$|x_j| \le |x| \le \sum_{i=1}^n |x_i|.$$

(One approach is to start by noting that $x_j = \langle x, e_j\rangle$ and recalling equation (2.1).) When can each "$\le$" be an "$=$"?

2.2.9. Prove the distance properties.

2.2.10. Working in $\mathbb{R}^2$, depict the nonzero vectors x and y as arrows from the origin and depict $x - y$ as an arrow from the endpoint of y to the endpoint of x. Let θ denote the angle (in the usual geometric sense) between x and y. Use the law of cosines to show that

$$\cos\theta = \frac{\langle x, y\rangle}{|x||y|},$$

so that our notion of angle agrees with the geometric one, at least in $\mathbb{R}^2$.

2.2.11. Prove that for every nonzero $x \in \mathbb{R}^n$, $\sum_{i=1}^{n} \cos^2\theta_{x,e_i} = 1$.

2.2.12. Prove that two nonzero vectors x, y are orthogonal if and only if $|x + y|^2 = |x|^2 + |y|^2$.

2.2.13. Use vectors in $\mathbb{R}^2$ to show that the diagonals of a parallelogram are perpendicular if and only if the parallelogram is a rhombus.

2.2.14. Use vectors to show that every angle inscribed in a semicircle is right.

2.2.15. Let x and y be vectors, with x nonzero. Define the **parallel** component of y along x and the **normal** component of y to x to be

$$y_{(\|x)} = \frac{\langle x, y\rangle}{|x|^2}x \qquad \text{and} \qquad y_{(\perp x)} = y - y_{(\|x)}.$$

(a) Show that $y = y_{(\|x)} + y_{(\perp x)}$; show that $y_{(\|x)}$ is a scalar multiple of x; show that $y_{(\perp x)}$ is orthogonal to x. Show that the decomposition of y as a sum of vectors parallel and perpendicular to x is unique. Draw an illustration.

(b) Show that

$$|y|^2 = |y_{(\|x)}|^2 + |y_{(\perp x)}|^2.$$

What theorem from classical geometry does this encompass?

(c) Explain why it follows from (b) that

$$|y_{(\|x)}| \le |y|,$$

with equality if and only if y is a scalar multiple of x. Use this inequality to give another proof of the Cauchy–Schwarz inequality. This argument gives the geometric content of Cauchy–Schwarz: *the parallel component of one vector along another is at most as long as the original vector.*

(d) The proof of the Cauchy–Schwarz inequality in part (c) refers to parts (a) and (b), part (a) refers to orthogonality, orthogonality refers to an angle, and as explained in the text, the fact that angles make sense depends on the Cauchy–Schwarz inequality. And so the proof in part (c) apparently relies on circular logic. Explain why the logic is in fact not circular.

2.2.16. Given nonzero vectors $x_1, x_2, \dots, x_n$ in $\mathbb{R}^n$, the **Gram–Schmidt process** is to set

$$\begin{aligned}
x'_1 &= x_1\\
x'_2 &= x_2 - (x_2)_{(\parallel x'_1)}\\
x'_3 &= x_3 - (x_3)_{(\parallel x'_2)} - (x_3)_{(\parallel x'_1)}\\
&\vdots\\
x'_n &= x_n - (x_n)_{(\parallel x'_{n-1})} - \cdots - (x_n)_{(\parallel x'_1)}.
\end{aligned}$$

(a) What is the result of applying the Gram–Schmidt process to the vectors $x_1 = (1,0,0)$, $x_2 = (1,1,0)$, and $x_3 = (1,1,1)$?

(b) Returning to the general case, show that $x'_1, \dots, x'_n$ are pairwise orthogonal and that each x'_j has the form

$$x'_j = a_{j1}x_1 + a_{j2}x_2 + \cdots + a_{j,j-1}x_{j-1} + x_j.$$

Thus every linear combination of the new $\{x'_j\}$ is also a linear combination of the original $\{x_j\}$. The converse is also true and will be shown in Exercise 3.3.13.

2.3 Analysis: Continuous Mappings

A **mapping** from $\mathbb{R}^n$ to $\mathbb{R}^m$ is some rule that assigns to each point x in $\mathbb{R}^n$ a point in $\mathbb{R}^m$. Generally, mappings will be denoted by letters such as f, g, h. When $m = 1$, we usually say *function* instead of mapping.

For example, the mapping

$$f : \mathbb{R}^2 \longrightarrow \mathbb{R}^2$$

defined by

$$f(x,y) = (x^2 - y^2, 2xy)$$

takes the real and imaginary parts of a complex number $z = x + iy$ and returns the real and imaginary parts of z^2. By the nature of multiplication of complex numbers, this means that each output point has modulus equal to the square of the modulus of the input point and has angle equal to twice the angle of the input point. Make sure that you see how this is shown in Figure 2.9.

Mappings expressed by formulas may be undefined at certain points (e.g., $f(x) = 1/|x|$ is undefined at $\mathbf{0}$), so we need to restrict their domains. For a given dimension n, a given set $A \subset \mathbb{R}^n$, and a second dimension m, let $\mathcal{M}(A, \mathbb{R}^m)$ denote the set of all mappings $f : A \longrightarrow \mathbb{R}^m$. This set forms a vector space over $\mathbb{R}$ (whose *points* are functions) under the operations

$$+ : \mathcal{M}(A, \mathbb{R}^m) \times \mathcal{M}(A, \mathbb{R}^m) \longrightarrow \mathcal{M}(A, \mathbb{R}^m),$$

$$h = 6.55 \times 10^{-27} \text{ erg-sec.}\dagger$$

The precise agreement between these two calculations—which have nothing in common but the quantum postulates—is very impressive. Surely this is the strongest kind of evidence for the validity of the quantum theory in general, and for the Einstein photon concept in particular. But in 1915 it was not enough to establish any kind of general belief in photons. Even Millikan was skeptical. He admitted the empirical strength of the Einstein photoelectric equation—but no more: "I spent ten years of my life testing that 1905 equation of Einstein's, and, contrary to all my expectations, I was compelled in 1915 to assert its unambiguous experimental verification in spite of its unreasonableness. . . ." When Millikan described his results in 1916 he felt that the photon concept was hardly worthy of comment: "I shall not attempt to present the basis for such an assumption, for, as a matter of fact, it had almost none at the time." Nevertheless, he had to marvel at "the astonishing situation that these facts [the photoelectric equation] were correctly and exactly predicted nine years ago by a form of quantum theory which has now been pretty generally abandoned."

The Compton Effect

The story of the further trials of Einstein's quantum theory, and the accumulation of the mountain of evidence which finally brought photons into the world of physics, must be cut short for lack of space. We shall proceed to what was effectively the final episode in the story, the work of Arthur H. Compton on the scattering of X rays, first reported in 1923.

Compton's investigation concerned the "secondary radiation" produced by irradiating thin layers of such light elements as carbon with a "primary" beam formed in a conventional X-ray tube. Compton measured the wavelengths of the secondary, or scattered, radiation (using a Bragg crystal spectrometer) at various wavelengths of the primary radiation and at various angles with respect

---

† This calculation involves using the Planck distribution law (8) to derive an equation for the frequency ν_m or wavelength λ_m of maximum energy density and a theoretical version of the Stefan-Boltzmann equation (1). When measured values for ν_m and the Stefan constant σ are introduced into these two equations, two unknown quantities remain, h and the Boltzmann constant k. Planck's result for h is quoted; Planck obtained

$$k = 1.346 \times 10^{-16} \text{ erg deg}^{-1}.$$

to the direction of the primary beam. He found a difference in wavelength between the primary and secondary radiation. The difference was not large, but there was, unquestionably, a difference. The scattered wavelengths were always larger than those of the primary beam, and the magnitude of this wavelength was dependent only on the angle at which the secondary radiation was observed, and not at all on the scattering material or on the wavelength of the primary beam.

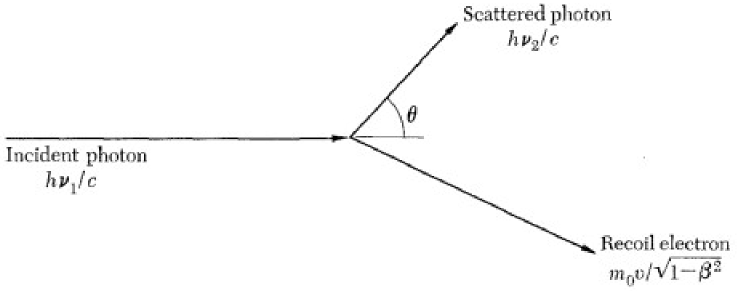
For some years before Compton's experiments it had been surmised that the scattering of X rays was due to interactions between the incident X rays and the electrons of the scattering material. A classical theory, based on the assumption that radiation was strictly wavelike, was available. However, when this theory was applied in a simple form to the X-ray–electron scattering interaction, it predicted that the primary and scattered radiation should have exactly the same wavelength, in direct disagreement with Compton's observations. After a futile attempt to elaborate the classical theory to fit the scattering data, Compton arrived at a highly successful quantum interpretation.

The central idea, as in Einstein's explanation of the photoelectric effect, is that the radiation beam (X rays, in this case) contains photons, each one of which carries an amount of energy $h\nu$. These are the same attractively simple radiation particles that Einstein had proposed, to no avail, almost twenty years earlier. If anything, the Compton concept of the photon is even simpler than that of Einstein. The photon-electron scattering interaction is, from the mechanical viewpoint, nothing more than a collision between two minute billiard balls. An electron belonging to an atom such as carbon is struck by an X-ray photon from the primary beam. Before the collision the electron is imagined to be stationary and free (actually it is bound by an atom, but the binding energy is negligible compared to the large energy which the photon brings to the collision), and the collision sets it in motion, billiard-ball fashion. To be sure, the electron, after the collision, is an exceedingly rapidly moving billiard ball. Its speed is so great that it must be described, from the relativistic viewpoint, as having a momentum of

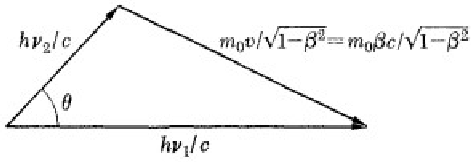
$$m_0 v/\sqrt{1-\beta^2} \qquad \text{or} \qquad m_0 \beta c/\sqrt{1-\beta^2},$$

where m_0 is the electron's rest mass and β is v/c, the ratio between the electron's velocity v and the velocity of light c. The corresponding kinetic energy is $m_0 c^2(1/\sqrt{1-\beta^2} - 1)$. To represent the photon energy before and after the scattering collision, write $h\nu_1$ and $h\nu_2$, respectively; the corresponding momenta are $h\nu_1/c$ and $h\nu_2/c$.[†]

In Compton's words, the scattering event is "an X-ray particle colliding with an electron and bounding elastically from it with reduced energy, the lost energy appearing as the recoil energy of the electron." The momentum changes are shown with a vector diagram as follows:



Conservation of momentum requires that the incident photon vector be equal to the vectors representing the scattered photon and the recoil electron:



and this (with the law of cosines) leads to the equation

$$(m_0\beta c/\sqrt{1-\beta^2})^2 = (h\nu_1/c)^2 + (h\nu_2/c)^2 - 2(h\nu_1/c)(h\nu_2/c)\cos\theta.$$

Conservation of energy can also be stated, to the effect that the incident photon energy is equivalent to the total of the energy of

---

[†] That $h\nu/c$ is a measure of photon momentum can be seen by equating two Einstein equations for total energy, $E = h\nu$ and $E = mc^2$: $h\nu = mc^2$. The quantity on the left is the photon energy specified by Einstein's quantum theory and the quantity on the right is the total energy of any particle whose mass is m, as prescribed by Einstein's special theory of relativity. Since c is the velocity of the photon, mc is its momentum, and this, according to the above energy equation, is equivalent to $h\nu/c$. The situation is especially simple for the photon because it has no rest mass. For a particle with rest mass m_0 the momentum p is

$$\begin{aligned} p &= \sqrt{(mc^2)^2 - (m_0c^2)^2}/c \\ &= (\sqrt{m^2 - m_0{}^2})c. \end{aligned}$$

the scattered photon and the kinetic energy of the recoil electron:

$$h\nu_1 = h\nu_2 + m_0c^2(1/\sqrt{1-\beta^2} - 1).$$

This can be rearranged as:

$$m_0c^2/\sqrt{1-\beta^2} = h\nu_1 - h\nu_2 + m_0c^2$$
$$m_0c/\sqrt{1-\beta^2} = h\nu_1/c - h\nu_2/c + m_0c$$
$$(m_0c/\sqrt{1-\beta^2})^2 = (\quad)^2,$$

where ( ) has been written for the quantity $h\nu_1/c - h\nu_2/c + m_0c$. The last equation can be solved for β^2:

$$\beta^2 = 1 - m_0{}^2c^2/(\quad)^2,$$

so that

$$\begin{aligned}\beta^2(m_0c/\sqrt{1-\beta^2})^2 &= (\quad)^2 - m_0{}^2c^2\\ &= (h\nu_1/c - h\nu_2/c + m_0c)^2 - m_0{}^2c^2\\ &= (h\nu_1/c)^2 + (h\nu_2/c)^2 + 2m_0c(h\nu_1/c)\\ &\quad - 2m_0c(h\nu_2/c) - 2(h\nu_1/c)(h\nu_2/c).\end{aligned}$$

When this is subtracted from the momentum-balance equation, and the result is whittled down, a simple equation in the two frequencies (before and after the collision) is derived:

$$\nu_1/\nu_2 = 1 + 2(h\nu_1/m_0c^2)\sin^2(\theta/2).$$

Conversion to an equation in wavelength leads to †

$$\lambda_2/\lambda_1 = 1 + 2(h/m_0c\lambda_1)\sin^2(\theta/2), \quad \text{or} \quad \lambda_2 = \lambda_1 + (2h/m_0c)\sin^2(\theta/2).$$

The increase in wavelength $\lambda_2 - \lambda_1$ caused by the scattering of the primary X-ray beam at an angle of θ is therefore

$$(2h/m_0c)\sin^2(\theta/2) \qquad \text{or} \qquad 0.0484\sin^2(\theta/2)$$

when the wavelength is expressed in Angstroms (Å). For scattering at $\theta = 90°$ the theory calculates a wavelength increase of

$$(0.0484)/2 = 0.0242\ \text{Å},$$

regardless of the scattering material and the wavelength of the incident beam. Using X rays of wavelength 0.708 Å, Compton found an increase of 0.022 Å for the radiation scattered at 90°. When γ rays of wavelength 0.022 Å were used the scattered wavelength at 90° was 0.043 Å, an increase of 0.021 Å. In spite of the large difference between the primary X-ray wavelength and the γ-ray wavelength, the scattered wavelengths are nearly the same amount longer in the two cases, and this wavelength increase agrees reasonably well with the theoretical calculation. Compton used his basic premise to derive several other equations which could be checked experimentally. In all aspects the theory was successful.

---

† Wavelength and frequency for any electromagnetic disturbance are related by $\lambda\nu = c$, where λ is the wavelength. Thus, $\lambda_1/c = 1/\nu_1$, $\lambda_2/c = 1/\nu_2$, and $\nu_1/\nu_2 = \lambda_2/\lambda_1$.

With the publication of Compton's work, resistance to the photon concept was at last struck a mortal blow. But death came slowly and painfully. Compton wrote that his "results . . . immediately became a subject of the most lively scientific controversy that I had ever known." The chief opponent was William Duane of Harvard University, who had been willing to accept photons in other X-ray phenomena, but curiously opposed any thought of photons in the scattering process. For some reason Duane was unable to repeat Compton's scattering experiments in his own laboratory. There was a formal confrontation at a meeting of the American Physical Society, in which Compton and Duane defended their results and interpretations. Compton diplomatically decided not to press his criticism: "I might have criticized his interpretation of his results on rather obvious grounds, but thought it would be wiser to let Duane himself find the answer." † Later, Compton visited Harvard and Duane's laboratory. This visit seems to have been the occasion for some intense discussions; late one afternoon Compton was seen "disheveled, unshaven and obviously overtired." Duane's difficulty was not found then, but a new series of experiments was started which eventually turned up some spurious effects and Duane at last found himself in agreement with Compton. Compton's matter-of-fact assessment of his own work seems a good closing remark for this final scene in the story of the Einstein photon: "It may be fair to say that these experiments were the first to give, at least to physicists in the United States, a conviction of the fundamental validity of the quantum theory."

---

† After another Compton-Duane encounter, at the 1924 meeting of the British Association for the Advancement of Science, the Indian physicist C. V. Raman expressed himself to Compton with the remark: "Compton, you are good debater, but the truth is not in you." This story is told by Compton with the opinion that this same discussion may have inspired Raman to begin the investigation which led to the discovery of the "Raman effect," a scattering phenomenon involving ordinary photons which is in many ways, as it turns out, similar to the Compton X-ray scattering.

Duality

To do them justice, the enemies of the photon were disturbed by much more than the simple idea of particles of radiation. The "corpuscular" theory of radiation had long been known in physics: it was originally proposed by Newton. The difficulty was that nineteenth-century physics had very firmly established another, seemingly incompatible, theory of radiation. Such phenomena as refraction and diffraction had been studied with great care and explained to everyone's satisfaction on the assumption that radiation forms, such as light and X rays, have a wave-like structure. Among other things, there was a need to explain "interference" effects, the mixing of radiation beams to give alternating light and dark bands. The two beams seem to cancel in one part of the pattern and to reinforce in another part. As anyone knows who has watched water waves, this sort of behavior is possible where two trains of waves come together. A wave theory gives a natural and easy explanation of interference. A particle theory, on the other hand, cannot, at least apparently, explain interference patterns unless it is assumed that the particles from the two beams annihilate each other in the dark bands and produce more particles in the light bands. Such a theory is very unattractive to the physicist, who finds it advantageous to insist on the principle of conservation of energy with no complete annihilation processes and no creation of new particles.

So it was with nineteenth-century physics: a single picture, that of waves, sufficed to explain all the observed phenomena associated with radiation. Then came the quantum theory, Einstein's paper, and the unwelcome data on the photoelectric effect and X-ray scattering. Now there were observations which had simple *particle* explanations, and apparently no acceptable *wave* explanation. A strange duality had emerged: depending on how you looked at it, the same beam of light or X rays could seem to be either a shower of particles or a procession of waves. But which was it actually? Waves or particles?

Like most of the other perplexing problems of modern physics, this one was first recognized and partially resolved in the mind of Albert Einstein. His remarks in 1909 prophesied exactly the way physics would turn in about fifteen years:

> It is undeniable that there is an extensive group of data concerning radiation which shows that light has certain fundamental properties that can be understood much more readily from the

> standpoint of the Newton emission [particle] theory than from the standpoint of the wave theory. It is my opinion, therefore, that the next phase of the development of theoretical physics will bring us a theory of light that can be interpreted as a kind of fusion of the wave and emission theories.

In 1909 Einstein presented a theory which did indeed show a fusion of the wave and particle viewpoints. The central argument of this theory dealt with the statistical calculation of energy fluctuations. The elements of the calculation lie outside the scope of this chapter; it can only be said that Einstein's result showed two distinct kinds of fluctuations, one that could be traced to interference between wave trains and another that reflected deviations of a type familiar in collections of particles.†

The paradox of wave-particle duality, elaborated and extended in many different ways, and finally resolved by completely uprooting the great classical principle of determinism, became the dominant theme of the quantum theory in the 1920's. Finally, when applied to *matter*, that is, to electrons (which had previously been regarded strictly as particles, but suddenly in 1925 emerged in a wave manifestation), it brought forth the present form of the quantum theory, what is now known as "quantum mechanics." But that is a story for other chapters.

---

† This analysis made use of the full Planck radiation law, unlike Einstein's argument of the 1905 paper which was based on the Wien formula (3) and therefore restricted to low energy densities.

data 05 05 2020

(Pag.209) Whereas Lorentz had struggled to explain the invariance of the speed of light with a constructive theory that hypothesized motion-dependent molecular forces, Einstein bypassed all the complications by simply promoting the constancy to a postulate.

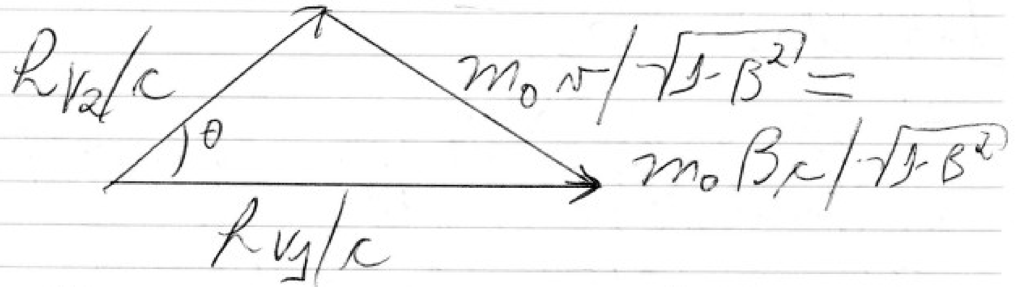
Conservation of momentum



Conservation of momentum requires that the incident photon vector be equal to the vectors representing the scattered photon and the recoil electron:

and this (with the law of cosines)

05 05 2020

leads to the equation:

$$(m_0 \beta c / \sqrt{1-\beta^2})^2 =$$
$$(h\nu_1/c)^2 + (h\nu_2/c)^2 - 2(h\nu_1/c)(h\nu_2/c)\cos\theta$$

Obs:
That $h\nu/c$ is a measure of photon momentum can be seen by the equation two Einstein's equations for total energy,
$E = h\nu$ and $E = mc^2$: $h\nu = mc^2$.

TRIÂNGULOS BELOS

Verificaremos como a propriedade de os três lados de um triângulo plano serem iguais resulta de uma combinação harmoniosa, e única, de lados e ângulos.

Um triângulo diz-se equilátero se os quocientes entre os comprimentos dos seus lados forem iguais a 1. Que triângulos do plano têm estes três quocientes racionais? Dado um triângulo no plano com lados de comprimentos a, b e c tais que existem números naturais p_1, p_2, p_3, q_1, q_2 e q_3 que verificam $a/b = p_1/q_1$, $b/c = p_2/q_2$ e $a/c = p_3/q_3$ podemos reescalonar o triângulo e obter outro semelhante com lados racionais. Para isso, basta usar a homotetia $H_1 : (x, y) \in \mathbb{R}^2 \mapsto (x/c,\ y/c)$, que transforma o triângulo inicial num de lados $a' = (p_1\, p_2)/(q_1\, q_2)$, $b' = p_2/q_2$ e $c' = 1$. Se, de seguida, aplicarmos a homotetia $H_2 : (x, y) \in \mathbb{R}^2 \mapsto (q_1\, q_2\, x,\ q_1\, q_2\, y)$, obtemos um triângulo de lados inteiros.

Se o triângulo é retângulo, com a versão semelhante que acabámos de construir entramos no mundo vasto dos triângulos pitagóricos. A figura 1 ilustra um deles: note-se que, além de os lados terem comprimentos inteiros, os três ângulos têm cossenos racionais, pois são $\pi/2$, $\arccos(3/5)$ e $\arccos(4/5)$.

Mas há muitas outras possibilidades. Veja-se, por exemplo, o triângulo escaleno de lados com comprimentos 5, 6 e 7: neste caso, os ângulos também têm cossenos racionais pois são $\arccos(1/5)$, $\arccos(5/7)$ e $\arccos(19/35)$. Repare-se agora no outro triângulo da figura 2: os quocientes entre as amplitudes dos ângulos são racionais, mas nem todos os quocientes dos lados o são.

Se, todavia, juntarmos as condições

Q_1: *Os quocientes entre os comprimentos dos três lados são racionais.*

Q_2: *Os quocientes entre as amplitudes dos três ângulos são racionais.*

então ficamos reduzidos aos triângulos equiláteros.

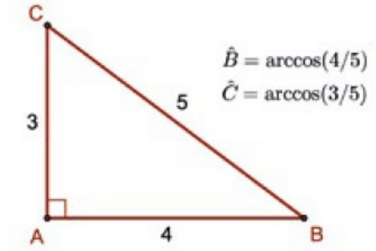

Figura 1

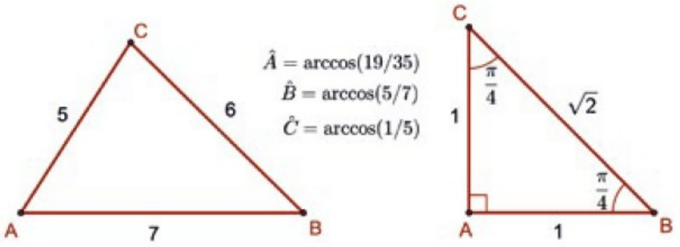

Figura 2

Obviamente, um triângulo equilátero satisfaz as duas hipóteses Q_1 e Q_2, com a particularidade de os seis quocientes em causa serem iguais a 1. Vejamos que também é válida a implicação recíproca, ou seja:

> $\mathcal{P}_1$: *Se, num triângulo, são racionais os quocientes entre os comprimentos dos três lados e entre as amplitudes dos três ângulos, então o triângulo é equilátero.*

Seja $\mathcal{T}$ um tal triângulo de lados a, b, c e ângulos $\angle A$, $\angle B$, $\angle C$. Reescalonando-o, como se explicou anteriormente, podemos supor que a, b, c são racionais (ou mesmo inteiros). Além disso, podemos reescrever $\angle A = \pi\,\alpha_A$, $\angle B = \pi\,\alpha_B$ e $\angle C = \pi\,\alpha_C$ para uma escolha adequada de reais positivos α_A, α_B, α_C. Acrescente-se que, pela hipótese Q_2, existem racionais positivos s_1, s_2 e s_3 tais que $\angle A/\angle B = s_1$, $\angle B/\angle C = s_2$ e $\angle A/\angle C = s_3$. Logo, tem-se $\alpha_A = s_3\,\alpha_C$ e $\alpha_B = s_2\,\alpha_C$, e, como a soma dos ângulos de um triângulo plano é igual a π, deduzimos que $s_3\,\alpha_C + s_2\,\alpha_C + \alpha_C = 1$. Consequentemente, $\alpha_C = 1/(1+s_2+s_3) \in \mathbb{Q}$. Em resumo: Se os quocientes das amplitudes dos ângulos de um triângulo plano são racionais, então os ângulos são múltiplos racionais de π.

Neste momento é oportuno reunirmos o que já sabemos sobre $\mathcal{T}$:

1. É semelhante a um triângulo com lados racionais (consequência de Q_1).
2. Os seus ângulos são múltiplos racionais de π(consequência de Q_2).

Conseguiremos obter mais informação sobre a forma de um tal triângulo se aliarmos as duas propriedades anteriores, o que pode ser feito através do Lei dos Cossenos. Sendo os lados a, b, c racionais, então

$$\cos(\angle A) = \frac{b^2+c^2-a^2}{2bc},\ \cos(\angle B) = \frac{a^2+c^2-b^2}{2ac} \text{ e}$$

$$\cos(\angle C) = \frac{a^2+b^2-c^2}{2ab}$$

são números racionais. Este é um dado muito bem-vindo, porque se conhecem todos os ângulos $\theta \in [0,\pi]$ que são múltiplos racionais de π e têm cosseno racional: θ é 0, π, $\pi/2$, $\pi/3$ ou $2\pi/3$, cujos cossenos são, respetivamente, ± 1, 0 e $\pm 1/2$. Com este resultado (pode ver-se uma prova em [2]), estamos em condições de estabelecer a caracterização que procurávamos para o triângulo $\mathcal{T}$. Realmente, $\mathcal{T}$ tem de ser equilátero porque é semelhante a um triângulo com lados racionais, cujos ângulos estão em $]0,\pi[$ mas nenhum deles é $\pi/2$ (caso contrário, um dos outros dois teria de ser menor ou igual a $\pi/4$ e o seu cosseno não teria um valor permitido) nem $2\pi/3$ (por razão idêntica); logo, os três ângulos são iguais a $\pi/3$.

Cada uma das propriedades $\mathcal{P}_1$ e

> $\mathcal{P}_2$: *Se $\theta \in [0,\pi]$ é um múltiplo racional de π e tem cosseno racional, então $\theta \in \{0, \pi, \pi/2, \pi/3, 2\pi/3\}$.*

pode ser deduzida a partir da outra.

Para o provar, e uma vez que $\cos(\{0,\pi,\pi/2\}) = \{1,-1,0\}$ e que $\cos(\theta) = -\cos(\pi-\theta)$, podemos restringir a análise a ângulos de $]0,\pi/2[$. Seja $\theta \in]0,\pi/2[$ um ângulo cuja amplitude é um múltiplo racional de π e tem cosseno racional. Construa-se o triângulo da figura 3, de lados 1, 1, $2\cos\theta$ e ângulos θ, θ, $\pi - 2\theta$. Observe-se que estes três ângulos são múltiplos racionais de π. Além disso, tendo em conta a hipótese de que $\cos\theta$ é um número racional, os quocientes dos comprimentos dos lados deste triângulo são racionais. Logo, podemos aplicar $\mathcal{P}_1$ e concluir que o triângulo é equilátero. E, portanto, $\theta = \pi/3$.

Note-se que, no que aqui ficou dito, fizemos uso de várias propriedades dos triângulos planos que não são válidas em geometrias não euclidianas, ainda que nelas um triângulo equilátero possa ser também equiângulo. Por exemplo, na esfera de raio $2/\pi$ podemos traçar o triângulo (pitagórico) de lados 1, 1, 2 e ângulos $\pi/2$, $\pi/2$, π (figura 4). E, nela, estão também: o triângulo com estes mesmos lados mas de ângulos $3\pi/2$, $3\pi/2$ e π; um triângulo equilátero cujos três lados se situam no equador e que tem os três ângulos iguais a π; um triângulo pitagórico e equilátero de lado 1 e com os três ângulos iguais a $\pi/2$. (Podem construir-se imagens destes triângulos em [1]). Qual será a versão esférica da caracterização dos triângulos equiláteros planos?

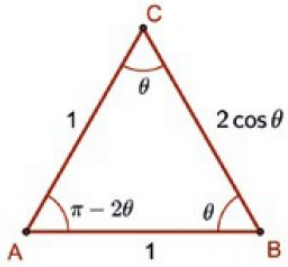

Figura 3

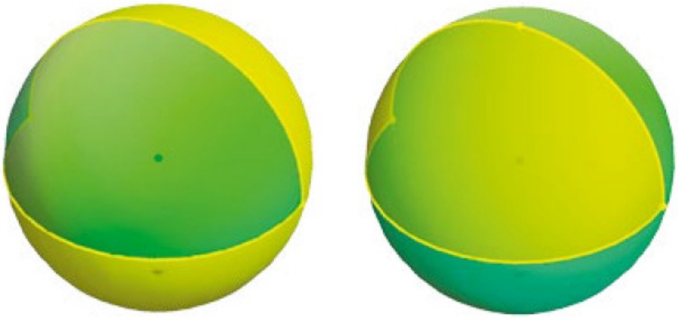

Figura 4

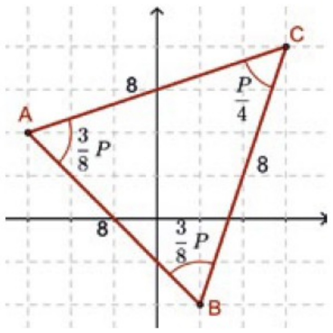

Figura 5

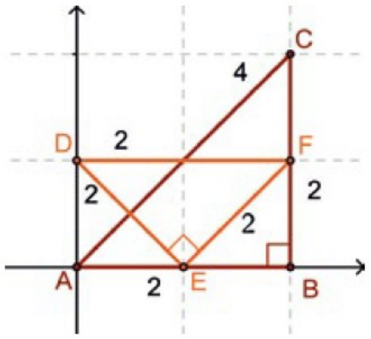

Figura 6

Seria também interessante analisar, na perspetiva anterior, as propriedades dos triângulos equiláteros planos quando optamos por outros modos de medir as distâncias em $\mathbb{R}^2$. Considere-se, por exemplo, a geometria-do-táxi. Neste modo de medir comprimentos, uma circunferência tem a forma de um quadrado da geometria euclideana com os lados fazendo 45º com os eixos coordenados; π é substituído por $P = 4$; e a soma dos ângulos de qualquer triângulo é P. Contudo, um triângulo equilátero pode não ser equiângulo. Observe-se, por exemplo, o triângulo da figura 5 cujos lados medem 8, dois dos ângulos têm amplitude $^3/_8P$ e o terceiro mede $P/4$.

E há outras diferenças. O Teorema de Pitágoras não admite uma extensão a esta métrica, como mostram os triângulos DEF e EBF da figura 6, um de lados 1, 1, 2, ângulo retângulo em B e hipotenusa medindo 2, e outro que é equilátero, retângulo em E e cuja hipotenusa também mede 2. Adicionalmente, falham testes de semelhança que foram fundamentais no argumento anterior. Por exemplo, os triângulos ABC e DEF da figura 6 indicam que um triângulo nesta geometria não está univocamente determinado se forem conhecidos dois lados e o ângulo por eles formado.

Haverá algum critério, análogo ao que vimos no plano com a métrica euclidiana, para testar se um triângulo na geometria-do-táxi é equilátero? Para explorar esta questão, o leitor é convidado a utilizar o módulo interativo em [2], que permite calcular rapidamente distâncias e ângulos nesta métrica. (Uma imagem dessa utilização consta da figura 7.)

O Papiro de Rhind, obra incontornável no estudo da matemática na Antiguidade, dá-nos muitas razões para nos surpreendermos com as capacidades dos egípcios de há milénios. Escrito no século XVII a.C., sendo cópia de trabalho mais antigo, é essencialmente uma colecção de problemas e soluções. Hoje falaremos um pouco do Problema 50, que, em linguagem anacrónica, pode dizer-se tratar da quadratura do círculo.

A interpretação de texto tão antigo não pode ser sempre consensual. A lacónica escrita do escriba Ahmes não facilita a vida aos estudiosos. No caso do nosso problema 50, a questão parece ser a de obter um valor para a área de um círculo de diâmetro d.

O procedimento descrito consiste em aproximar o círculo por um octógono, cuja área seja fácil de determinar.

Comecemos por considerar um quadrado circunscrito à figura.

Vamos dividir cada lado em nove partes, cada uma de comprimento $d/9$. Conservando o terço central de cada lado e unindo as extremidades, obtemos um octógono, que, como o quadriculado da figura sugere, aproxima *bem* o círculo.

O quadriculado da ilustração permite determinar com facilidade a área do polígono. Se tomarmos para unidade o quadradinho de lado $d/9$, esta área será

$$81 - 4 \times \frac{3 \times 3}{2} = 63\,.$$

Ora, 63 é um número que ... é quase 64 e este é um quadrado perfeito: $64 = 8^2$. Tomemos então 64 como valor aproximado para a área do círculo!

Em linguagem corrida: a área de um círculo de diâmetro d é aproximadamente igual à de um quadrado de lado $(8/9)d$.

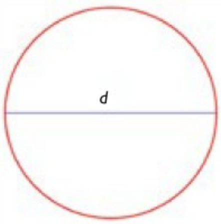
Usando o diâmetro original $d = 2r$, temos, para valor da área do círculo, $A_{\bigcirc}$,

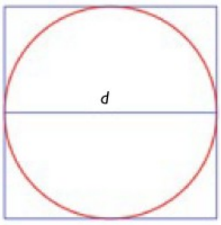
$$A_{\bigcirc} = \left(\frac{8}{9}d\right)^2 = \left(\frac{16}{9}\right)^2 r^2\,.$$

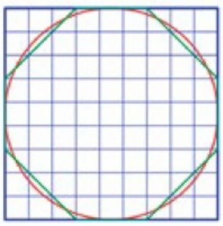
Como sabemos, a fórmula correta é $A_{\bigcirc} = \pi r^2$, pelo que a expressão deduzida do argumento de Ahmes corresponde a tomar

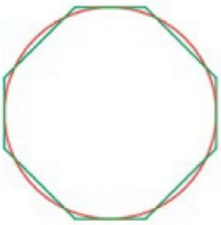
$$\pi = \left(\frac{16}{9}\right)^2 = 3.160493827\ldots$$

que difere do valor exato por menos de 0.02. Esta aproximação é notável em si e impressiona também pela facilidade









com que é obtida. Sugerimos ao leitor que tente obter outras aproximações usando métodos semelhantes a este, a ver se consegue melhorar este resultado ...

Suponhamos agora que se usava a mesma figura para aproximar o perímetro do círculo.

Tomando de novo como unidade $d/9$ e após uma aplicação do Teorema de Pitágoras, obtemos para o perímetro do octógono o valor

$$\frac{4}{3}\left(1+\sqrt{2}\right)d\,.$$

Como o valor correto para o perímetro do círculo é $P_{\bigcirc} = \pi d$, o valor aproximado baseado na aproximação pelo octógono corresponde a tomar

$$\pi = \frac{4}{3}\left(1+\sqrt{2}\right) = 3.218951\ldots$$

que difere do valor exato por menos de 0.08.

É certo que os egípcios antigos não conheciam a bela estrutura da matemática de Euclides ou Arquimedes, mas, não esqueçamos, eles construíram as impressionantes Pirâmides, testemunhos perenes do seu engenho.

AS BOLAS DA FIFA NÃO SÃO GRANDE COISA

Trunquem um pouco mais fundo o icosaedro truncado e farão da Telstar uma bola melhor.

Negócio de bolas é assunto sério. Há laboratórios sofisticados inovando para melhor vender, e adivinham-se empresas de *marketing* com a missão de conceber ideias e ficções que a FIFA certifica. São exemplos a publicidade hiperbólica quadrienal e a caução 'científica' de inovações mal experimentadas. O caso da Jabulani, a bola do Mundial 2010, deu que falar; aos elogios dos vendedores – a mais perfeita de sempre, de aerodinâmica superlativa, nunca vista, etc. – opuseram-se os protestos de arqueiros, zagueiros e pontas-de-lança, que não a pouparam: horrorosa, dançarina, bola de supermercado. Houve mesmo quem lhe atirasse as culpas pelo fiasco do Mundial 2010: é que de entre todos os mundiais ele ocupa o penúltimo lugar na média de golos por jogo.

Mas o problema a tratar aqui é outro. Seria pouco razoável fabricar uma bola de futebol com quatro peças triangulares (de cabedal ou material sintético) cosidas de modo a formar um tetraedro. Depois de insuflado ar, a pressão arredondaria a bola de raiz tetraédrica, mas o jogo seria outro, mais imprevisível do que o râguebi. O princípio lógico é o de que quanto mais rotundo for o poliedro não inflado, mais rotunda e resistente será a bola depois de cheia.

A UEFA escolheu, nos anos 60 do século passado, o icosaedro truncado como modelo, com as faces pentagonais pintadas de negro, a que foi dado o *nom de guerre* Telstar, roubado a um então famoso satélite de telecomunicações. Anos depois, a Telstar venceu o concurso 'Miss Bola' para o Mundial do México-1970. Hoje, contas feitas, o arquimediano a preto e branco ou a cores por encomenda já leva mais de meio século de reinado.

Em 1981, J. M. Göthals e J. J. Seidel, num artigo justamente intitulado *The football*[1], mostraram que a bola podia ser melhorada. Os argumentos envolvem teoria dos invariantes, fórmulas de quadratura de Sobolev e órbitas do grupo icosaedral. A FIFA não se deixou convencer e, tanto quanto sabemos, a bola continuou a mesma.

O Canto Délfico espera ter mais sucesso junto das autoridades com uma abordagem bem mais modesta. Usando dois critérios elementares, distintos dos de 81, somos levados à mesma conclusão: a Telstar não está bem.

QUÃO *ROTUNDA* É UMA BOLA?

Expressões da linguagem quotidiana do género "este sólido é mais rotundo do que aquele" podem precisar-se por muitos métodos. Um dos mais simples começa por chamar *raio interno* de um sólido[2] ao maior dos raios das esferas nele contidas, e *raio externo* de um sólido ao menor dos raios das esferas que o contêm. Em seguida, define-se *esfericidade* do sólido como sendo a razão do raio interno pelo raio externo. Claro que

> *A esfericidade é um número positivo que não excede 1, sendo igual a 1 quando e só quando o sólido é uma esfera.*

Outro critério de avaliação da rotundidade baseia-se no chamado quociente isoperimétrico (QI) de um sólido S, que se define por

$$36\pi \frac{V^2}{A^3},$$

onde V é o volume de S e A a área da sua superfície envolvente. Este quociente satisfaz uma propriedade elementar importante: qualquer homotético de S tem o mesmo QI que S. O factor 36π destina-se exclusivamente a obter 1 como quociente isoperimétrico das esferas.

O teorema isoperimétrico tridimensional pode enunciar-se assim:

> *O quociente isoperimétrico dum sólido é um número positivo que não excede 1, sendo igual a 1 quando e só quando o sólido é uma esfera.*

Estamos perante um enunciado muito simples, com um lastro histórico notável e uma demonstração de elevado grau de dificuldade, em claro contraste com o gémeo trivial sobre a esfericidade.

Cada uma das funções, esfericidade e quociente isoperimétrico, permite comparar quaisquer sólidos quanto à sua rotundidade. Mas são critérios diferentes que podem, por isso, conduzir a conclusões díspares. Por exemplo, os cinco platónicos ficam assim ordenados, por ordem crescente dos seus quocientes isoperimétricos: tetraedro (.3023), cubo (.5236), octaedro (.6046), dodecaedro (.7547), icosaedro (.8288). Na corrida da esfericidade ganham o icosaedro e o dodecaedro, *ex-æquo* (.7947), o cubo e o octaedro ficam em terceiro lugar, *ex-æquo* (.5774), e o tetraedro em quinto (.3333), sozinho por não ter irmão dual.[3]

No caso dos poliedros arquimedianos, os dois critérios conduzem a ordenações algo diferentes; por exemplo, os quatro mais rotundos são os mesmos para os dois

Esfericidade à moda da FIFA

Na sua página digital das bolas, uma foto sugere o modo como avaliam a esfericidade: entalam a bola, sem a pressionar, entre duas placas planas paralelas e medem com grande rigor a distância entre os planos. Dizem repetir a medida para 45.000 posições da bola. O quociente do mínimo pelo máximo dessas distâncias é a esfericidade-*F*, da FIFA. Destaca o *site* que as bolas da classe FIFA PRO apresentam uma esfericidade-*F* de cerca de 98,5%.

Sugerimos que a bola oficial passe a ter a forma de castanha de revolução que a figura ilustra, com esfericidade-*F* inultrapassável.

Isoperimétrico O termo tem a sua raiz num problema bidimensional, famoso e muito antigo: *de entre as curvas planas simples fechadas com certo perímetro fixo, quais as que delimitam maior área?* O assunto foi desenvolvido na Grécia Antiga, datando desse período a intuição correcta de que as circunferências são a chave da questão. As referências remontam aos antigos pitagóricos, tendo sido, no entanto, o ateniense Zenodoro (séc. II a.C.) quem nos legou os resultados mais relevantes. Por testemunhos indirectos sabemos que ele provou teoremas isoperimétricos relativos a polígonos, como este: *de entre os polígonos fechados de perímetro fixo e um número fixo de vértices, os regulares são os que delimitam maior área.* Os *Elementos* de Euclides já continham a prova de que o quadrado tem a maior área de entre os rectângulos isoperimétricos.

Porém, só no terceiro quartel do séc. XIX, com K. Weierstrass à cabeça, surgiram as primeiras provas convincentes do famoso teorema isoperimétrico bidimensional.

---

[1] Vejam-se os artigos [1] - [3].

[2] Para tornar as coisas mais simples, *sólido* significa conjunto convexo, fechado, limitado e com, pelo menos, um ponto interior.

[3] Estes e outros números foram arredondados a quatro dígitos significativos.

critérios mas por ordens distintas, como mostra a tabela seguinte, onde *esf.* e *QI* abreviam esfericidade e quociente isoperimétrico:

	esf.	*QI*
Rombicosidodecaedro	.9246	.9390
Dodecaedro roscado[4]	.9189	.9470
Icosaedro truncado	.9150	.9032
Grande rombicosidodecaedro	.9049	.9136

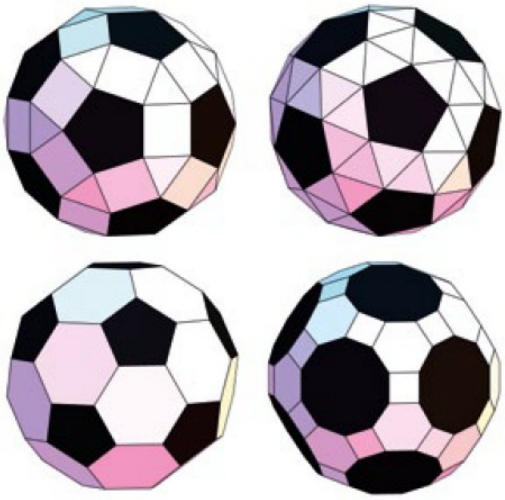

Figura 1. Os quatro mais rotundos.

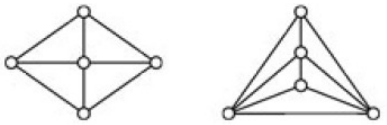
Zenodoro em 3D? *De entre os poliedros com n vértices (ou faces) quais são os que optimizam o QI, ou outro critério de rotundidade?* Cada valor de n origina problemas de dificuldade em geral elevada, nos quais, contrariamente ao caso 2D de Zenodoro, a regularidade não ajuda muito. Por exemplo, se n é ímpar, platónicos e arquimedianos ficam de fora, pois todos eles têm números pares de vértices e faces.

Para $n = 4$, o tetraedro regular é optimal, como o leitor interessado facilmente adivinha e comprova. Para cinco vértices, surge o problema de haver dois esqueletos (grafos de arestas) não isomorfos, os que a figura mostra, correspondentes à pirâmide quadrangular e à bipirâmide triangular.



Neste caso, os poliedros mais rotundos não são os mesmos para o QI e para a esfericidade, e não têm faces regulares. Saltando para o caso de oito vértices, o cubo tem menor QI e menor esfericidade do que o anti-prisma de base quadrada; mas a questão não fica resolvida só com isto, pois existem 257 esqueletos possíveis de poliedros com oito vértices; veja-se em [4] a sequência

1, 2, 7, 34, 257, 2606, 32.300,...

A figura 1 mostra os quatro vencedores, fortes candidatos a bolas da FIFA, pintados a preceito. Como sabemos, há mais de meio século a UEFA seleccionou o icosaedro truncado como modelo das bolas de futebol. A escolha parece acertada, dadas a pouca formosura do Grande Rombi e a complexidade estrutural dos dois mais rotundos – imaginem, por exemplo, o que seria coser à mão 12 pentágonos e 80 pequenos triângulos de cabedal num total de 150 costuras!

TRUNQUEM MAIS FUNDO!

Imaginemos que a FIFA, num momento de lucidez, encomendava à *Gazeta* o desenho duma bola de futebol à moda antiga. A ideia mais imediata consiste em tomar um dos cinco platónicos e truncar-lhe os vértices quanto baste. Por motivos estéticos, dinâmicos e funcionais, a truncatura deve consistir na remoção de pequenas pirâmides regulares, uma por cada vértice e de modo igual para todos os vértices. Admitindo que o nosso platónico tem arestas de medida 1, chamamos *profundidade* da truncatura à medida t das arestas laterais das pirâmides removidas. A figura 2 mostra o mais rotundo dos platónicos – e, por isso, o melhor candidato à truncatura – truncado a diversas profundidades.

A questão matemática cuja solução oferecemos à FIFA é esta: escolhido um critério de rotundidade e um sólido platónico,

> *Que profundidade(s) de truncatura desse platónico optimiza(m) a rotundidade?*

Mais precisamente, neste Canto Délfico resolvemos o caso do icosaedro truncado e convidamos o leitor a mandar à FIFA o tratamento dos outros quatro platónicos truncados.

O primeiro critério a considerar vai ser o de mais fácil tratamento, a esfericidade. Seja $\mathfrak{I}_t$ o icosaedro truncado

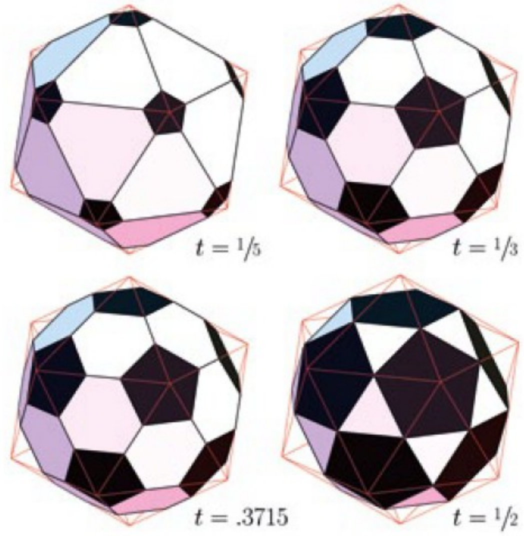


Figura 2. Truncaturas de um icosaedro.

à profundidade t; denotem-se por $r(t)$ e $R(t)$ os raios interno e externo de $\mathfrak{I}_t$. Por definição, a esfericidade de $\mathfrak{I}_t$ é

$$\epsilon(t) = \frac{r(t)}{R(t)}.$$

Note-se que t percorre o intervalo $[0, 1/2]$. Crescendo t, cada vértice de $\mathfrak{I}_t$ aproxima-se do centro de cada face triangular a que pertence, pelo que $R(t)$ é estritamente decrescente. O raio $r(t)$ é a menor das distâncias das faces hexagonais e pentagonais ao centro de $\mathfrak{I}_t$; portanto, $r(t)$mantém-se constante para t num intervalo $[0, c]$, onde c é o número *crítico* para o qual todas as faces de $\mathfrak{I}_c$ são tangentes à esfera interna do icosaedro.

Para qualquer arquimediano, as faces mais próximas do centro são as de maior número de vértices. Por escolha da FIFA, a Telstar é arquimediana, com $1/3$ de profundidade de truncatura. Portanto, $c > 1/3$, o que prova, para o critério vigente, que

> *A Telstar não é boa bola, pois pode aumentar-se a esfericidade truncando o icosaedro um pouco mais fundo.*

Não será difícil mostrar que o valor crítico de t é dado por

$$c = \frac{12\sqrt{5} - (\sqrt{54} + \sqrt{30})\sqrt{5 - \sqrt{5}}}{12(\sqrt{5} - 1)},$$

com valor aproximado .3715. A Telstar crítica está representada na figura 2; as suas faces hexagonais são irregulares, com arestas de dois comprimentos distintos, na razão de 1 para .6920. A prova da sua optimalidade e a determinação da esfericidade óptima exigem mergulhar as mãos em pormenores.

CONTAS

A determinação de uma fórmula para a esfericidade $\epsilon(t)$ requer alguns cálculos envolvendo a geometria do triângulo, do pentágono e do hexágono regulares, a indispensável percepção tridimensional e aplicações adequadas do teorema de Pitágoras. É complicado, aborrecido, mas elementar. A figura 3 mostra um corte do icosaedro (de arestas 1) em vias de ser truncado à profundidade t.

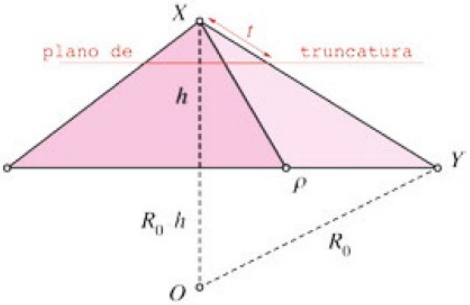

Figura 3. Corte do icosaedro.

Em destaque estão o centro O do icosaedro e dois dos seus vértices, X e Y. O polígono colorido representa a pirâmide pentagonal do icosaedro com vértice em X; o plano da base está de topo, tal como o plano de truncatura, e a aresta $[X, Y]$ está no plano da figura. Interessa calcular o raio externo ρ da base da pirâmide, a sua altura h e o raio externo R_0 do icosaedro:

$$\begin{aligned} \rho &= \sqrt{\frac{1}{10}(5 + \sqrt{5})} \\ h &= \sqrt{1 - \rho^2} \\ R_0 &= \frac{1}{2h} = \sqrt{\frac{1}{8}(5 + \sqrt{5})}. \end{aligned}$$

---

[4] Tentativa de tradução do inglês *snub*. A "snubificação" de um poliedro consiste em tomar o invólucro convexo da configuração que se obtém por expansão, *i.e.*, por translação radial das faces do poliedro, acompanhada de rotação planar de cada face em torno do seu centro.

Da figura 3 facilmente resulta que $R_0 - ht$ é a distância das faces pentagonais de $\Im_t$ ao seu centro, e que o raio interno do icosaedro é

$$\Delta = \frac{1}{4}\sqrt{3} + \frac{1}{12}\sqrt{15}.$$

O raio externo $R(t)$ também se 'vê' em verdadeira grandeza na figura. De tudo isto resulta

$$\begin{aligned} r(t) &= \min\{\Delta, R_0 - ht\} \\ R(t) &= \sqrt{R_0^2 - (1-t)t}. \end{aligned}$$

O parâmetro crítico é a solução da equação $\Delta = R_0 - ht$; calculando e simplificando obtemos o valor de c acima anunciado. Para $t \geqslant c$, a esfericidade é

$$\epsilon(t) = \frac{R_0 - ht}{\sqrt{R_0^2 - (1-t)t}}$$

com numerador e denominador decrescentes. A identidade

$$2h\frac{R(t)^4}{R_0 - ht}\epsilon(t)\epsilon'(t) = (h^2 - 1)t,$$

válida para $t \geqslant c$, mostra que $\epsilon'(t) < 0$ e que $\epsilon(t)$ é decrescente no intervalo em estudo. Portanto, $\Im_c$ é optimal. Pode determinar-se uma expressão exacta, com radicais, para a esfericidade óptima, pouco útil pela complexidade que se adivinha; o valor aproximado

$$\epsilon(c) \approx .9226$$

mostra que o icosaedro decentemente truncado produz uma bola de esfericidade superior à do dodecaedro roscado.

O *QI* DUM ICOSAEDRO TRUNCADO

Sejam V_0 e A_0 o volume do platónico que vai truncar-se e a área da sua superfície limítrofe. Considera-se, em dado vértice X, a pirâmide P que é removida quando truncamos X à profundidade $t=1$. Sejam v_P o volume de P e δ_P a diferença entre a sua área lateral e a da base. O volume e a área da superfície limítrofe do platónico truncado à profundidade t são dados por

$$V(t) = V_0 - nv_Pt^3 \quad \text{e} \quad A(t) = A_0 - n\delta_Pt^2,$$

onde n denota o número de vértices do platónico em causa. No caso do icosaedro, que está na berlinda, $n=12$ e P é a pirâmide da figura 3. (No caso do tetraedro, P é o tetraedro.) O quociente isoperimétrico do platónico truncado é, pois,

$$q(t) = \frac{V(t)^2}{A(t)^3}.$$

As identidades

$$\begin{aligned} A^6\left(\frac{V^2}{A^3}\right)' &= 2VV'A^3 - 2A^2A'V^2 \\ &= 6nVA^2t(\delta_PV - v_PAt) \\ &= 6nVA^2t(\delta_PV_0 - v_PA_0t) \end{aligned}$$

mostram que o sinal da derivada de $q(t)$ é o sinal de $\delta_PV_0 - v_PA_0t$. Portanto, a derivada de $q(t)$ anula-se para um só valor de t, nomeadamente

$$t_0 = \frac{\delta_PV_0}{v_PA_0},$$

$q'(t)$ é positiva para $t < t_0$ e negativa para $t > t_0$. Sendo assim, a truncatura de profundidade t_0 é a única que maximiza o quociente isoperimétrico. A surpresa é que t_0 é o parâmetro crítico c encontrado acima!

> *O icosaedro truncado vencedor do concurso da esfericidade é, também, o de maior QI.*

Mais um desaire para a FIFA, que assim perde em três tabuleiros. O que importa ao matemático, criatura pouco sensível a estas vaidades e que desconfia de coincidências, é encontrar motivos da surpresa mais nobres do que as contas que a ela conduziram.

Ao Professor João Queiró agradeço os muitos aperfeiçoamentos do texto.

ARQUIMEDES E O VOLUME DA ESFERA

Fátima Vinagre
Escola Secundária da Azambuja
mfatimavinagre@gmail.com

Arquimedes de Siracusa (287 a.C.– 212 a.C.) é muito provavelmente um dos maiores matemáticos de sempre. Tendo realizado os seus estudos em Alexandria, no Egito, capital do mundo helénico, manteve correspondência com matemáticos alexandrinos como Eratóstenes e Aristarco.

A sua vasta obra matemática não padeceu de grande divulgação, uma vez que o próprio Arquimedes contribuiu, em parte, para isso. Os seus trabalhos dedicados à quadratura do círculo e da parábola, ao estudo da espiral, ao volume da esfera e de outros corpos redondos, ao estudo do centro de gravidade e aos problemas da flutuação eram escritos na forma de breves tratados, dirigidos aos matemáticos da escola de Alexandria. O estilo elíptico, a densidade de referências internas e a dificuldade das demonstrações não favoreceram a difusão, mesmo entre os matemáticos, apesar da grande originalidade dos seus trabalhos.

Foi apenas em 1906 que o filósofo e historiador dinamarquês Johan Ludvig Heiberg (1854-1928) estudou um palimpsesto[1], o qual continha além de textos matemáticos de Arquimedes subjacentes a um texto religioso do século X, um texto grego, "Sobre os corpos flutuantes". Mas foi entre os textos de Arquimedes que fez a sua maior descoberta, "O método sobre teoremas mecânicos", atualmente conhecido por "O Método", no qual Arquimedes apresentava a Eratóstenes, de Alexandria, o procedimento heurístico que empregava para obter as suas conclusões, que consistia na descrição de um "método mecânico" para investigar questões matemáticas, explicando várias das suas descobertas, entre as quais aquela que pode ser considerada uma das maiores descobertas matemáticas de todos os tempos, a fórmula para calcular o volume de uma esfera.

Existem diversas formas de demonstrar como se calcula o volume de uma esfera em função do seu raio. Contudo, neste artigo, pretende-se fazê-lo com base na lei da alavanca de Arquimedes de Siracusa (287 a.C.– 212 a.C.).

Arquimedes sabia que o volume de cone é igual a um terço do volume de um cilindro com a mesma altura e a mesma base e que o volume de um cilindro é dado pelo produto da área de uma das suas bases pela sua altura, e apresentou uma dedução teórica da **lei da alavanca** na sua obra "Sobre o Equilíbrio dos Planos" ou "Sobre os Centros de Gravidade das Figuras Planas", tendo-a engenhosamente aplicado na demonstração da fórmula de cálculo do volume de uma esfera.

Tenhamos, por base, o conceito de centro de gravidade de um corpo de Arquimedes:

> "Dois pesos w_1 e w_2 nas extremidades de uma barra de peso desprezável e distantes x_1 e x_2 respetivamente de um ponto de apoio estão em equilíbrio se $w_1 x_1 = w_2 x_2$."

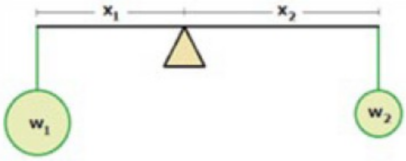

Figura 1: Ilustração do conceito de centro de gravidade de um corpo.

Segundo o geómetra, o centro de gravidade de qualquer corpo é um ponto, pertencente ao corpo ou localizado no espaço vazio, tal que, se for concebido que o corpo está suspenso por este ponto, o corpo assim sustentado permanece em repouso e preserva a sua posição original, sem se inclinar em nenhuma direção, qualquer que seja a sua orientação inicial em relação à Terra [1] e que todo o corpo, suspenso por qualquer ponto, assume um estado de equilíbrio quando o ponto de suspensão e o centro de gravidade do corpo estão ao longo de uma mesma linha vertical.[2]

Considere-se, ainda, o postulado 6 (no qual assenta a lei da alavanca) e os resultados teóricos tratados por Arquimedes na sua obra "Sobre o Equilíbrio dos Planos", relevantes para o presente artigo:

---

[1] Um pergaminho usado para nele se escrever várias vezes.

[2] Segundo Arquimedes afirma, no decorrer da demonstração da proposição 6, que comprovou o enunciado ao qual a autora se refere, num outro trabalho, hoje perdido.

Postulado 6: *Se grandezas se equilibram a certas distâncias*[3]*, então grandezas equivalentes*[4] *a estas grandezas equilibrar-se-ão, por sua vez, nas mesmas distâncias.*[5]*[1]*

Proposição 4: *Se duas grandezas iguais não possuem o mesmo centro de gravidade, o centro de gravidade da grandeza composta por estas [duas] grandezas estará no ponto médio do segmento de reta ligando os centros de gravidade das [duas] grandezas. [3]*

Proposições 6 e 7: *Se [duas] grandezas são comensuráveis [proposição 6] ou incomensuráveis [proposição 7], elas equilibrar-se-ão em distâncias inversamente proporcionais às grandezas. [3]*

Façamos, agora, algumas considerações acerca do que se entende por alavanca.

A alavanca consiste num corpo rígido, geralmente linear, capaz de girar ao redor de um eixo horizontal fixo em relação à Terra (o fulcro ou ponto de sustentação PS). O eixo de rotação é, em geral, ortogonal à alavanca, com os dois ficando usualmente no plano horizontal quando a alavanca está parada em relação à Terra.

É como se fosse uma balança, mas com a possibilidade de colocarmos pesos a distâncias diferentes do fulcro.

Chamamos braço da alavanca à distância horizontal, d, entre o ponto de apoio de um corpo sobre o travessão (ou haste da alavanca) e o plano vertical passando pelo fulcro. Para facilitar a linguagem, usaremos a expressão de distância entre o peso e o fulcro, mas em geral deve entender-se distância horizontal entre o ponto de atuação do peso na alavanca e o plano vertical passando pelo fulcro.

Quando falarmos de dois braços da alavanca, deve entender-se que estes estão em lados opostos do plano vertical que passa pelo fulcro.

Para se utilizar a lei da alavanca, pressupõe-se que a alavanca seja sensível, isto é, tenha liberdade de oscilação e de giro ao redor do fulcro; verifique as razões $\Delta P/PA$ (onde ΔP é a diferença entre os pesos que estão dos dois lados da alavanca e PA é o peso da alavanca) e d/h (onde h é a distância vertical entre o ponto de sustentação e centro de gravidade do travessão, e a distância d é o menor dos braços da alavanca).

Os dois lados do travessão da alavanca devem ter-lhes apostas diversas distâncias iguais em relação à vertical que passa pelo fulcro.

Mais, para que haja equilíbrio de dois corpos numa alavanca, apenas é relevante o seu peso e a sua distância ao fulcro.

A lei da alavanca determina, tal como Arquimedes expressou com a proposição 6 suprarreferida, que ao colocar-se um número N_A de corpos com o mesmo peso $P(P_A \equiv N_A P)$ atuando juntos num dos braços d_A de uma alavanca e um número N_B de corpos com o mesmo peso $P(P_B N_B P)$ atuando juntos no outro braço da alavanca d_B e soltando-a do repouso na horizontal, ela permanece parada na horizontal quando $d_B/d_A = P_A/P_B = N_A/N_B$.

Este princípio determina que ao se colocar N pesos $P_1, P_2, \ldots, P_N$ de um dos lados da alavanca suspensos, respetivamente, nas distâncias $d_1, d_2, \ldots, d_N$ do plano vertical que passa pelo fulcro e M pesos $P_{N+1}, P_{N+2}, \ldots, P_{N+M}$ do outro lado da alavanca suspensos, respetivamente, nas distâncias $d_{N+1}, d_{N+2}, \ldots, d_{N+M}$ do plano vertical que passa pelo fulcro e soltar-se do repouso a alavanca com esta na horizontal, a alavanca permanece em equilíbrio, verificando-se

$$\sum_{i=1}^{N} \frac{P_i}{P_0} \frac{d_i}{d_0} = \sum_{i=N+1}^{N+M} \frac{P_i}{P_0} \frac{d_i}{d_0}.$$

Para determinarmos algebricamente o centro de gravidade entre dois corpos, procedemos da seguinte forma:

Considere-se uma alavanca em equilíbrio estável[6] na horizontal sem a colocação de outros corpos. Suponha-se que essa alavanca tem uma haste homogénea tal que quando o fulcro fica ao longo de um plano vertical que divide a haste em duas partes com o mesmo comprimento, a alavanca permanece em equilíbrio ao ser solta do repouso, parada na horizontal. O centro de gravidade do travessão está verticalmente abaixo do fulcro, ou do ponto de sustentação.

Sabemos que este equilíbrio mantém-se caso sejam colocados dois corpos A e B suspensos em lados opostos da alavanca, desde que se verifique $d_B/d_A = P_A/P_B$, onde d_A e d_B são as distâncias horizontais entre os pontos de suspensão de A e de B até ao plano vertical passando pelo fulcro, sendo P_A e P_B os pesos de A e de B, respetivamente. Isto significa que o centro de gravidade destes dois corpos também se encontra no plano vertical que passa pelo fulcro.

Tomemos um eixo horizontal, x, ao longo da haste da alavanca de comprimento L e com origem (escolhida de forma arbitrária) em $x = 0$.

Suponha-se que as extremidades da haste da alavanca estão localizadas em X_E e $X_D = X_E + L$, que colocamos os corpos A e B suspensos nas posições X_A e X_B do eixo X, respetivamente, e que a alavanca permanece em equilíbrio ao ser solta do repouso com os corpos A e B

atuando nestas posições, conforme se pode observar na figura seguinte.

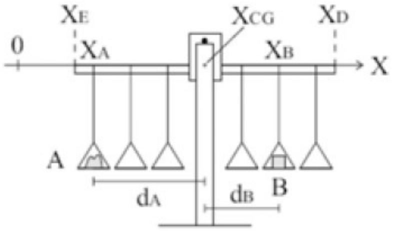

Figura 2: Encontrando a expressão algébrica para o centro de gravidade.

O centro de gravidade deste sistema tem de estar sobre o plano vertical que passa pelo fulcro quando $d_B/d_A = P_A/P_B$, uma vez que a alavanca permanece em equilíbrio.

Represente-se a localização do centro de gravidade dos corpos A e B por X_{CG}.

Então, $d_A = X_{CG}X_A$ e $d_B = X_BX_{CG}$.

Pela lei da alavanca, a posição X_{CG} do centro de gravidade deste sistema de dois corpos ao longo do eixo X é dada por:

$$\frac{X_B - X_{CG}}{X_{CG} - X_A} = \frac{P_A}{P_B},$$

ou seja,

$$X_{CG} = \frac{P_A}{P_T}X_A + \frac{P_B}{P_T}X_B,$$

onde $P_T = P_A + P_B$ é o peso total dos dois corpos.

Facilmente se observa que quando $P_A = P_B$, X_{CG} é o ponto médio entre X_A e X_B.

Feitas as considerações anteriores, estamos em condições de deduzir, utilizando a lei da alavanca de Arquimedes, a fórmula para calcular o volume de uma esfera de raio r.

Pretende-se colocar os sólidos a seguir descritos suspensos nas extremidades de uma alavanca, como mostra a figura 3.

Para tal, comecemos por considerar os três sólidos de revolução seguintes: uma esfera gerada pela rotação do seu círculo maior de raio r em torno do seu diâmetro, um cone de raio e altura iguais ao diâmetro da esfera e um cilindro de raio e altura iguais ao diâmetro da esfera cujo eixo coincide com o diâmetro da esfera, dispostos conforme a figura 4.

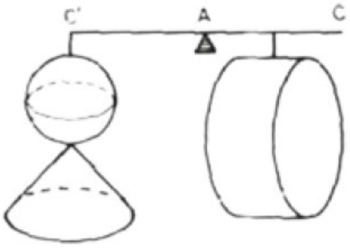

Figura 3: Alavanca com os sólidos suspensos e com fulcro em *A*.

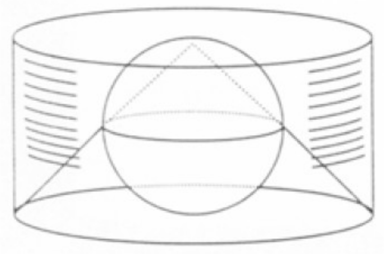

Figura 4: Posição dos sólidos.

Deixemos a cargo do leitor a justificação da importância da posição dos sólidos.

Tomemos o ponto de suspensão dos sólidos no vértice do cone. Então, os centros de gravidade dos três sólidos encontram-se numa mesma linha reta vertical.

Considere-se uma alavanca HC de braços HA e AC em equilíbrio sem os sólidos suspensos, cujo comprimento dos braços é $2r$ e com fulcro no ponto médio de HC

---

[3] Entenda-se "grandezas a certas distâncias" como "grandezas cujos centros de gravidade estão às mesmas distâncias do fulcro."

[4] Entenda-se "grandezas equivalentes" como "grandezas com o mesmo peso."

[5] Este postulado permitia a Arquimedes substituir um corpo *A* suspenso numa alavanca através do seu centro de gravidade localizado à distância horizontal *d* do plano vertical passando pelo fulcro, por outro corpo *B* conveniente que tivesse o mesmo peso que *A*, sem afetar o equilíbrio da alavanca, desde que o centro de gravidade deste corpo *B* também estivesse pendurado na alavanca à mesma distância horizontal *d* do plano vertical passando pelo fulcro.

[6] Equilíbrio estável é quando qualquer perturbação na posição do corpo fizer com que o centro de gravidade suba em relação à sua posição anterior.

(para que o plano vertical que passa pelo fulcro divida ao meio o travessão da alavanca). Seja A o fulcro.

Comece-se por considerar que o fulcro se encontra no vértice do cone e, por comodidade, faça-se um corte transversal nos três sólidos passando pelo fulcro e suponha-se que os sólidos estão suspensos neste ponto de apoio[7]. Obtém-se a figura 5.

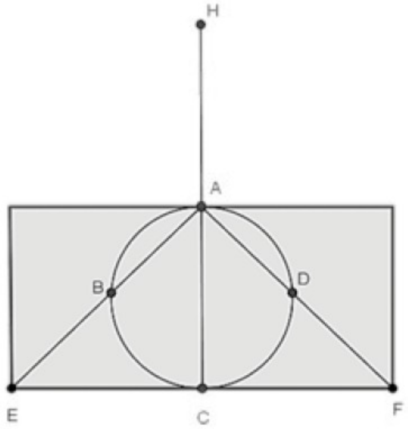

Figura 5: Secção transversal dos sólidos.

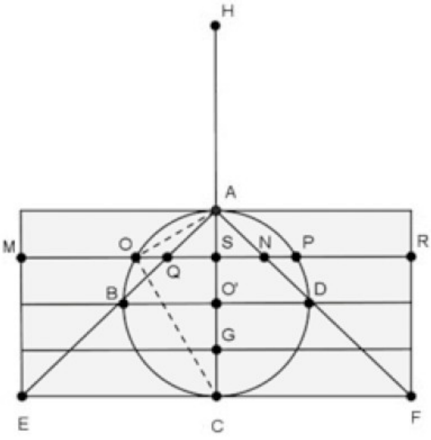

Figura 6: Designação de pontos da secção.

De seguida, através deste corte transversal, tentemos encontrar pontos de suspensão para os sólidos em ambos os braços da alavanca, que não perturbem o equilíbrio da mesma.

Para tal, façam-se três cortes nos sólidos segundo planos paralelos à base do cilindro, tais que o cilindro fique dividido em quatro partes iguais[8]. Tais planos cortam AC em quatro partes iguais.

Denominem-se por S, O' e G os pontos de interseção dos planos com o eixo de rotação do cilindro.

Centremo-nos, agora, na secção transversal dos sólidos.

Designem-se pelas letras O e P os pontos de interseção do círculo com a reta MR e Q e N os pontos de interseção da reta MR com o triângulo AEH, assinalados na figura 6 e considere-se o triângulo AOC.

Como

$$\frac{AS}{AC} = \frac{AS}{AC} \cdot \frac{AC}{AC} =$$

$$= \frac{AS \cdot AC}{AC^2} = \frac{AS \cdot (AS + SC)}{AC^2} = \frac{AS^2 + AS \cdot SC}{AC^2}$$

e $AS \cdot SC = OS \cdot SP$, dado que AC e OP são cordas da circunferência que se intersetam em S, podemos afirmar que

$$\frac{AS}{AC} = \frac{AS^2 + OS \cdot SP}{AC^2} = \frac{AS^2 + OS^2}{AC^2}$$

e, portanto,

$$AS \cdot AC^2 = AC \cdot (AS^2 + OS^2). \qquad (1)$$

Como, por construção, se sabe que $AH = AC = MS$, atendendo a que o triângulo AQS é isósceles (porque os ângulos $\angle QAS$ e $\angle AQS$ têm as mesmas amplitudes, são ambos de 45°), tem-se que $QS = AS$.

Consequentemente, a igualdade (1) é equivalente a

$$AS \cdot MS^2 = AH \cdot (QS^2 + OS^2),$$

ou seja,

$$\frac{AS}{AH} = \frac{QS^2 + OS^2}{MS^2} \Leftrightarrow \frac{AS}{AH} = \frac{\pi \cdot (QS^2 + OS^2)}{\pi \cdot MS^2}$$

$$\Leftrightarrow \frac{AS}{AH} = \frac{\pi \cdot QS^2 + \pi \cdot OS^2}{\pi \cdot MS^2}.$$

Assim, como $\pi \cdot QS^2, \pi \cdot OS^2$ e $\pi \cdot MS^2$ representam as áreas dos círculos de raios QS, OS e MS, respetivamente, e como o equilíbrio de dois corpos se mantém, se as distâncias horizontais entre os pontos de suspensão destes forem inversamente proporcionais ao seu peso, podemos concluir que o equilíbrio da alavanca não é perturbado, se colocarmos os círculos de raios QS e OS suspensos na extremidade H da alavanca e o círculo de raio MS suspenso no ponto S pertencente ao outro braço da alavanca, ou seja, a uma distância horizontal do fulcro igual a $r/2$.

Tendo em conta que todos os resultados deduzidos através da secção transversal mantêm as mesmas propriedades se considerarmos S a variar de A até O', tomemos o cilindro como união infinita dos círculos de raio igual a MS, o cone como união infinita dos círculos de raio igual a QS e a semiesfera como união infinita dos círculos de raio igual a OS, com S a variar de A até O'.[9]

Podemos concluir que o equilíbrio da alavanca não é perturbado se remontássemos os sólidos e os colocássemos suspensos no travessão da alavanca da seguinte forma: a semiesfera e o cone na extremidade H da alavanca e o cilindro no ponto de suspensão S situado no outro braço da alavanca.

Designem-se por V_S, V_C e V_i os volumes da semiesfera, do cone e do cilindro, respetivamente.

Como a alavanca se mantém equilibrada com a suspensão dos sólidos, verifica-se a relação $\frac{V_c+V_s}{V_i} = \frac{AS}{AH}$ ou seja,

$$\frac{V_c+V_s}{V_i} = \frac{r}{2}2r \Leftrightarrow \frac{V_c+V_s}{V_i} = \frac{1}{4}. \qquad (2)$$

Atendendo a que $V_c = 1/3 \cdot \pi r^2 \cdot r$ e $V_i = (2r)^2 \pi r$, substituindo em (2), vem:

$$\frac{\frac{1}{3} \cdot \pi r^2 \cdot r + V_s}{(2r)^2 \cdot \pi r} = \frac{1}{4} \Leftrightarrow \frac{1}{3} \cdot \pi r^3 + V_s = \frac{(2r)^2 \cdot \pi r}{4}$$

$$\Leftrightarrow V_s = \pi r^3 - \frac{1}{3} \cdot \pi r^3 \Leftrightarrow V_s = \frac{2}{3} \cdot \pi r^3.$$

Como o volume da esfera inicial é o dobro do volume desta semiesfera, podemos concluir que o volume da esfera inicial é $4/3 \cdot \pi r^3$.

This indicates that when a tensor is invertible, there is a one-to-one mapping of vectors **a** and **b**. On the other hand, if a tensor **T** does not have an inverse, then, for a given **b**, there are in general more than one **a** that transform into **b**. This fact is illustrated in the following example.

Example 2.14.2

Consider the tensor $\mathbf{T} = \mathbf{cd}$ (the dyadic product of **c** and **d**).

(a) Obtain the determinant of **T**.

(b) Show that if $\mathbf{Ta} = \mathbf{b}$, then $\mathbf{T}(\mathbf{a} + \mathbf{h}) = \mathbf{b}$, where **h** is any vector perpendicular to the vector **d**.

Solution

(a) $[\mathbf{T}] = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \end{bmatrix} [\, d_1 \quad d_2 \quad d_3 \,] = \begin{bmatrix} c_1 d_1 & c_1 d_2 & c_1 d_3 \\ c_2 d_1 & c_2 d_2 & c_2 d_3 \\ c_3 d_1 & c_3 d_2 & c_3 d_3 \end{bmatrix}$ and $\det [\mathbf{T}] = c_1 c_2 c_3 d_1 d_2 d_3 \begin{vmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{vmatrix} = 0.$

That is, **T** is a singular tensor, for which an inverse does not exist.

(b) $\mathbf{T}(\mathbf{a}+\mathbf{h}) = (\mathbf{cd})(\mathbf{a}+\mathbf{h}) = \mathbf{c}(\mathbf{d} \cdot \mathbf{a}) + \mathbf{c}(\mathbf{d} \cdot \mathbf{h})$. Now $\mathbf{d} \cdot \mathbf{h} = 0$ (**h** is perpendicular to **d**); therefore,

$$\mathbf{T}(\mathbf{a} + \mathbf{h}) = \mathbf{c}(\mathbf{d} \cdot \mathbf{a}) = (\mathbf{cd})\mathbf{a} = \mathbf{Ta} = \mathbf{b}.$$

That is, all vectors $\mathbf{a} + \mathbf{h}$ transform into the vector **b**, and it is not a one-to-one transformation.

2.15 ORTHOGONAL TENSORS

An *orthogonal tensor* is a linear transformation under which the transformed vectors preserve their lengths and angles. Let **Q** denote an orthogonal tensor; then by definition, $|\mathbf{Qa}| = |\mathbf{a}|$, $|\mathbf{Qb}| = |\mathbf{b}|$, and $\cos(\mathbf{a},\mathbf{b}) = \cos(\mathbf{Qa}, \mathbf{Qb})$. Therefore,

$$\mathbf{Qa} \cdot \mathbf{Qb} = \mathbf{a} \cdot \mathbf{b} \tag{2.15.1}$$

for any vectors **a** and **b**.

Since by the definition of transpose, Eq. (2.11.1), $(\mathbf{Qa}) \cdot (\mathbf{Qb}) = \mathbf{b} \cdot \mathbf{Q}^{\mathrm{T}}(\mathbf{Qa})$, thus

$$\mathbf{b} \cdot \mathbf{a} = \mathbf{b} \cdot (\mathbf{Q}^{\mathrm{T}}\mathbf{Q})\mathbf{a} \quad \text{or} \quad \mathbf{b} \cdot \mathbf{Ia} = \mathbf{b} \cdot \mathbf{Q}^{\mathrm{T}}\mathbf{Qa}.$$

Since **a** and **b** are arbitrary, it follows that

$$\mathbf{Q}^{\mathrm{T}}\mathbf{Q} = \mathbf{I}. \tag{2.15.2}$$

This means that for an orthogonal tensor, the inverse is simply the transpose,

$$\mathbf{Q}^{-1} = \mathbf{Q}^{\mathrm{T}}. \tag{2.15.3}$$

Thus [see Eq. (2.14.8)],

$$\mathbf{Q}^{\mathrm{T}}\mathbf{Q} = \mathbf{Q}\mathbf{Q}^{\mathrm{T}} = \mathbf{I}. \tag{2.15.4}$$

In matrix notation, Eq. (2.15.4) takes the form:

$$[\mathbf{Q}]^{\mathrm{T}}[\mathbf{Q}] = [\mathbf{Q}][\mathbf{Q}]^{\mathrm{T}} = [\mathbf{I}], \tag{2.15.5}$$

and in subscript notation, we have

$$Q_{mi}Q_{mj} = Q_{im}Q_{jm} = \delta_{ij}. \tag{2.15.6}$$

Example 2.15.1

The tensor given in Example 2.7.2, being a reflection, is obviously an orthogonal tensor. Verify that $[\mathbf{T}][\mathbf{T}]^{\mathrm{T}} = [\mathbf{I}]$ for the $[\mathbf{T}]$ in that example. Also, find the determinant of $[\mathbf{T}]$.

Solution

Evaluating the matrix product:

$$[\mathbf{T}][\mathbf{T}]^{\mathrm{T}} = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

The determinant of $\mathbf{T}$ is

$$|\mathbf{T}| = \begin{vmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{vmatrix} = -1.$$

Example 2.15.2

The tensor given in Example 2.7.3, being a rigid body rotation, is obviously an orthogonal tensor. Verify that $[\mathbf{R}][\mathbf{R}]^{\mathrm{T}} = [\mathbf{I}]$ for the $[\mathbf{R}]$ in that example. Also find the determinant of $[\mathbf{R}]$.

Solution

$$[\mathbf{R}][\mathbf{R}]^{\mathrm{T}} = \begin{bmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

$$\det[\mathbf{R}] = |\mathbf{R}| = \begin{vmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{vmatrix} = 1.$$

The determinant of the matrix of any orthogonal tensor $\mathbf{Q}$ is easily shown to be equal to either $+1$ or -1. In fact, since

$$[\mathbf{Q}][\mathbf{Q}]^{\mathrm{T}} = [\mathbf{I}],$$

therefore,

$$|[\mathbf{Q}][\mathbf{Q}]^{\mathrm{T}}| = |\mathbf{Q}||\mathbf{Q}^{\mathrm{T}}| = |\mathbf{I}|.$$

Now $|\mathbf{Q}| = |\mathbf{Q}^{\mathrm{T}}|$ and $|\mathbf{I}| = 1$, therefore, $|\mathbf{Q}|^2 = 1$, thus

$$|\mathbf{Q}| = \pm 1. \tag{2.15.7}$$

From the previous examples, we can see that for a rotation tensor the determinant is +1, whereas for a reflection tensor, it is −1.

2.16 TRANSFORMATION MATRIX BETWEEN TWO RECTANGULAR CARTESIAN COORDINATE SYSTEMS

Suppose that $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ and $\{\mathbf{e}_1', \mathbf{e}_2', \mathbf{e}_3'\}$ are unit vectors corresponding to two rectangular Cartesian coordinate systems (see Figure 2.16-1). It is clear that $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ can be made to coincide with $\{\mathbf{e}_1', \mathbf{e}_2', \mathbf{e}_3'\}$ through either a rigid body rotation (if both bases are same-handed) or a rotation followed by a reflection (if different-handed). That is, $\{\mathbf{e}_i\}$ and $\{\mathbf{e}_i'\}$ are related by an orthogonal tensor $\mathbf{Q}$ through the equations below.

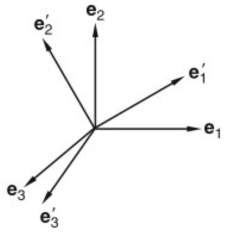

FIGURE 2.16-1

$$\mathbf{e}_i' = \mathbf{Q}\mathbf{e}_i = Q_{mi}\mathbf{e}_m, \tag{2.16.1}$$

that is,

$$\begin{aligned} \mathbf{e}_1' &= Q_{11}\mathbf{e}_1 + Q_{21}\mathbf{e}_2 + Q_{31}\mathbf{e}_3, \\ \mathbf{e}_2' &= Q_{12}\mathbf{e}_1 + Q_{22}\mathbf{e}_2 + Q_{32}\mathbf{e}_3, \\ \mathbf{e}_3' &= Q_{13}\mathbf{e}_1 + Q_{23}\mathbf{e}_2 + Q_{33}\mathbf{e}_3, \end{aligned} \tag{2.16.2}$$

where

$$Q_{im}Q_{jm} = Q_{mi}Q_{mj} = \delta_{ij}, \tag{2.16.3}$$

or

$$\mathbf{Q}\mathbf{Q}^{\mathrm{T}} = \mathbf{Q}^{\mathrm{T}}\mathbf{Q} = \mathbf{I}. \tag{2.16.4}$$

We note that

$$\begin{aligned} Q_{11} &= \mathbf{e}_1 \cdot \mathbf{Q}\mathbf{e}_1 = \mathbf{e}_1 \cdot \mathbf{e}_1' = \text{cosine of the angle between } \mathbf{e}_1 \text{ and } \mathbf{e}_1', \\ Q_{12} &= \mathbf{e}_1 \cdot \mathbf{Q}\mathbf{e}_2 = \mathbf{e}_1 \cdot \mathbf{e}_2' = \text{cosine of the angle between } \mathbf{e}_1 \text{ and } \mathbf{e}_2', \text{etc.} \end{aligned}$$

That is, in general, Q_{ij} = cosine of the angle between $\mathbf{e}_i$ and $\mathbf{e}_j'$, which may be written:

$$Q_{ij} = \cos(\mathbf{e}_i, \mathbf{e}_j'). \tag{2.16.5}$$

The matrix of these direction cosines, i.e., the matrix

$$[\mathbf{Q}] = \begin{bmatrix} Q_{11} & Q_{12} & Q_{13} \\ Q_{21} & Q_{22} & Q_{23} \\ Q_{31} & Q_{32} & Q_{33} \end{bmatrix}, \tag{2.16.6}$$

is called the *transformation matrix* between $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ and $\{\mathbf{e}'_1, \mathbf{e}'_2, \mathbf{e}'_3\}$. Using this matrix, we shall obtain in the following sections the relationship between the two sets of components, with respect to these two sets of base vectors, of a vector and a tensor.

Example 2.16.1

Let $\{\mathbf{e}'_1, \mathbf{e}'_2, \mathbf{e}'_3\}$ be obtained by rotating the basis $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ about the $\mathbf{e}_3$ axis through 30°, as shown in Figure 2.16-2. In this figure, $\mathbf{e}_3$ and $\mathbf{e}'_3$ coincide.

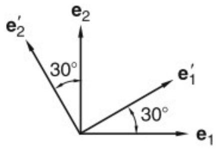

FIGURE 2.16-2

Solution

We can obtain the transformation matrix in two ways:

1. Using Eq. (2.16.5), we have

$$Q_{11} = \cos(\mathbf{e}_1, \mathbf{e}'_1) = \cos 30^\circ = \sqrt{3}/2, \quad Q_{12} = \cos(\mathbf{e}_1, \mathbf{e}'_2) = \cos 120^\circ = -1/2, \quad Q_{13} = \cos(\mathbf{e}_1, \mathbf{e}'_3) = \cos 90^\circ = 0,$$
$$Q_{21} = \cos(\mathbf{e}_2, \mathbf{e}'_1) = \cos 60^\circ = 1/2, \quad Q_{22} = \cos(\mathbf{e}_2, \mathbf{e}'_2) = \cos 30^\circ = \sqrt{3}/2, \quad Q_{23} = \cos(\mathbf{e}_2, \mathbf{e}'_3) = \cos 90^\circ = 0,$$
$$Q_{31} = \cos(\mathbf{e}_3, \mathbf{e}'_1) = \cos 90^\circ = 0, \quad Q_{32} = \cos(\mathbf{e}_3, \mathbf{e}'_2) = \cos 90^\circ = 0, \quad Q_{23} = \cos(\mathbf{e}_3, \mathbf{e}'_3) = \cos 0^\circ = 1.$$

2. It is easier to simply look at Figure 2.16-2 and decompose each of the $\mathbf{e}'_i$ into its components in the $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ directions, i.e.,

$$\mathbf{e}'_1 = \cos 30^\circ \mathbf{e}_1 + \sin 30^\circ \mathbf{e}_2 = \frac{\sqrt{3}}{2}\mathbf{e}_1 + \frac{1}{2}\mathbf{e}_2,$$
$$\mathbf{e}'_2 = -\sin 30^\circ \mathbf{e}_1 + \cos 30^\circ \mathbf{e}_3 = -\frac{1}{2}\mathbf{e}_1 + \frac{\sqrt{3}}{2}\mathbf{e}_2,$$
$$\mathbf{e}'_3 = \mathbf{e}_3.$$

Thus, by Eq. (2.16.2), we have

$$[\mathbf{Q}] = \begin{bmatrix} \sqrt{3}/2 & -1/2 & 0 \\ 1/2 & \sqrt{3}/2 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

2.17 TRANSFORMATION LAW FOR CARTESIAN COMPONENTS OF A VECTOR

Consider any vector **a**. The Cartesian components of the vector **a** with respect to $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ are:

$$a_i = \mathbf{a} \cdot \mathbf{e}_i, \tag{2.17.1}$$

and its components with respect to $\{\mathbf{e}'_1, \mathbf{e}'_2, \mathbf{e}'_3\}$ are:

$$a'_i = \mathbf{a} \cdot \mathbf{e}'_i. \tag{2.17.2}$$

Now $\mathbf{e}'_i = Q_{mi}\mathbf{e}_m$ [see Eq. (2.16.1)]; therefore,

$$a'_i = \mathbf{a} \cdot Q_{mi}\mathbf{e}_m = Q_{mi}(\mathbf{a} \cdot \mathbf{e}_m), \tag{2.17.3}$$

that is,

$$a'_i = Q_{mi}a_m. \tag{2.17.4}$$

In matrix notation, Eq. (2.17.4) is

$$\begin{bmatrix} a'_1 \\ a'_2 \\ a'_3 \end{bmatrix} = \begin{bmatrix} Q_{11} & Q_{21} & Q_{31} \\ Q_{12} & Q_{22} & Q_{32} \\ Q_{13} & Q_{23} & Q_{33} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix}, \tag{2.17.5}$$

or

$$[\mathbf{a}]' = [\mathbf{Q}]^{\mathrm{T}}[\mathbf{a}]. \tag{2.17.6}$$

Equation (2.17.4), or Eq. (2.17.5), or Eq. (2.17.6) is the transformation law relating components of the *same* vector with respect to different rectangular Cartesian unit bases. It is very important to note that in Eq. (2.17.6), $[\mathbf{a}]'$ denotes the matrix of the vector **a** with respect to the primed basis $\{\mathbf{e}'_i\}$, and $[\mathbf{a}]$ denotes the same vector with respect to the unprimed basis $\{\mathbf{e}_i\}$. Eq. (2.17.6) is not the same as $\mathbf{a}' = \mathbf{Q}^{\mathrm{T}}\mathbf{a}$. The distinction is that $[\mathbf{a}]'$ and $[\mathbf{a}]$ are matrices of the same vector, whereas **a** and $\mathbf{a}'$ are two different vectors—$\mathbf{a}'$ being the transformed vector of **a** (through the transformation $\mathbf{a}' = \mathbf{Q}^{\mathrm{T}}\mathbf{a}$).

If we premultiply Eq. (2.17.6) with $[\mathbf{Q}]$, we get

$$[\mathbf{a}] = [\mathbf{Q}][\mathbf{a}]'. \tag{2.17.7}$$

The indicial notation for this equation is:

$$a_i = Q_{im}a'_m. \tag{2.17.8}$$

Example 2.17.1

Given that the components of a vector **a** with respect to $\{\mathbf{e}_i\}$ are given to be [2,0,0]. That is, $\mathbf{a} = 2\mathbf{e}_1$, find its components with respect to $\{\mathbf{e}'_i\}$, where the $\{\mathbf{e}'_i\}$ axes are obtained by a 90° counter-clockwise rotation of the $\{\mathbf{e}_i\}$ axis about its $\mathbf{e}_3$ axis.

Solution

The answer to the question is obvious from Figure 2.17-1, that is,

$$\mathbf{a} = 2\mathbf{e}_1 = -2\mathbf{e}'_2.$$

To show that we can get the same answer from Eq. (2.17.6), we first obtain the transformation matrix of **Q**. Since $\mathbf{e}_1' = \mathbf{e}_2, \mathbf{e}_2' = -\mathbf{e}_1$ and $\mathbf{e}_3' = \mathbf{e}_3$, we have

$$[\mathbf{Q}] = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Thus,

$$[\mathbf{a}]' = [\mathbf{Q}]^{\mathrm{T}}[\mathbf{a}] = \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 2 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ -2 \\ 0 \end{bmatrix},$$

that is,

$$\mathbf{a} = -2\mathbf{e}_2'.$$

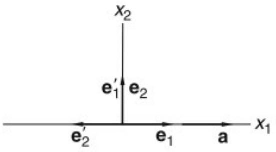

FIGURE 2.17-1

2.18 TRANSFORMATION LAW FOR CARTESIAN COMPONENTS OF A TENSOR

Consider any tensor **T**. The components of **T** with respect to the basis $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ are:

$$T_{ij} = \mathbf{e}_i \cdot \mathbf{T}\mathbf{e}_j. \tag{2.18.1}$$

Its components with respect to $\{\mathbf{e}_1', \mathbf{e}_2', \mathbf{e}_3'\}$ are:

$$T_{ij}' = \mathbf{e}_i' \cdot \mathbf{T}\mathbf{e}_j'. \tag{2.18.2}$$

With $\mathbf{e}_i' = Q_{mi}\mathbf{e}_m$, we have

$$T_{ij}' = Q_{mi}\mathbf{e}_m \cdot \mathbf{T}Q_{nj}\mathbf{e}_n = Q_{mi}Q_{nj}\mathbf{e}_m \cdot \mathbf{T}\mathbf{e}_n,$$

that is,

$$T_{ij}' = Q_{mi}Q_{nj}T_{mn}. \tag{2.18.3}$$

In matrix notation, the preceding equation reads:

$$\begin{bmatrix} T_{11}' & T_{12}' & T_{13}' \\ T_{21}' & T_{22}' & T_{23}' \\ T_{31}' & T_{32}' & T_{33}' \end{bmatrix} = \begin{bmatrix} Q_{11} & Q_{21} & Q_{31} \\ Q_{12} & Q_{22} & Q_{32} \\ Q_{13} & Q_{23} & Q_{33} \end{bmatrix} \begin{bmatrix} T_{11} & T_{12} & T_{13} \\ T_{21} & T_{22} & T_{23} \\ T_{31} & T_{32} & T_{33} \end{bmatrix} \begin{bmatrix} Q_{11} & Q_{12} & Q_{13} \\ Q_{21} & Q_{22} & Q_{23} \\ Q_{31} & Q_{32} & Q_{33} \end{bmatrix}, \tag{2.18.4}$$

or

$$[\mathbf{T}]' = [\mathbf{Q}]^{\mathrm{T}}\,[\mathbf{T}]\,[\mathbf{Q}]. \tag{2.18.5}$$

We can also express the unprimed components in terms of the primed components. Indeed, if we premultiply the preceding equation with $[\mathbf{Q}]$ and post-multiply it with $[\mathbf{Q}]^{\mathrm{T}}$, we obtain, since

$$[\mathbf{Q}]\,[\mathbf{Q}]^{\mathrm{T}} = [\mathbf{Q}]^{\mathrm{T}}[\mathbf{Q}] = [\mathbf{I}], \tag{2.18.6}$$

$$[\mathbf{T}] = [\mathbf{Q}]\,[\mathbf{T}]'\,[\mathbf{Q}]^{\mathrm{T}}. \tag{2.18.7}$$

In indicial notation, Eq. (2.18.7) reads

$$T_{ij} = Q_{im}Q_{jn}T'_{mn}. \tag{2.18.8}$$

Equations (2.18.5) [or Eq. (2.18.3)] and Eq. (2.18.7) [or Eq. (2.18.8)] are the transformation laws relating components of the *same* tensor with respect to different Cartesian unit bases. Again, it is important to note that in Eqs. (2.18.5) and (2.18.7), $[\mathbf{T}]$ and $[\mathbf{T}]'$ are different matrices of the *same* tensor $\mathbf{T}$. We note that the equation $[\mathbf{T}]' = [\mathbf{Q}]^{\mathrm{T}}[\mathbf{T}][\mathbf{Q}]$ differs from $\mathbf{T}' = \mathbf{Q}^{\mathrm{T}}\mathbf{T}\mathbf{Q}$ in that the former relates the components of the same tensor $\mathbf{T}$ whereas the latter relates the two different tensors $\mathbf{T}$ and $\mathbf{T}'$.

Example 2.18.1

Given that with respect to the basis $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$, the matrix of a tensor $\mathbf{T}$ is given by

$$[\mathrm{T}] = \begin{bmatrix} 0 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Find $[\mathbf{T}]'$, that is, find the matrix of $\mathbf{T}$ with respect to the $\mathbf{e}'_i$ basis, where $\{\mathbf{e}'_1, \mathbf{e}'_2, \mathbf{e}'_3\}$ is obtained by rotating $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ about its $\mathbf{e}_3$-axis through 90° (see Figure 2.17-1).

Solution

Since $\mathbf{e}'_1 = \mathbf{e}_2, \mathbf{e}'_2 = -\mathbf{e}_1$ and $\mathbf{e}'_3 = \mathbf{e}_3$, by Eq. (2.7.1) we have

$$[\mathbf{Q}] = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Thus, Eq. (2.18.5) gives

$$[\mathbf{T}]' = \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 2 & -1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

that is,

$$T'_{11} = 2, \quad T'_{12} = -1, \quad T'_{13} = 0, \quad T'_{22} = 0, \quad T'_{23} = 0, \quad T'_{33} = 1.$$

Example 2.18.2

Given a tensor $\mathbf{T}$ and its components T_{ij} and T'_{ij} with respect to two sets of bases $\{\mathbf{e}_i\}$ and $\{\mathbf{e}'_i\}$. Show that T_{ii} is invariant with respect to these bases, i.e., $T_{ii} = T'_{ii}$.

Solution

The primed components are related to the unprimed components by Eq. (2.18.3):

$$T'_{ij} = Q_{mi}Q_{nj}T_{mn},$$

thus,

$$T'_{ii} = Q_{mi}Q_{ni}T_{mn}.$$

But $Q_{mi}Q_{ni} = \delta_{mn}$ [Eq. (2.15.6)], therefore,

$$T'_{ii} = \delta_{mn}T_{mn} = T_{mm} = T_{ii},$$

that is,

$$T_{11} + T_{22} + T_{33} = T'_{11} + T'_{22} + T'_{33}.$$

We see from Example 2.18.1 that we can calculate all nine components of a tensor **T** with respect to $\{\mathbf{e}'_i\}$ from the matrix $[\mathrm{T}]_{\{\mathbf{e}_i\}}$ by using Eq. (2.18.5). However, there are often times when we need only a few components. Then it is more convenient to use Eq. (2.18.1). In matrix form, this equation is written:

$$T'_{ij} = [\mathbf{e}'_i]^{\mathrm{T}}[\mathbf{T}]\,[\mathbf{e}'_j], \tag{2.18.9}$$

where $[\mathbf{e}'_i]^{\mathrm{T}}$ denote the row matrix whose elements are the components of $\mathbf{e}'_i$ with respect to the basis $\{\mathbf{e}_i\}$.

Example 2.18.3

Obtain T'_{12} for the tensor **T** and the bases $\{\mathbf{e}_i\}$ and $\{\mathbf{e}'_i\}$ given in Example 2.18.1 by using Eq. (2.18.1).

Solution

Since $\mathbf{e}'_1 = \mathbf{e}_2$ and $\mathbf{e}'_2 = -\mathbf{e}_1$, therefore,

$$T'_{12} = \mathbf{e}'_1 \cdot \mathbf{T}\mathbf{e}'_2 = \mathbf{e}_2 \cdot \mathbf{T}(-\mathbf{e}_1) = -T_{21} = -1.$$

Alternatively, using Eq. (2.18.9), we have

$$T'_{12} = [\mathbf{e}'_1]^{\mathrm{T}}[\mathbf{T}][\mathbf{e}'_2] = [0 \quad 1 \quad 0]\begin{bmatrix} 0 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} -1 \\ 0 \\ 0 \end{bmatrix} = [0 \quad 1 \quad 0]\begin{bmatrix} 0 \\ -1 \\ 0 \end{bmatrix} = -1.$$

2.19 DEFINING TENSOR BY TRANSFORMATION LAWS

Equation (2.17.4) or (2.18.3) states that when the components of a vector or a tensor with respect to $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ are known, then its components with respect to any $\{\mathbf{e}'_1, \mathbf{e}'_2, \mathbf{e}'_3\}$ are uniquely determined from them. In other words, the components a_i or T_{ij} with respect to one set of $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ completely characterize a vector or a tensor. Thus, it is perfectly meaningful to use a statement such as "*consider a tensor* T_{ij}," meaning consider the tensor **T** whose components with respect to some set of $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ are T_{ij}. In fact, an alternative way of defining a tensor is through the use of transformation laws relating components of a tensor with respect to different bases. Confining ourselves to only rectangular Cartesian coordinate systems and using unit vectors along positive coordinate directions as base vectors, we now define Cartesian components of tensors of different orders in terms of their transformation laws in the following, where the primed quantities are

2.60 Do the previous problem for the following matrix: $[\mathbf{T}] = \begin{bmatrix} 3 & 0 & 0 \\ 0 & 0 & 4 \\ 0 & 4 & 0 \end{bmatrix}$.

2.61 A tensor **T** has a matrix given below. Find the principal values and three mutually perpendicular principal directions.

$$[\mathbf{T}] = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 2 \end{bmatrix}.$$

PART C: TENSOR CALCULUS

2.26 TENSOR-VALUED FUNCTIONS OF A SCALAR

Let $\mathbf{T} = \mathbf{T}(t)$ be a tensor-valued function of a scalar t (such as time). The derivative of **T** with respect to t is defined to be a second-order tensor given by:

$$\frac{d\mathbf{T}}{dt} = \lim_{\Delta t \to 0} \frac{\mathbf{T}(t+\Delta t) - \mathbf{T}(t)}{\Delta t}. \tag{2.26.1}$$

The following identities can be easily established:

$$\frac{d}{dt}(\mathbf{T}+\mathbf{S}) = \frac{d\mathbf{T}}{dt} + \frac{d\mathbf{S}}{dt}, \tag{2.26.2}$$

$$\frac{d}{dt}(\alpha(t)\mathbf{T}) = \frac{d\alpha}{dt}\mathbf{T} + \alpha\frac{d\mathbf{T}}{dt}, \tag{2.26.3}$$

$$\frac{d}{dt}(\mathbf{TS}) = \frac{d\mathbf{T}}{dt}\mathbf{S} + \mathbf{T}\frac{d\mathbf{S}}{dt}, \tag{2.26.4}$$

$$\frac{d}{dt}(\mathbf{Ta}) = \frac{d\mathbf{T}}{dt}\mathbf{a} + \mathbf{T}\frac{d\mathbf{a}}{dt}, \tag{2.26.5}$$

$$\frac{d}{dt}(\mathbf{T}^{\mathrm{T}}) = \left(\frac{d\mathbf{T}}{dt}\right)^{\mathrm{T}}. \tag{2.26.6}$$

We shall prove here only Eq. (2.26.5). The other identities can be proven in a similar way. Using the definition given in Eq. (2.26.1), we have

$$\begin{aligned}
\frac{d}{dt}(\mathbf{Ta}) &= \lim_{\Delta t \to 0} \frac{\mathbf{T}(t+\Delta t)\mathbf{a}(t+\Delta t) - \mathbf{T}(t)\mathbf{a}(t)}{\Delta t} \\
&= \lim_{\Delta t \to 0} \frac{\mathbf{T}(t+\Delta t)\mathbf{a}(t+\Delta t) - \mathbf{T}(t)\mathbf{a}(t) - \mathbf{T}(t)\mathbf{a}(t+\Delta t) + \mathbf{T}(t)\mathbf{a}(t+\Delta t)}{\Delta t} \\
&= \lim_{\Delta t \to 0} \frac{\mathbf{T}(t+\Delta t)\mathbf{a}(t+\Delta t) - \mathbf{T}(t)\mathbf{a}(t+\Delta t) + \mathbf{T}(t)\mathbf{a}(t+\Delta t) - \mathbf{T}(t)\mathbf{a}(t)}{\Delta t} \\
&= \lim_{\Delta t \to 0} \frac{\mathbf{T}(t+\Delta t) - \mathbf{T}(t)}{\Delta t}\mathbf{a}(t+\Delta t) + \lim_{\Delta t \to 0} \mathbf{T}(t)\frac{\mathbf{a}(t+\Delta t) - \mathbf{a}(t)}{\Delta t}.
\end{aligned}$$

Thus,

$$\frac{d(\mathbf{Ta})}{dt} = \frac{d\mathbf{T}}{dt}\mathbf{a} + \mathbf{T}\frac{d\mathbf{a}}{dt}.$$

Example 2.26.1

Show that in Cartesian coordinates, the components of $d\mathbf{T}/dt$, i.e., $(d\mathbf{T}/dt)_{ij}$ are given by the derivatives of the components dT_{ij}/dt.

Solution

From

$$T_{ij} = \mathbf{e}_i \cdot \mathbf{T}\mathbf{e}_j,$$

we have

$$\frac{dT_{ij}}{dt} = \frac{d\mathbf{e}_i}{dt} \cdot \mathbf{T}\mathbf{e}_j + \mathbf{e}_i \cdot \frac{d\mathbf{T}}{dt}\mathbf{e}_j + \mathbf{e}_i \cdot \mathbf{T}\frac{d\mathbf{e}_j}{dt}.$$

Since the base vectors are fixed, their derivatives are zero; therefore,

$$\frac{dT_{ij}}{dt} = \mathbf{e}_i \cdot \frac{d\mathbf{T}}{dt}\mathbf{e}_j = \left(\frac{d\mathbf{T}}{dt}\right)_{ij}.$$

Example 2.26.2

Show that for an orthogonal tensor $\mathbf{Q}(t)$, $\left(\frac{d\mathbf{Q}}{dt}\right)\mathbf{Q}^{\mathrm{T}}$ is an antisymmetric tensor.

Solution

Since $\mathbf{Q}\mathbf{Q}^{\mathrm{T}} = \mathbf{I}$, we have

$$\frac{d\left(\mathbf{Q}\mathbf{Q}^{\mathrm{T}}\right)}{dt} = \mathbf{Q}\frac{d\mathbf{Q}^{\mathrm{T}}}{dt} + \frac{d\mathbf{Q}}{dt}\mathbf{Q}^{\mathrm{T}} = \frac{d\mathbf{I}}{dt} = \mathbf{0}.$$

Since [see Eq. (2.26.6)] $\frac{d\mathbf{Q}^{T}}{dt} = \left(\frac{d\mathbf{Q}}{dt}\right)^{\mathrm{T}}$, therefore, the above equation leads to

$$\mathbf{Q}\left(\frac{d\mathbf{Q}}{dt}\right)^{\mathrm{T}} = -\frac{d\mathbf{Q}}{dt}\mathbf{Q}^{\mathrm{T}}.$$

Now $\mathbf{Q}\left(\frac{d\mathbf{Q}}{dt}\right)^{\mathrm{T}} = \left(\frac{d\mathbf{Q}}{dt}\mathbf{Q}^{\mathrm{T}}\right)^{\mathrm{T}}$; therefore,

$$\left(\frac{d\mathbf{Q}}{dt}\mathbf{Q}^{\mathrm{T}}\right)^{\mathrm{T}} = -\frac{d\mathbf{Q}}{dt}\mathbf{Q}^{\mathrm{T}},$$

that is, $\left(\frac{d\mathbf{Q}}{dt}\right)\mathbf{Q}^{\mathrm{T}}$ is an antisymmetric tensor.

Example 2.26.3

A time-dependent rigid body rotation about a fixed point can be represented by a rotation tensor $\mathbf{R}(t)$, so that a position vector $\mathbf{r}_{\mathrm{o}}$ is transformed through the rotation into $\mathbf{r}(t) = \mathbf{R}(t)\mathbf{r}_{\mathrm{o}}$. Derive the equation

$$\frac{d\mathbf{r}}{dt} = \boldsymbol{\omega} \times \mathbf{r}, \tag{2.26.7}$$

where $\boldsymbol{\omega}$ is the dual vector of the antisymmetric tensor $\frac{d\mathbf{R}}{dt}\mathbf{R}^{\mathrm{T}}$.

Solution

From $\mathbf{r}(t) = \mathbf{R}(t)\mathbf{r}_o$, we obtain

$$\frac{d\mathbf{r}}{dt} = \frac{d\mathbf{R}}{dt}\mathbf{r}_o = \frac{d\mathbf{R}}{dt}\mathbf{R}^{-1}\mathbf{r} = \frac{d\mathbf{R}}{dt}\mathbf{R}^{\mathrm{T}}\mathbf{r}. \tag{i}$$

But $\frac{d\mathbf{R}}{dt}\mathbf{R}^{\mathrm{T}}$ is an antisymmetric tensor (see the previous example, Example 2.26.2) so that

$$\frac{d\mathbf{r}}{dt} = \boldsymbol{\omega} \times \mathbf{r}, \tag{ii}$$

where $\boldsymbol{\omega}$ is the dual vector of $\frac{d\mathbf{R}}{dt}\mathbf{R}^{\mathrm{T}}$. From the well-known equation in rigid body kinematics, we can identify $\boldsymbol{\omega}$ as the angular velocity of the rigid body.

2.27 SCALAR FIELD AND GRADIENT OF A SCALAR FUNCTION

Let $\phi(\mathbf{r})$ be a scalar-valued function of the position vector $\mathbf{r}$. That is, for each position $\mathbf{r}$, $\phi(\mathbf{r})$ gives the value of a scalar, such as density, temperature, or electric potential at the point. In other words, $\phi(\mathbf{r})$ describes a scalar field. Associated with a scalar field is a vector field, called the *gradient* of ϕ. The gradient of ϕ at a point is defined to be a vector, denoted by grad ϕ or by $\nabla\phi$ such that its dot product with $d\mathbf{r}$ gives the difference of the values of the scalar at $\mathbf{r} + d\mathbf{r}$ and $\mathbf{r}$, i.e.,

$$d\phi = \phi(\mathbf{r} + d\mathbf{r}) - \phi(\mathbf{r}) = \nabla\phi \cdot d\mathbf{r}. \tag{2.27.1}$$

If dr denote the magnitude of $d\mathbf{r}$, and $\mathbf{e}$ the unit vector in the direction of $d\mathbf{r}$ (*Note:* $\mathbf{e} = d\mathbf{r}/dr$). Then the above equation gives, for $d\mathbf{r}$ in the $\mathbf{e}$ direction,

$$\frac{d\phi}{dr} = \nabla\phi \cdot \mathbf{e}. \tag{2.27.2}$$

That is, the component of $\nabla\phi$ in the direction of $\mathbf{e}$ gives the rate of change of ϕ in that direction (directional derivative). In particular, the components of $\nabla\phi$ in the coordinate directions $\mathbf{e}_i$ are given by

$$\frac{\partial\phi}{\partial x_i} = \left(\frac{d\phi}{dr}\right)_{\mathbf{e}_i - dir} = \nabla\phi \cdot \mathbf{e}_i. \tag{2.27.3}$$

Therefore, the Cartesian components of $\nabla\phi$ are $\partial\phi/\partial x_i$, that is,

$$\nabla\phi = \frac{\partial\phi}{\partial x_1}\mathbf{e}_1 + \frac{\partial\phi}{\partial x_2}\mathbf{e}_2 + \frac{\partial\phi}{\partial x_3}\mathbf{e}_3 = \frac{\partial\phi}{\partial x_i}\mathbf{e}_i. \tag{2.27.4}$$

The gradient vector has a simple geometrical interpretation. For example, if $\phi(\mathbf{r})$ describes a temperature field, then, on a surface of constant temperature (i.e., isothermal surface), $\phi =$ a constant. Let $\mathbf{r}$ be a point on an isothermal surface. Then, for any and all neighboring point $\mathbf{r}+d\mathbf{r}$ on the same isothermal surface, $d\phi = 0$. Thus,$\nabla\phi \cdot d\mathbf{r} = 0$. In other words, $\nabla\phi$ is a vector, perpendicular to the surface at the point $\mathbf{r}$. On the other hand, the dot product $\nabla\phi \cdot d\mathbf{r}$ is a maximum when $d\mathbf{r}$ is in the same direction as $\nabla\phi$. In other words, $\nabla\phi$ is greatest if $d\mathbf{r}$ is normal to the surface of constant ϕ and in this case, $d\phi = |\nabla\phi|dr$, or

$$\left(\frac{d\phi}{dr}\right)_{\max} = |\nabla\phi|, \tag{2.27.5}$$

for $d\mathbf{r}$ in the direction normal to the surface of constant temperature.

Example 2.27.1

If $\phi = x_1x_2 + 2x_3$, find a unit vector **n** normal to the surface of a constant ϕ passing through the point (2,1,0).

Solution

By Eq. (2.27.4),

$$\nabla\phi = \frac{\partial\phi}{\partial x_1}\mathbf{e}_1 + \frac{\partial\phi}{\partial x_2}\mathbf{e}_2 + \frac{\partial\phi}{\partial x_3}\mathbf{e}_3 = x_2\mathbf{e}_1 + x_1\mathbf{e}_2 + 2\mathbf{e}_3.$$

At the point (2,1,0), $\nabla\phi = \mathbf{e}_1 + 2\mathbf{e}_2 + 2\mathbf{e}_3$. Thus,

$$\mathbf{n} = \frac{1}{3}(\mathbf{e}_1 + 2\mathbf{e}_2 + 2\mathbf{e}_3).$$

Example 2.27.2

If **q** denotes the heat flux vector (rate of heat transfer/area), the Fourier heat conduction law states that

$$\mathbf{q} = -k\nabla\Theta, \tag{i}$$

where Θ is the temperature field and k is thermal conductivity. If $\Theta = 2(x_1^2 + x_2^2)$, find $\nabla\Theta$ at the location A (1,0) and $B\left(1/\sqrt{2}, 1/\sqrt{2}\right)$. Sketch curves of constant Θ (isotherms) and indicate the vectors **q** at the two points.

Solution

By Eq. (2.27.4),

$$\nabla\Theta = \frac{\partial\Theta}{\partial x_1}\mathbf{e}_1 + \frac{\partial\Theta}{\partial x_2}\mathbf{e}_2 + \frac{\partial\Theta}{\partial x_3}\mathbf{e}_3 = 4x_1\mathbf{e}_1 + 4x_2\mathbf{e}_2.$$

Thus,

$$\mathbf{q} = -4k(x_1\mathbf{e}_1 + x_2\mathbf{e}_2).$$

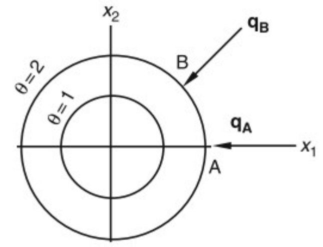

FIGURE 2.27-1

At point A,

$$\mathbf{q}_A = -4k\mathbf{e}_1,$$

and at point B,

$$\mathbf{q}_B = -2\sqrt{2}k(\mathbf{e}_1 + \mathbf{e}_2).$$

Clearly, the isotherms, Figure 2.27-1, are circles and the heat flux is an inward radial vector (consistent with heat flowing from higher to lower temperatures).

Example 2.27.3

A more general heat conduction law can be given in the following form:

$$\mathbf{q} = -\mathbf{K}\nabla\Theta,$$

where **K** is a tensor known as thermal conductivity tensor. (a) What tensor **K** corresponds to the Fourier heat conduction law mentioned in the previous example? (b) Find **q** if $\Theta = 2x_1 + 3x_2$, and

$$[\mathbf{K}] = \begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & 0 \\ 0 & 0 & 3 \end{bmatrix}.$$

Solution

(a) Clearly, $\mathbf{K} = k\mathbf{I}$, so that $\mathbf{q} = -k\mathbf{I}\nabla\Theta = -k\nabla\Theta$.

(b) $\nabla\Theta = 2\mathbf{e}_1 + 3\mathbf{e}_2$ and

$$[\mathbf{q}] = -\begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & 0 \\ 0 & 0 & 3 \end{bmatrix}\begin{bmatrix} 2 \\ 3 \\ 0 \end{bmatrix} = \begin{bmatrix} -1 \\ -4 \\ 0 \end{bmatrix}$$

that is,

$$\mathbf{q} = -\mathbf{e}_1 - 4\mathbf{e}_2,$$

which is clearly not normal to the isotherm (see Figure 2.27-2).

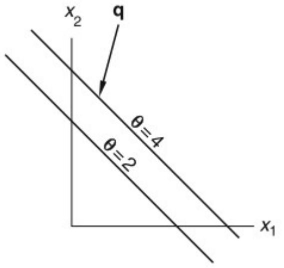

FIGURE 2.27-2

2.28 VECTOR FIELD AND GRADIENT OF A VECTOR FUNCTION

Let $\mathbf{v}(\mathbf{r})$ be a vector-valued function of position describing, for example, a displacement or a velocity field. Associated with $\mathbf{v}(\mathbf{r})$, is a tensor field, called the *gradient* of v, which is of considerable importance. The gradient of $\mathbf{v}$ (denoted by $\nabla\mathbf{v}$ or grad $\mathbf{v}$) is defined to be the second-order tensor, which, when operating on $d\mathbf{r}$, gives the difference of $\mathbf{v}$ at $\mathbf{r} + d\mathbf{r}$ and $\mathbf{r}$. That is,

$$d\mathbf{v} = \mathbf{v}(\mathbf{r} + d\mathbf{r}) - \mathbf{v}(\mathbf{r}) = (\nabla\mathbf{v})d\mathbf{r}. \tag{2.28.1}$$

Again, let dr denote $|d\mathbf{r}|$ and $\mathbf{e}$ denote $d\mathbf{r}/dr$; we have

$$\left(\frac{d\mathbf{v}}{dr}\right)_{\text{in } \mathbf{e}-\text{direction}} = (\nabla\mathbf{v})\mathbf{e}. \tag{2.28.2}$$

Therefore, the second-order tensor $\nabla\mathbf{v}$ transforms a unit vector $\mathbf{e}$ into the vector describing the rate of change of $\mathbf{v}$ in that direction. In Cartesian coordinates,

$$\left(\frac{d\mathbf{v}}{dr}\right)_{\text{in } \mathbf{e}_j-\text{direction}} = \frac{\partial\mathbf{v}}{\partial x_j} = (\nabla\mathbf{v})\mathbf{e}_j, \tag{2.28.3}$$

therefore, the components of $\nabla\mathbf{v}$ in indicial notation are given by

$$(\nabla\mathbf{v})_{ij} = \mathbf{e}_i \cdot (\nabla\mathbf{v})\mathbf{e}_j = \mathbf{e}_i \cdot \frac{\partial\mathbf{v}}{\partial x_j} = \frac{\partial(\mathbf{v}\cdot\mathbf{e}_i)}{\partial x_j} = \frac{\partial v_i}{\partial x_j}, \tag{2.28.4}$$

and in matrix form

$$[\nabla\mathbf{v}] = \begin{bmatrix} \frac{\partial v_1}{\partial x_1} & \frac{\partial v_1}{\partial x_2} & \frac{\partial v_1}{\partial x_3} \\ \frac{\partial v_2}{\partial x_1} & \frac{\partial v_2}{\partial x_2} & \frac{\partial v_2}{\partial x_3} \\ \frac{\partial v_3}{\partial x_1} & \frac{\partial v_3}{\partial x_2} & \frac{\partial v_3}{\partial x_3} \end{bmatrix}. \tag{2.28.5}$$

Geometrical interpretation of $\nabla\mathbf{v}$ will be given later in connection with the deformation of a continuum (Chapter 3).

2.29 DIVERGENCE OF A VECTOR FIELD AND DIVERGENCE OF A TENSOR FIELD

Let $\mathbf{v}(\mathbf{r})$ be a vector field. The *divergence* of $\mathbf{v}(\mathbf{r})$ is defined to be a scalar field given by the trace of the gradient of $\mathbf{v}$. That is,

$$\text{div } \mathbf{v} \equiv \text{tr}(\nabla\mathbf{v}). \tag{2.29.1}$$

In Cartesian coordinates, this gives

$$\text{div } \mathbf{v} = \frac{\partial v_1}{\partial x_1} + \frac{\partial v_2}{\partial x_2} + \frac{\partial v_3}{\partial x_3} = \frac{\partial v_i}{\partial x_i}. \tag{2.29.2}$$

Let $\mathbf{T}(\mathbf{r})$ be a tensor field. The divergence of $\mathbf{T}(\mathbf{r})$ is defined to be a vector field, denoted by div $\mathbf{T}$, such that for any vector $\mathbf{a}$

$$(\text{div } \mathbf{T}) \cdot \mathbf{a} \equiv \text{div}\left(\mathbf{T}^{\mathrm{T}}\mathbf{a}\right) - \text{tr}\left(\mathbf{T}^{\mathrm{T}}\nabla\mathbf{a}\right). \tag{2.29.3}$$

To find the Cartesian components of the vector div $\mathbf{T}$, let $\mathbf{b} = \text{div } \mathbf{T}$, then (*Note:* $\nabla\mathbf{e}_i = \mathbf{0}$ for Cartesian coordinates), from (2.29.3), we have

$$b_i = \mathbf{b} \cdot \mathbf{e}_i = \text{div}\left(\mathbf{T}^{\mathrm{T}}\mathbf{e}_i\right) - \text{tr}\left(\mathbf{T}^{\mathrm{T}}\nabla\mathbf{e}_i\right) = \text{div}\left(T_{ij}\mathbf{e}_j\right) - 0 = \partial T_{ij}/\partial x_j. \tag{2.29.4}$$

In other words,

$$\text{div } \mathbf{T} = \left(\partial T_{ij}/\partial x_j\right)\mathbf{e}_i. \tag{2.29.5*}$$

Example 2.29.1

Let $\alpha = \alpha(\mathbf{r})$ and $\mathbf{a} = \mathbf{a}(\mathbf{r})$. Show that $\text{div}(\alpha\mathbf{a}) = \alpha\text{div } \mathbf{a} + (\nabla\mathbf{v}) \cdot \mathbf{a}$.

Solution

Let $\mathbf{b} = \alpha\mathbf{a}$. Then $b_i = \alpha a_i$, so

$$\text{div } \mathbf{b} = \frac{\partial b_i}{\partial x_i} = \alpha\frac{\partial a_i}{\partial x_i} + \frac{\partial\alpha}{\partial x_i}a_i.$$

That is,

$$\text{div } (\alpha\mathbf{a}) = \alpha \text{ div } \mathbf{a} + (\nabla\alpha) \cdot \mathbf{a}. \tag{2.29.6}$$

Example 2.29.2

Given $\alpha = \alpha(\mathbf{r})$ and $\mathbf{T} = \mathbf{T}(\mathbf{r})$, show that

$$\text{div } (\alpha\mathbf{T}) = \mathbf{T}(\nabla\alpha) + \alpha \text{ div } \mathbf{T}. \tag{2.29.7}$$

Solution

We have, from (2.29.5),

$$\text{div } (\alpha\mathbf{T}) = \frac{\partial\left(\alpha T_{ij}\right)}{\partial x_j}\mathbf{e}_i = \frac{\partial\alpha}{\partial x_j}T_{ij}\mathbf{e}_i + \alpha\frac{\partial T_{ij}}{\partial x_j}\mathbf{e}_i = \mathbf{T}(\nabla\alpha) + \alpha \text{ div } \mathbf{T}.$$

---

*We note that the Cartesian components of the third-order tensor $\mathbf{M} \equiv \nabla\mathbf{T} = \nabla\left(T_{ij}\mathbf{e}_i\mathbf{e}_j\right)$are $\partial T_{ij}/\partial x_k$. In terms of $\mathbf{M} = M_{ijk}\mathbf{e}_i\mathbf{e}_j\mathbf{e}_k$, div $\mathbf{T}$ is a vector given by $M_{ijj}\mathbf{e}_i$. More on the components of $\nabla\mathbf{T}$ will be given in Chapter 8.

2.30 CURL OF A VECTOR FIELD

Let $\mathbf{v}(\mathbf{r})$ be a vector field. The *curl* of $\mathbf{v}(\mathbf{r})$ is defined to be a vector field given by twice the dual vector of the antisymmetric part of $\nabla\mathbf{v}$. That is

$$\text{curl } \mathbf{v} \equiv 2\mathbf{t}^{\mathbf{A}}, \tag{2.30.1}$$

where $\mathbf{t}^{\mathrm{A}}$ is the dual vector of $(\nabla\mathbf{v})^{\mathrm{A}}$.

In rectangular Cartesian coordinates,

$$[\nabla\mathbf{v}]^{\mathrm{A}} = \begin{bmatrix} 0 & \frac{1}{2}\left(\frac{\partial v_1}{\partial x_2} - \frac{\partial v_2}{\partial x_1}\right) & \frac{1}{2}\left(\frac{\partial v_1}{\partial x_3} - \frac{\partial v_3}{\partial x_1}\right) \\ -\frac{1}{2}\left(\frac{\partial v_1}{\partial x_2} - \frac{\partial v_2}{\partial x_1}\right) & 0 & \frac{1}{2}\left(\frac{\partial v_2}{\partial x_3} - \frac{\partial v_3}{\partial x_2}\right) \\ -\frac{1}{2}\left(\frac{\partial v_1}{\partial x_3} - \frac{\partial v_3}{\partial x_1}\right) & -\frac{1}{2}\left(\frac{\partial v_2}{\partial x_3} - \frac{\partial v_3}{\partial x_2}\right) & 0 \end{bmatrix}. \tag{2.30.2}$$

Thus, the curl of $\mathbf{v}(\mathbf{r})$ is given by [see Eq. (2.21.3)]:

$$\text{curl } \mathbf{v} = 2\mathbf{t}^{\mathrm{A}} = \left(\frac{\partial v_3}{\partial x_2} - \frac{\partial v_2}{\partial x_3}\right)\mathbf{e}_1 + \left(\frac{\partial v_1}{\partial x_3} - \frac{\partial v_3}{\partial x_1}\right)\mathbf{e}_2 + \left(\frac{\partial v_2}{\partial x_1} - \frac{\partial v_1}{\partial x_2}\right)\mathbf{e}_3. \tag{2.30.3}$$

It can be easily verified that in indicial notation

$$\text{curl } \mathbf{v} = -\varepsilon_{ijk}\frac{\partial v_j}{\partial x_k}\mathbf{e}_i. \tag{2.30.4}$$

2.31 LAPLACIAN OF A SCALAR FIELD

Let $f(\mathbf{r})$ be a scalar-valued function of the position vector $\mathbf{r}$. The definition of the Laplacian of a scalar field is given by

$$\nabla^2 f = \text{div } (\nabla f) = \text{tr}(\nabla(\nabla f)). \tag{2.31.1}$$

In rectangular coordinates the Laplacian becomes

$$\nabla^2 f = \text{tr}(\nabla(\nabla f)) = \frac{\partial^2 f}{\partial x_i \partial x_i} = \frac{\partial^2 f}{\partial x_1^2} + \frac{\partial^2 f}{\partial x_2^2} + \frac{\partial^2 f}{\partial x_3^2}. \tag{2.31.2}$$

2.32 LAPLACIAN OF A VECTOR FIELD

Let $\mathbf{v}(\mathbf{r})$ be a vector field. The Laplacian of $\mathbf{v}$ is defined by the following:

$$\nabla^2\mathbf{v} = \nabla\ (\text{div } \mathbf{v}) - \text{curl } (\text{curl } \mathbf{v}). \tag{2.32.1}$$

In rectangular coordinates,

$$\nabla(\text{div }\mathbf{v}) = \frac{\partial}{\partial x_i}\left(\frac{\partial v_k}{\partial x_k}\right)\mathbf{e}_i, \quad \text{curl }\mathbf{v} = -\varepsilon_{\alpha jk}\left(\frac{\partial v_j}{\partial x_k}\right)\mathbf{e}_\alpha, \tag{2.32.2}$$

and

$$\text{curl (curl }\mathbf{v}) = -\varepsilon_{i\alpha\beta}\frac{\partial}{\partial x_\beta}\left(-\varepsilon_{\alpha jk}\frac{\partial v_j}{\partial x_k}\right)\mathbf{e}_i = \varepsilon_{i\alpha\beta}\varepsilon_{\alpha jk}\frac{\partial}{\partial x_\beta}\left(\frac{\partial v_j}{\partial x_k}\right)\mathbf{e}_i. \tag{2.32.3}$$

Now $\varepsilon_{i\alpha\beta}\varepsilon_{\alpha jk} = -\varepsilon_{\alpha i\beta}\varepsilon_{\alpha jk} = -\left(\delta_{ij}\delta_{\beta k} - \delta_{ik}\delta_{\beta j}\right)$ [see Prob. 2.12], therefore,

$$\text{curl (curl }\mathbf{v}) = -\left(\delta_{ij}\delta_{\beta k} - \delta_{ik}\delta_{\beta j}\right)\frac{\partial}{\partial x_\beta}\left(\frac{\partial v_j}{\partial x_k}\right)\mathbf{e}_i = \left\{-\frac{\partial}{\partial x_\beta}\left(\frac{\partial v_i}{\partial x_\beta}\right) + \frac{\partial}{\partial x_\beta}\left(\frac{\partial v_\beta}{\partial x_i}\right)\right\}\mathbf{e}_i. \tag{2.32.4}$$

Thus,

$$\nabla^2\mathbf{v} = \nabla\text{ (div }\mathbf{v}) - \text{curl (curl }\mathbf{v}) = \frac{\partial}{\partial x_i}\left(\frac{\partial v_k}{\partial x_k}\right)\mathbf{e}_i - \left\{-\frac{\partial}{\partial x_\beta}\left(\frac{\partial v_i}{\partial x_\beta}\right) + \frac{\partial}{\partial x_i}\left(\frac{\partial v_\beta}{\partial x_\beta}\right)\right\}\mathbf{e}_i. \tag{2.32.5}$$

That is, in rectangular coordinates,

$$\nabla^2\mathbf{v} = \frac{\partial^2 v_i}{\partial x_\beta \partial x_\beta}\mathbf{e}_i = \nabla^2 v_i \mathbf{e}_\mathrm{i}. \tag{2.32.6}$$

In long form,

$$\nabla^2\mathbf{v} = \left(\frac{\partial^2 v_1}{\partial x_1^2} + \frac{\partial^2 v_1}{\partial x_2^2} + \frac{\partial^2 v_1}{\partial x_3^2}\right)\mathbf{e}_1 + \left(\frac{\partial^2 v_2}{\partial x_1^2} + \frac{\partial^2 v_2}{\partial x_2^2} + \frac{\partial^2 v_2}{\partial x_3^2}\right)\mathbf{e}_2 + \left(\frac{\partial^2 v_3}{\partial x_1^2} + \frac{\partial^2 v_3}{\partial x_2^2} + \frac{\partial^2 v_3}{\partial x_3^2}\right)\mathbf{e}_3. \tag{2.32.7}$$

Expressions for the polar, cylindrical, and spherical coordinate systems are given in Part D.

PROBLEMS FOR PART C

2.62 Prove the identity $\frac{d}{dt}(\mathbf{T}+\mathbf{S}) = \frac{d\mathbf{T}}{dt} + \frac{d\mathbf{S}}{dt}$ using the definition of derivative of a tensor.

2.63 Prove the identity $\frac{d}{dt}(\mathbf{TS}) = \mathbf{T}\frac{d\mathbf{S}}{dt} + \frac{d\mathbf{T}}{dt}\mathbf{S}$ using the definition of derivative of a tensor.

2.64 Prove that $\frac{d\mathbf{T}^\mathrm{T}}{dt} = \left(\frac{d\mathbf{T}}{dt}\right)^\mathrm{T}$ by differentiating the definition $\mathbf{a}\cdot\mathbf{Tb} = \mathbf{b}\cdot\mathbf{T}^\mathrm{T}\mathbf{a}$, where **a** and **b** are arbitrary constant vectors.

2.65 Consider the scalar field $\phi = x_1^2 + 3x_1x_2 + 2x_3$. (a) Find the unit vector normal to the surface of constant ϕ at the origin and at (1,0,1). (b) What is the maximum value of the directional derivative of ϕ at the origin? at (1,0,1)? (c) Evaluate $d\phi/dr$ at the origin if $d\mathbf{r} = ds(\mathbf{e}_1 + \mathbf{e}_3)$.

2.66 Consider the ellipsoidal surface defined by the equation $x^2/a^2 + y^2/b^2 + z^2/b^2 = 1$. Find the unit vector normal to the surface at a given point (x, y, z).

2.67 Consider the temperature field given by $\Theta = 3x_1x_2$. (a) If $\mathbf{q} = -k\nabla\Theta$, find the heat flux at the point $A(1,1,1)$. (b) If $\mathbf{q} = -\mathbf{K}\nabla\Theta$, find the heat flux at the same point, where

$$[\mathbf{K}] = \begin{bmatrix} k & 0 & 0 \\ 0 & 2k & 0 \\ 0 & 0 & 3k \end{bmatrix}.$$

2.68 Let $\phi(x_1, x_2, x_3)$ and $\psi(x_1, x_2, x_3)$ be scalar fields, and let $\mathbf{v}\ (x_1, x_2, x_3)$ and $\mathbf{w}\ (x_1, x_2, x_3)$ be vector fields. By writing the subscripted components form, verify the following identities:

(a) $\nabla(\phi + \psi) = \nabla\phi + \nabla\psi$, sample solution:

$$[\nabla(\phi + \psi)]_i = \frac{\partial(\phi + \psi)}{\partial x_i} = \frac{\partial\phi}{\partial x_i} + \frac{\partial\psi}{\partial x_i} = \nabla\phi + \nabla\psi,$$

(b) $\text{div}(\mathbf{v} + \mathbf{w}) = \text{div}\ \mathbf{v} + \text{div}\ \ \mathbf{w}$, (c) $\text{div}(\phi\mathbf{v}) = (\nabla\phi)\mathbf{v} + \phi(\text{div}\ \mathbf{v})$ and (d) $\text{div}(\text{curl}\ \mathbf{v}) = 0$.

2.69 Consider the vector field $\mathbf{v} = x_1^2\mathbf{e}_1 + x_3^2\mathbf{e}_2 + x_2^2\mathbf{e}_3$. For the point (1,1,0), find (a) $\nabla\mathbf{v}$, (b) $(\nabla\mathbf{v})\mathbf{v}$, (c) div $\mathbf{v}$ and curl $\mathbf{v}$, and (d) the differential $d\mathbf{v}$ for $d\mathbf{r} = ds(\mathbf{e}_1 + \mathbf{e}_2 + \mathbf{e}_3)/\sqrt{3}$.

PART D: CURVILINEAR COORDINATES

In Part C, the Cartesian components for various vector and tensor operations such as the gradient, the divergence, and the Laplacian of a scalar field and tensor fields were derived. In this part, components in polar, cylindrical, and spherical coordinates for these same operations will be derived.

2.33 POLAR COORDINATES

Consider polar coordinates (r,θ), (see Figure 2.33-1) such that

$$r = \sqrt{x_1^2 + x_2^2} \quad \text{and} \quad \theta = \tan^{-1}\frac{x_2}{x_1}. \tag{2.33.1}$$

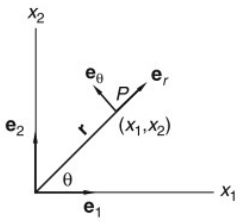

FIGURE 2.33-1

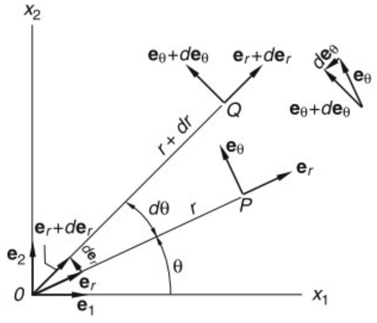
The unit base vectors $\mathbf{e}_r$ and $\mathbf{e}_\theta$ can be expressed in terms of the Cartesian base vectors $\mathbf{e}_1$ and $\mathbf{e}_2$ as

$$\mathbf{e}_r = \cos\theta\,\mathbf{e}_1 + \sin\theta\,\mathbf{e}_2, \quad \mathbf{e}_\theta = -\sin\theta\,\mathbf{e}_1 + \cos\theta\,\mathbf{e}_2. \tag{2.33.2}$$



x_2
$\mathbf{e}_\theta+d\mathbf{e}_\theta$
$\mathbf{e}_r+d\mathbf{e}_r$
$d\mathbf{e}_\theta$
$\mathbf{e}_\theta$
Q
$\mathbf{e}_\theta+d\mathbf{e}_\theta$
$r+dr$
$\mathbf{e}_\theta$
$\mathbf{e}_r$
$d\theta$
r
P
$\mathbf{e}_r+d\mathbf{e}_r$
$d\mathbf{e}_r$
$\mathbf{e}_2$

$\mathbf{e}_r$
0
$\mathbf{e}_1$
x_1

FIGURE 2.33-2

These unit base vectors vary in direction as θ changes. In fact, from Eqs. (2.33.2), we have

$$d\mathbf{e}_r = (-\sin\theta\mathbf{e}_1 + \cos\theta\mathbf{e}_2)d\theta = d\theta\mathbf{e}_\theta, \quad d\mathbf{e}_\theta = (-\cos\theta\mathbf{e}_1 - \sin\theta\mathbf{e}_2)d\theta = -d\theta\mathbf{e}_r. \tag{2.33.3}$$

The geometrical representation of $d\mathbf{e}_r$ and $d\mathbf{e}_\theta$ are shown in Figure 2.33-2, where one notes that $\mathbf{e}_r(P)$ has rotated an infinitesimal angle $d\theta$ to become $\mathbf{e}_r(Q) = \mathbf{e}_r(P) + d\mathbf{e}_r$ where $d\mathbf{e}_r$ is perpendicular to $\mathbf{e}_r(P)$ with a magnitude $|d\mathbf{e}_r| = (1)d\theta = d\theta$. Similarly, $d\mathbf{e}_\theta$ is perpendicular to $\mathbf{e}_\theta$ (P) but pointing in the negative $\mathbf{e}_r$ direction, and its magnitude is also $d\theta$.

Now, from the position vector

$$\mathbf{r} = r\mathbf{e}_r, \tag{2.33.4}$$

we have

$$d\mathbf{r} = dr\mathbf{e}_r + rd\mathbf{e}_r. \tag{2.33.5}$$

Using Eq. (2.33.3), we get

$$d\mathbf{r} = dr\mathbf{e}_r + rd\theta\mathbf{e}_\theta. \tag{2.33.6}$$

The geometrical representation of this equation is also easily seen if one notes that $d\mathbf{r}$ is the vector PQ in the preceding figure.

The components of ∇f, $\nabla\mathbf{v}$, div $\mathbf{v}$, div $\mathbf{T}$, $\nabla^2 f$ and $\nabla^2\mathbf{v}$ in polar coordinates will now be obtained.

(i) Components of ∇f:

Let $f(r,\theta)$ be a scalar field. By definition of the gradient of f, we have

$$df = \nabla f\cdot d\mathbf{r} = (a_r\mathbf{e}_r + a_\theta\mathbf{e}_\theta)\cdot(dr\mathbf{e}_r + rd\theta\mathbf{e}_\theta) = a_r dr + a_\theta rd\theta, \tag{2.33.7}$$

where a_r and a_θ are components of ∇f in the $\mathbf{e}_r$ and $\mathbf{e}_\theta$ direction, respectively. But from calculus,

$$df = \frac{\partial f}{\partial r}dr + \frac{\partial f}{\partial\theta}d\theta. \tag{2.33.8}$$

Since Eqs. (2.33.7) and (2.33.8) must yield the same result for all increments $dr, d\theta$, we have

$$a_r = \frac{\partial f}{\partial r}, \quad a_\theta = \frac{1}{r}\frac{\partial f}{\partial\theta}, \tag{2.33.9}$$

thus,

$$\nabla f = \frac{\partial f}{\partial r}\mathbf{e}_r + \frac{1}{r}\frac{\partial f}{\partial \theta}\mathbf{e}_\theta. \tag{2.33.10}$$

(ii) Components of $\nabla\mathbf{v}$: Let

$$\mathbf{v}(r,\theta) = v_r(r,\theta)\mathbf{e}_r + \mathrm{v}_\theta(r,\theta)\mathbf{e}_\theta. \tag{2.33.11}$$

By definition of $\nabla\mathbf{v}$, we have

$$d\mathbf{v} = \nabla\mathbf{v}d\mathbf{r}. \tag{2.33.12}$$

Let $\mathbf{T} = \nabla\mathbf{v}$. Then

$$d\mathbf{v} = \mathbf{T}d\mathbf{r} = \mathbf{T}(dr\mathbf{e}_r + rd\theta\mathbf{e}_\theta) = dr\mathbf{T}\mathbf{e}_r + rd\theta\mathbf{T}\mathbf{e}_\theta. \tag{2.33.13}$$

Now

$$\mathbf{T}\mathbf{e}_r = T_{rr}\mathbf{e}_r + T_{\theta r}\mathbf{e}_\theta \quad \text{and} \quad \mathbf{T}\mathbf{e}_\theta = T_{r\theta}\mathbf{e}_r + T_{\theta\theta}\mathbf{e}_\theta, \tag{2.33.14}$$

therefore,

$$d\mathbf{v} = (T_{rr}dr + T_{r\theta}rd\theta)\mathbf{e}_r + (T_{\theta r}dr + T_{\theta\theta}rd\theta)\mathbf{e}_\theta. \tag{2.33.15}$$

From Eq. (2.33.11), we also have

$$d\mathbf{v} = dv_r\mathbf{e}_r + v_r d\mathbf{e}_r + d\mathrm{v}_\theta\mathbf{e}_\theta + \mathrm{v}_\theta d\mathbf{e}_\theta. \tag{2.33.16}$$

Since [see Eq. (2.33.3)]

$$d\mathbf{e}_r = d\theta\mathbf{e}_\theta, \quad d\mathbf{e}_\theta = -d\theta\mathbf{e}_r, \tag{2.33.17}$$

therefore, Eq. (2.33.16) becomes

$$d\mathbf{v} = (dv_r - \mathrm{v}_\theta d\theta)\mathbf{e}_r + (v_r d\theta + d\mathrm{v}_\theta)\mathbf{e}_\theta. \tag{2.33.18}$$

From calculus,

$$dv_r = \frac{\partial v_r}{\partial r}dr + \frac{\partial v_r}{\partial \theta}d\theta, \quad d\mathrm{v}_\theta = \frac{\partial \mathrm{v}_\theta}{\partial r}dr + \frac{\partial \mathrm{v}_\theta}{\partial \theta}d\theta. \tag{2.33.19}$$

Substituting Eq. (2.33.19) into Eq. (2.33.18), we have

$$d\mathbf{v} = \left[\frac{\partial v_r}{\partial r}dr + \left(\frac{\partial v_r}{\partial \theta} - \mathrm{v}_\theta\right)d\theta\right]\mathbf{e}_r + \left[\frac{\partial \mathrm{v}_\theta}{\partial r}dr + \left(\frac{\partial \mathrm{v}_\theta}{\partial \theta} + v_r\right)d\theta\right]\mathbf{e}_\theta. \tag{2.33.20}$$

Eq. (2.33.15) and Eq. (2.33.20), then, give

$$\frac{\partial v_r}{\partial r}dr + \left(\frac{\partial v_r}{\partial \theta} - \mathrm{v}_\theta\right)d\theta = T_{rr}dr + T_{r\theta}rd\theta, \quad \frac{\partial \mathrm{v}_\theta}{\partial r}dr + \left(\frac{\partial \mathrm{v}_\theta}{\partial \theta} + v_r\right)d\theta = T_{\theta r}dr + T_{\theta\theta}rd\theta. \tag{2.33.21}$$

Eq. (2.33.21) must hold for any values of dr and $d\theta$. Thus,

$$T_{rr} = \frac{\partial v_r}{\partial r}, \quad T_{r\theta} = \frac{1}{r}\left(\frac{\partial v_r}{\partial \theta} - \mathrm{v}_\theta\right), \quad T_{\theta r} = \frac{\partial \mathrm{v}_\theta}{\partial r}, \quad T_{\theta\theta} = \frac{1}{r}\left(\frac{\partial \mathrm{v}_\theta}{\partial \theta} + v_r\right). \tag{2.33.22}$$

In matrix form,

$$[\nabla \mathbf{v}] = \begin{bmatrix} \dfrac{\partial v_r}{\partial r} & \dfrac{1}{r}\left(\dfrac{\partial v_r}{\partial \theta} - v_\theta\right) \\ \dfrac{\partial v_\theta}{\partial r} & \dfrac{1}{r}\left(\dfrac{\partial v_\theta}{\partial \theta} + v_r\right) \end{bmatrix}. \tag{2.33.23}$$

(iii) div **v**:
Using the components of $\nabla \mathbf{v}$ given in (ii), that is, Eq. (2.33.23), we have

$$\operatorname{div} \mathbf{v} = \operatorname{tr}(\nabla \mathbf{v}) = \frac{\partial v_r}{\partial r} + \frac{1}{r}\left(\frac{\partial v_\theta}{\partial \theta} + v_r\right). \tag{2.33.24}$$

(iv) Components of curl **v:**
The antisymmetric part of $\nabla \mathbf{v}$ is

$$[\nabla \mathbf{v}]^{\mathrm{A}} = \frac{1}{2}\begin{bmatrix} 0 & \dfrac{1}{r}\left(\dfrac{\partial v_r}{\partial \theta} - v_\theta\right) - \dfrac{\partial v_\theta}{\partial r} \\ -\left\{\dfrac{1}{r}\left(\dfrac{\partial v_r}{\partial \theta} - v_\theta\right) - \dfrac{\partial v_\theta}{\partial r}\right\} & 0 \end{bmatrix}. \tag{2.33.25}$$

Therefore, from the definition that curl $\mathbf{v}$ = twice the dual vector of $(\nabla \mathbf{v})^{\mathrm{A}}$, we have

$$\operatorname{curl} \mathbf{v} = \left(\frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} - \frac{1}{r}\frac{\partial v_r}{\partial \theta}\right)\mathbf{e}_3. \tag{2.33.26}$$

(v) Components of div **T:**
The invariant definition of the divergence of a second-order tensor is

$$(\operatorname{div} \mathbf{T}) \cdot \mathbf{a} = \operatorname{div}(\mathbf{T}^{\mathrm{T}}\mathbf{a}) - \operatorname{tr}((\nabla \mathbf{a})\mathbf{T}^{\mathrm{T}}) \text{ for any } \mathbf{a}. \tag{2.33.27}$$

Take $\mathbf{a} = \mathbf{e}_r$; then the preceding equation gives

$$(\operatorname{div} \mathbf{T})_r = \operatorname{div}(\mathbf{T}^{\mathrm{T}}\mathbf{e}_r) - \operatorname{tr}((\nabla \mathbf{e}_r)\mathbf{T}^{\mathrm{T}}). \tag{2.33.28}$$

To evaluate the first term on the right-hand side, we note that

$$\mathbf{T}^{\mathrm{T}}\mathbf{e}_r = T_{rr}\mathbf{e}_r + T_{r\theta}\mathbf{e}_\theta, \tag{2.33.29}$$

so that according to Eq. (2.33.24),

$$\operatorname{div}(\mathbf{T}^{\mathrm{T}}\mathbf{e}_r) = \operatorname{div}(T_{rr}\mathbf{e}_r + T_{r\theta}\mathbf{e}_\theta) = \frac{\partial T_{rr}}{\partial r} + \frac{1}{r}\left(\frac{\partial T_{r\theta}}{\partial \theta} + T_{rr}\right). \tag{2.33.30}$$

To evaluate the second term, we first use Eq. (2.33.23) to obtain $\nabla \mathbf{e}_r$. In fact, since $\mathbf{e}_r = (1)\mathbf{e}_r + (0)\mathbf{e}_\theta$, we have, with $v_r = 1$ and $v_\theta = 0$,

$$[\nabla \mathbf{e}_r] = \begin{bmatrix} 0 & 0 \\ 0 & \dfrac{1}{r} \end{bmatrix}, \quad [\nabla \mathbf{e}_r][\mathbf{T}^{\mathrm{T}}] = \begin{bmatrix} 0 & 0 \\ \dfrac{T_{r\theta}}{r} & \dfrac{T_{\theta\theta}}{r} \end{bmatrix}, \quad \mathrm{tr}([\nabla \mathbf{e}_r][\mathbf{T}^{\mathrm{T}}]) = \frac{T_{\theta\theta}}{r}. \tag{2.33.31}$$

Thus, Eq. (2.33.28) gives

$$(\mathrm{div}\,\mathbf{T})_r = \frac{\partial T_{rr}}{\partial r} + \frac{1}{r}\frac{\partial T_{r\theta}}{\partial \theta} + \frac{T_{rr} - T_{\theta\theta}}{r}. \tag{2.33.32}$$

In a similar manner, one can derive

$$(\mathrm{div}\,\mathbf{T})_\theta = \frac{\partial T_{\theta r}}{\partial r} + \frac{1}{r}\frac{\partial T_{\theta\theta}}{\partial \theta} + \frac{T_{r\theta} + T_{\theta r}}{r}. \tag{2.33.33}$$

(vi) Laplacian of $f(\mathbf{x})$:
Given a scalar field $f(\mathbf{x})$, the Laplacian of $f(\mathbf{x})$ is given by $\nabla^2 f = \mathrm{div}(\nabla f) = \mathrm{tr}(\nabla(\nabla f))$. In polar coordinates,

$$\nabla f = \frac{\partial f}{\partial r}\mathbf{e}_r + \frac{1}{r}\frac{\partial f}{\partial \theta}\mathbf{e}_\theta. \tag{2.33.34}$$

From, $\mathrm{div}\,\mathbf{v} = \dfrac{\partial v_r}{\partial r} + \dfrac{1}{r}\dfrac{\partial v_\theta}{\partial \theta} + \dfrac{v_r}{r}$, we have

$$\nabla^2 f = \mathrm{div}\,\nabla f = \frac{\partial^2 f}{\partial r^2} + \frac{1}{r^2}\frac{\partial^2 f}{\partial \theta^2} + \frac{1}{r}\frac{\partial f}{\partial r}. \tag{2.33.35}$$

(vii) Laplacian of a vector field $\mathbf{v}(\mathbf{x})$:
Laplacian of $\mathbf{v}$ is given by: $\nabla^2 \mathbf{v} = \nabla(\mathrm{div}\,\mathbf{v}) - \mathrm{curl}\,\mathrm{curl}\,\mathbf{v}$. Now, in polar coordinates:

$$\begin{aligned} \nabla(\mathrm{div}\,\mathbf{v}) &= \frac{\partial}{\partial r}\left(\frac{\partial v_r}{\partial r} + \frac{1}{r}\frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r}\right)\mathbf{e}_\mathrm{r} + \frac{1}{r}\frac{\partial}{\partial \theta}\left(\frac{\partial v_r}{\partial r} + \frac{1}{r}\frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r}\right)\mathbf{e}_\theta \\ &= \left(\frac{\partial^2 v_r}{\partial r^2} + \frac{1}{r}\frac{\partial^2 v_\theta}{\partial r \partial \theta} - \frac{1}{r^2}\frac{\partial v_\theta}{\partial \theta} + \frac{1}{r}\frac{\partial v_r}{\partial r} - \frac{v_r}{r^2}\right)\mathbf{e}_\mathrm{r} + \left(\frac{1}{r}\frac{\partial^2 v_r}{\partial \theta \partial r} + \frac{1}{r^2}\frac{\partial^2 v_\theta}{\partial \theta^2} + \frac{1}{r^2}\frac{\partial v_r}{\partial \theta}\right)\mathbf{e}_\theta, \end{aligned} \tag{2.33.36}$$

and

$$\mathrm{curl}\,\mathbf{v} = \left(\frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} - \frac{1}{r}\frac{\partial v_r}{\partial \theta}\right)\mathbf{e}_z. \tag{2.33.37}$$

Since [see Eq. (2.34.7)]

$$\mathrm{curl}\,\mathbf{v} = \left(\frac{1}{r}\frac{\partial v_z}{\partial \theta} - \frac{\partial v_\theta}{\partial z}\right)\mathbf{e}_r + \left(\frac{\partial v_r}{\partial z} - \frac{\partial v_z}{\partial r}\right)\mathbf{e}_\theta + \left(\frac{\partial v_\theta}{\partial r} + \frac{\mathrm{v}_\theta}{r} - \frac{1}{r}\frac{\partial v_r}{\partial \theta}\right)\mathbf{e}_z,$$

therefore,

$$(\mathrm{curl}\,\mathrm{curl}\,\mathbf{v})_r = \frac{1}{r}\frac{\partial}{\partial \theta}\left(\frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} - \frac{1}{r}\frac{\partial v_r}{\partial \theta}\right) = \left(\frac{1}{r}\frac{\partial^2 v_\theta}{\partial \theta \partial r} + \frac{1}{r^2}\frac{\partial v_\theta}{\partial \theta} - \frac{1}{r^2}\frac{\partial^2 v_r}{\partial \theta^2}\right), \tag{2.33.38}$$

$$(\text{curl curl }\mathbf{v})_\theta = -\frac{\partial}{\partial r}\left(\frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} - \frac{1}{r}\frac{\partial v_r}{\partial \theta}\right) = \left(-\frac{\partial^2 v_\theta}{\partial r^2} - \frac{1}{r}\frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r^2} + \frac{1}{r}\frac{\partial^2 v_r}{\partial r \partial \theta} - \frac{1}{r^2}\frac{\partial v_r}{\partial \theta}\right). \tag{2.33.39}$$

Thus,

$$(\nabla^2 \mathbf{v})_r = \frac{\partial^2 v_r}{\partial r^2} + \frac{1}{r^2}\frac{\partial^2 v_r}{\partial \theta^2} + \frac{\partial^2 v_r}{\partial z^2} + \frac{1}{r}\frac{\partial v_r}{\partial r} - \frac{2}{r^2}\frac{\partial v_\theta}{\partial \theta} - \frac{v_r}{r^2}, \tag{2.33.40}$$

and

$$(\nabla^2 \mathbf{v})_\theta = \frac{\partial^2 v_\theta}{\partial r^2} + \frac{1}{r^2}\frac{\partial^2 v_\theta}{\partial \theta^2} + \frac{1}{r}\frac{\partial v_\theta}{\partial r} + \frac{2}{r^2}\frac{\partial v_r}{\partial \theta} - \frac{v_\theta}{r^2}. \tag{2.33.41}$$

2.34 CYLINDRICAL COORDINATES

In cylindrical coordinates, the position of a point P is determined by (r, θ, z), where r and θ determine the position of the vertical projection of the point P on the xy plane (the point P' in Figure 2.34-1) and the coordinate z determines the height of the point P from the xy plane. In other words, the cylindrical coordinates is a polar coordinate (r, θ) in the xy plane plus a coordinate z perpendicular to the xy plane.

We shall denote the position vector of P by $\mathbf{R}$, rather than $\mathbf{r}$, to avoid confusion between the position vector $\mathbf{R}$ and the coordinate r (which is a radial distance in the xy plane). The unit vector $\mathbf{e}_r$ and $\mathbf{e}_\theta$ are on the xy plane and it is clear from Figure 2.34-1 that

$$\mathbf{R} = r\mathbf{e}_r + z\mathbf{e}_z, \tag{2.34.1}$$

and

$$d\mathbf{R} = dr\mathbf{e}_r + rd\mathbf{e}_r + dz\mathbf{e}_z + zd\mathbf{e}_z. \tag{2.34.2}$$

In the preceding equation, $d\mathbf{e}_r$ is given by exactly the same equation given earlier for the polar coordinates [Eq. (2.33.3)]. We note also that $\mathbf{e}_z$ never changes its direction or magnitude regardless where the point P is, thus $d\mathbf{e}_z = 0$. Therefore,

$$d\mathbf{R} = dr\mathbf{e}_r + rd\theta\,\mathbf{e}_\theta + dz\mathbf{e}_z. \tag{2.34.3}$$

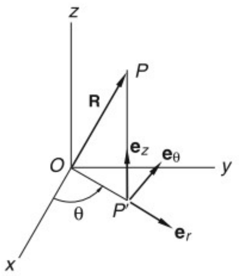

FIGURE 2.34-1

By retracing all the steps used in the previous section on polar coordinates, we can easily obtain the following results:

(i) Components of ∇f:

$$\nabla f = \frac{\partial f}{\partial r}\mathbf{e}_r + \frac{1}{r}\frac{\partial f}{\partial \theta}\mathbf{e}_\theta + \frac{\partial f}{\partial z}\mathbf{e}_z. \tag{2.34.4}$$

(ii) Components of $\nabla \mathbf{v}$:

$$[\nabla \mathbf{v}] = \begin{bmatrix} \dfrac{\partial v_r}{\partial r} & \dfrac{1}{r}\left(\dfrac{\partial v_r}{\partial \theta} - \mathrm{v}_\theta\right) & \dfrac{\partial v_r}{\partial z} \\[2ex] \dfrac{\partial v_\theta}{\partial r} & \dfrac{1}{r}\left(\dfrac{\partial v_\theta}{\partial \theta} + v_r\right) & \dfrac{\partial v_\theta}{\partial z} \\[2ex] \dfrac{\partial v_z}{\partial r} & \dfrac{1}{r}\dfrac{\partial v_z}{\partial \theta} & \dfrac{\partial v_z}{\partial z} \end{bmatrix}. \tag{2.34.5}$$

(iii) div $\mathbf{v}$:

$$\operatorname{div} \mathbf{v} = \frac{\partial v_r}{\partial r} + \frac{1}{r}\left(\frac{\partial v_\theta}{\partial \theta} + v_r\right) + \frac{\partial v_z}{\partial z}. \tag{2.34.6}$$

(iv) Components of curl $\mathbf{v}$:
The vector curl $\mathbf{v}$ = twice the dual vector of $(\nabla \mathbf{v})^{\mathrm{A}}$, thus,

$$\operatorname{curl} \mathbf{v} = \left(\frac{1}{r}\frac{\partial v_z}{\partial \theta} - \frac{\partial v_\theta}{\partial z}\right)\mathbf{e}_r + \left(\frac{\partial v_r}{\partial z} - \frac{\partial v_z}{\partial r}\right)\mathbf{e}_\theta + \left(\frac{\partial v_\theta}{\partial r} + \frac{\mathrm{v}_\theta}{r} - \frac{1}{r}\frac{\partial v_r}{\partial \theta}\right)\mathbf{e}_z. \tag{2.34.7}$$

(v) Components of div $\mathbf{T}$:

$$(\operatorname{div} \mathbf{T})_r = \frac{\partial T_{rr}}{\partial r} + \frac{1}{r}\frac{\partial T_{r\theta}}{\partial \theta} + \frac{T_{rr} - T_{\theta\theta}}{r} + \frac{\partial T_{rz}}{\partial z}, \tag{2.34.8}$$

$$(\operatorname{div} \mathbf{T})_\theta = \frac{\partial T_{\theta r}}{\partial r} + \frac{1}{r}\frac{\partial T_{\theta\theta}}{\partial \theta} + \frac{T_{r\theta} + T_{\theta r}}{r} + \frac{\partial T_{\theta z}}{\partial z}, \tag{2.34.9}$$

$$(\operatorname{div} \mathbf{T})_z = \frac{\partial T_{zr}}{\partial r} + \frac{1}{r}\frac{\partial T_{z\theta}}{\partial \theta} + \frac{\partial T_{zz}}{\partial z} + \frac{T_{zr}}{r}. \tag{2.34.10}$$

(vi) Laplacian of f:

$$\nabla^2 f = \operatorname{div} \nabla f = \frac{\partial^2 f}{\partial r^2} + \frac{1}{r^2}\frac{\partial^2 f}{\partial \theta^2} + \frac{1}{r}\frac{\partial f}{\partial r} + \frac{\partial^2 f}{\partial z^2}. \tag{2.34.11}$$

(vii) Laplacian of $\mathbf{v}$:

$$(\nabla^2 \mathbf{v})_r = \frac{\partial^2 v_r}{\partial r^2} + \frac{1}{r^2}\frac{\partial^2 v_r}{\partial \theta^2} + \frac{\partial^2 v_r}{\partial z^2} + \frac{1}{r}\frac{\partial v_r}{\partial r} - \frac{v_r}{r^2} - \frac{2}{r^2}\frac{\partial v_\theta}{\partial \theta}, \tag{2.34.12}$$

$$(\nabla^2\mathbf{v})_\theta = \frac{\partial^2 v_\theta}{\partial r^2} + \frac{1}{r^2}\frac{\partial^2 v_\theta}{\partial \theta^2} + \frac{\partial^2 v_\theta}{\partial z^2} + \frac{1}{r}\frac{\partial v_\theta}{\partial r} + \frac{2}{r^2}\frac{\partial v_r}{\partial \theta} - \frac{v_\theta}{r^2}, \tag{2.34.13}$$

$$(\nabla^2\mathbf{v})_z = \frac{\partial^2 v_z}{\partial r^2} + \frac{1}{r^2}\frac{\partial^2 v_z}{\partial \theta^2} + \frac{1}{r}\frac{\partial v_z}{\partial r} + \frac{\partial^2 v_z}{\partial z^2}. \tag{2.34.14}$$

2.35 SPHERICAL COORDINATES

In Figure 2.35-1, we show the spherical coordinates (r, θ, ϕ) of a general point P. In this figure, $\mathbf{e}_r$, $\mathbf{e}_\theta$ and $\mathbf{e}_\phi$ are unit vectors in the direction of increasing r, θ and ϕ, respectively.

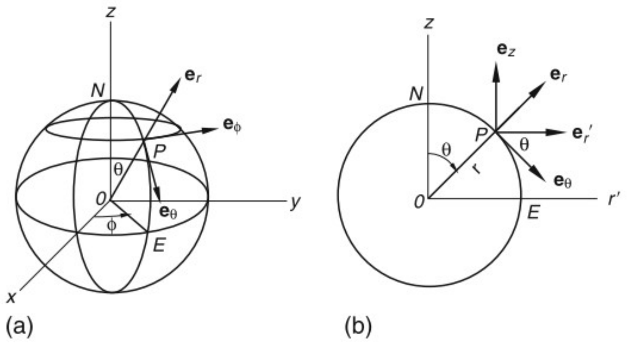

FIGURE 2.35-1

The position vector for the point P can be written as

$$\mathbf{r} = r\mathbf{e}_r, \tag{2.35.1}$$

where r is the magnitude of the vector $\mathbf{r}$. Thus,

$$d\mathbf{r} = dr\mathbf{e}_r + rd\mathbf{e}_r. \tag{2.35.2}$$

To evaluate $d\mathbf{e}_r$ we note from Figure 2.35-1(b) that

$$\mathbf{e}_r = \cos\theta\mathbf{e}_z + \sin\theta\mathbf{e}_r', \quad \mathbf{e}_\theta = \cos\theta\mathbf{e}_r' - \sin\theta\mathbf{e}_z, \tag{2.35.3}$$

where $\mathbf{e}_r'$ is the unit vector in the OE (i.e., r') direction (r' is in the xy plane). Thus,

$$d\mathbf{e}_r = -\sin\theta d\theta\mathbf{e}_z + \cos\theta d\mathbf{e}_z + \cos\theta d\theta\mathbf{e}_r' + \sin\theta d\mathbf{e}_r' = \left(-\sin\theta\mathbf{e}_z + \cos\theta\mathbf{e}_r'\right)d\theta + \sin\theta d\mathbf{e}_r',$$

that is,

$$d\mathbf{e}_r = d\theta\mathbf{e}_\theta + \sin\theta d\mathbf{e}_r'. \tag{2.35.4}$$

Now, just as in polar coordinates, due to $d\phi$,

$$d\mathbf{e}_r' = d\phi\mathbf{e}_\phi, \tag{2.35.5}$$

therefore,

$$d\mathbf{e}_r = d\theta\,\mathbf{e}_\theta + \sin\theta\, d\phi\,\mathbf{e}_\phi. \tag{2.35.6}$$

Now, from the second equation of (2.35.3), we have,

$$d\mathbf{e}_\theta = -\sin\theta\, d\theta\,\mathbf{e}_r' + \cos\theta\, d\mathbf{e}_r' - \cos\theta\, d\theta\,\mathbf{e}_z = -\left(\sin\theta\,\mathbf{e}_r' + \cos\theta\,\mathbf{e}_z\right)d\theta + \cos\theta\, d\mathbf{e}_r'.$$

Using Eq. (2.35.3) and Eq. (2.35.5), the preceding equation becomes

$$d\mathbf{e}_\theta = -\mathbf{e}_r d\theta + \cos\theta\, d\phi\,\mathbf{e}_\phi. \tag{2.35.7}$$

From Figure 2.35-1(a) and similar to the polar coordinate, we have

$$d\mathbf{e}_\phi = d\phi\left(-\mathbf{e}_r'\right). \tag{2.35.8}$$

With $\mathbf{e}_r' = \cos\theta\,\mathbf{e}_\theta + \sin\theta\,\mathbf{e}_r$ (see Figure 2.35-1(b)), the preceding equation becomes

$$d\mathbf{e}_\phi = -\sin\theta\, d\phi\,\mathbf{e}_r - \cos\theta\, d\phi\,\mathbf{e}_\theta. \tag{2.35.9}$$

Summarizing the preceding, we have

$$d\mathbf{e}_r = d\theta\,\mathbf{e}_\theta + \sin\theta\, d\phi\,\mathbf{e}_\phi, \quad d\mathbf{e}_\theta = -\mathbf{e}_r d\theta + \cos\theta\, d\phi\,\mathbf{e}_\phi, \quad d\mathbf{e}_\phi = -\sin\theta\, d\phi\,\mathbf{e}_r - \cos\theta\, d\phi\,\mathbf{e}_\theta, \tag{2.35.10}$$

and from Eq. (2.35.2), we have

$$d\mathbf{r} = dr\,\mathbf{e}_r + r\,d\theta\,\mathbf{e}_\theta + r\,\sin\theta\, d\phi\,\mathbf{e}_\phi. \tag{2.35.11}$$

We can now obtain the components of ∇f, $\nabla\mathbf{v}$, div $\mathbf{v}$, curl $\mathbf{v}$, div $\mathbf{T}$, $\nabla^2 f$, and $\nabla^2\mathbf{v}$ for spherical coordinates.

(i) Components of ∇f:

Let $f(r,\theta,\phi)$ be a scalar field. By the definition of ∇f, we have

$$df = \nabla f\cdot d\mathbf{r} = \left[(\nabla f)_r\mathbf{e}_r + (\nabla f)_\theta\mathbf{e}_\theta + (\nabla f)_\phi\mathbf{e}_\phi\right]\cdot\left(dr\,\mathbf{e}_r + r\,d\theta\,\mathbf{e}_\theta + r\sin\theta\, d\phi\,\mathbf{e}_\phi\right), \tag{2.35.12}$$

that is,

$$df = (\nabla f)_r\, dr + (\nabla f)_\theta\, r\,d\theta + (\nabla f)_\phi\, r\sin\theta\, d\phi. \tag{2.35.13}$$

From calculus, the total derivative of df is

$$df = \frac{\partial f}{\partial r}dr + \frac{\partial f}{\partial\theta}d\theta + \frac{\partial f}{\partial\phi}d\phi. \tag{2.35.14}$$

Comparing Eq. (2.35.14) and Eq. (2.35.13), we have

$$(\nabla f)_r = \frac{\partial f}{\partial r}, \quad (\nabla f)_\theta = \frac{1}{r}\frac{\partial f}{\partial\theta}, \quad (\nabla f)_\phi = \frac{1}{r\sin\theta}\frac{\partial f}{\partial\phi}. \tag{2.35.15}$$

(ii) Components of $\nabla\mathbf{v}$:

Let the vector field be represented by

$$\mathbf{v}(r,\theta,\phi) = v_r(r,\theta,\phi)\mathbf{e}_r + v_\theta(r,\theta,\phi)\mathbf{e}_\theta + v_\phi(r,\theta,\phi)\mathbf{e}_\phi. \tag{2.35.16}$$

Letting $\mathbf{T} = \nabla\mathbf{v}$, we have

$$d\mathbf{v} = \mathbf{T}d\mathbf{r} = \mathbf{T}\left(dr\mathbf{e}_r + rd\theta\mathbf{e}_\theta + r\sin\theta d\phi\mathbf{e}_\phi\right) = dr\mathbf{T}\mathbf{e}_r + rd\theta\mathbf{T}\mathbf{e}_\theta + r\sin\theta d\phi\mathbf{T}\mathbf{e}_\phi. \tag{2.35.17}$$

By the definition of components of a tensor T in spherical coordinates, we have

$$\begin{aligned}\mathbf{T}\mathbf{e}_r &= T_{rr}\mathbf{e}_r + T_{\theta r}\mathbf{e}_\theta + T_{\phi r}\mathbf{e}_\phi,\\ \mathbf{T}\mathbf{e}_\theta &= T_{r\theta}\mathbf{e}_r + T_{\theta\theta}\mathbf{e}_\theta + T_{\phi\theta}\mathbf{e}_\phi,\\ \mathbf{T}\mathbf{e}_\phi &= T_{r\phi}\mathbf{e}_r + T_{\theta\phi}\mathbf{e}_\theta + T_{\phi\phi}\mathbf{e}_\phi.\end{aligned} \tag{2.35.18}$$

Substituting these into Eq. (2.35.17), we get

$$\begin{aligned}d\mathbf{v} = \left(T_{rr}dr + T_{r\theta}rd\theta + T_{r\phi}r\ \sin\theta d\phi\right)\mathbf{e}_r + \left(T_{\theta\theta}rd\theta + T_{\theta r}dr + T_{\theta\phi}r\ \sin\theta d\phi\right)\mathbf{e}_\theta\\ +\left(T_{\phi r}dr + T_{\phi\theta}rd\theta + T_{\phi\phi}r\ \sin\theta d\phi\right)\mathbf{e}_\phi.\end{aligned} \tag{2.35.19}$$

We also have, from Eq. (2.35.16),

$$d\mathbf{v} = dv_r\mathbf{e}_r + v_r d\mathbf{e}_r + dv_\theta\mathbf{e}_\theta + v_\theta d\mathbf{e}_\theta + dv_\phi\mathbf{e}_\phi + v_\phi d\mathbf{e}_\phi. \tag{2.35.20}$$

Using the expression for the total derivatives:

$$\begin{aligned}dv_r &= \frac{\partial v_r}{\partial r}dr + \frac{\partial v_r}{\partial\theta}d\theta + \frac{\partial v_r}{\partial\phi}d\phi,\\ dv_\theta &= \frac{\partial v_\theta}{\partial r}dr + \frac{\partial v_\theta}{\partial\theta}d\theta + \frac{\partial v_\theta}{\partial\phi}d\phi,\\ dv_\phi &= \frac{\partial v_\phi}{\partial r}dr + \frac{\partial v_\phi}{\partial\theta}d\theta + \frac{\partial v_\phi}{\partial\phi}d\phi,\end{aligned} \tag{2.35.21}$$

Eq. (2.35.10) and Eq. (2.35.20) become

$$\begin{aligned}d\mathbf{v} = &\left\{\frac{\partial v_r}{\partial r}dr + \left(\frac{\partial v_r}{\partial\theta} - v_\theta\right)d\theta + \left(\frac{\partial v_r}{\partial\phi} - v_\phi\sin\theta\right)d\phi\right\}\mathbf{e}_r\\ &+\left\{\frac{\partial v_\theta}{\partial r}dr + \left(v_r + \frac{\partial v_\theta}{\partial\theta}\right)d\theta + \left(\frac{\partial v_\theta}{\partial\phi} - v_\phi\ \cos\theta\right)d\phi\right\}\mathbf{e}_\theta\\ &+\left\{\frac{\partial v_\phi}{\partial r}dr + \frac{\partial v_\phi}{\partial\theta}d\theta + \left(\frac{\partial v_\phi}{\partial\phi} + v_r\ \sin\theta + v_\theta\ \cos\theta\right)d\phi\right\}\mathbf{e}_\phi.\end{aligned} \tag{2.35.22}$$

Now, comparing Eq. (2.35.22) with Eq. (2.35.19), we have

$$\begin{aligned}\left(T_{rr}dr + T_{r\theta}rd\theta + T_{r\phi}r\ \sin\theta d\phi\right) &= \left\{\frac{\partial v_r}{\partial r}dr + \left(\frac{\partial v_r}{\partial\theta} - v_\theta\right)d\theta + \left(\frac{\partial v_r}{\partial\phi} - v_\phi\ \sin\theta\right)d\phi\right\},\\ \left(T_{\theta r}dr + T_{\theta\theta}rd\theta + T_{\theta\phi}r\ \sin\theta d\phi\right) &= \left\{\frac{\partial v_\theta}{\partial r}dr + \left(v_r + \frac{\partial v_\theta}{\partial\theta}\right)d\theta + \left(\frac{\partial v_\theta}{\partial\phi} - v_\phi\ \cos\theta\right)d\phi\right\},\\ \left(T_{\phi r}dr + T_{\phi\theta}rd\theta + T_{\phi\phi}r\ \sin\theta d\phi\right) &= \left\{\frac{\partial v_\phi}{\partial r}dr + \frac{\partial v_\phi}{\partial\theta}d\theta + \left(\frac{\partial v_\phi}{\partial\phi} + v_r\ \sin\theta + v_\theta\ \cos\theta\right)d\phi\right\}.\end{aligned} \tag{2.35.23}$$

These equations must be valid for arbitrary values of dr, $d\theta$ and $d\phi$, therefore,

$$\begin{aligned}
&T_{rr}=\frac{\partial v_r}{\partial r},\quad T_{r\theta}r=\left(\frac{\partial v_r}{\partial\theta}-v_\theta\right),\quad T_{r\phi}r\sin\theta=\left(\frac{\partial v_r}{\partial\phi}-v_\phi\sin\theta\right),\\
&T_{\theta r}=\frac{\partial v_\theta}{\partial r},\quad T_{\theta\theta}r=\left(v_r+\frac{\partial v_\theta}{\partial\theta}\right),\quad T_{\theta\phi}r\sin\theta=\left(\frac{\partial v_\theta}{\partial\phi}-v_\phi\cos\theta\right),\\
&T_{\phi r}=\frac{\partial v_\phi}{\partial r},\quad T_{\phi\theta}r=\frac{\partial v_\phi}{\partial\theta},\quad T_{\phi\phi}r\sin\theta=\left(\frac{\partial v_\phi}{\partial\phi}+v_r\sin\theta+v_\theta\cos\theta\right).
\end{aligned}\tag{2.35.24}$$

In matrix form, we have

$$[\nabla\mathbf{v}]=\begin{bmatrix}
\dfrac{\partial v_r}{\partial r} & \dfrac{1}{r}\dfrac{\partial v_r}{\partial\theta}-\dfrac{v_\theta}{r} & \dfrac{1}{r\sin\theta}\dfrac{\partial v_r}{\partial\phi}-\dfrac{v_\phi}{r}\\
\dfrac{\partial v_\theta}{\partial r} & \dfrac{1}{r}\dfrac{\partial v_\theta}{\partial\theta}+\dfrac{v_r}{r} & \dfrac{1}{r\sin\theta}\dfrac{\partial v_\theta}{\partial\phi}-\dfrac{v_\phi\cot\theta}{r}\\
\dfrac{\partial v_\phi}{\partial r} & \dfrac{1}{r}\dfrac{\partial v_\phi}{\partial\theta} & \dfrac{1}{r\sin\theta}\dfrac{\partial v_\phi}{\partial\phi}+\dfrac{v_r}{r}+\dfrac{v_\theta\cot\theta}{r}
\end{bmatrix}.\tag{2.35.25}$$

(iii) div **v**:
Using Eq. (2.35.25), we obtain

$$\begin{aligned}
\operatorname{div}\mathbf{v}=\operatorname{tr}(\nabla\mathbf{v})&=\frac{\partial v_r}{\partial r}+\frac{1}{r}\frac{\partial v_\theta}{\partial\theta}+\frac{1}{r\sin\theta}\frac{\partial v_\phi}{\partial\phi}+\frac{2v_r}{r}+\frac{v_\theta\cot\theta}{r}\\
&=\frac{1}{r^2}\frac{\partial(r^2v_r)}{\partial r}+\frac{1}{r\sin\theta}\frac{\partial(v_\theta\sin\theta)}{\partial\theta}+\frac{1}{r\sin\theta}\frac{\partial v_\phi}{\partial\phi}.
\end{aligned}\tag{2.35.26}$$

(iv) Components of curl **v**:
The vector curl **v** = twice the dual vector of $(\nabla\mathbf{v})^{\mathrm{A}}$, therefore

$$\begin{aligned}
\operatorname{curl}\mathbf{v}=&\left\{\frac{v_\phi\cot\theta}{r}+\frac{1}{r}\frac{\partial v_\phi}{\partial\theta}-\frac{1}{r\sin\theta}\frac{\partial v_\theta}{\partial\phi}\right\}\mathbf{e}_r+\left\{\frac{1}{r\sin\theta}\frac{\partial v_r}{\partial\phi}-\frac{1}{r}\frac{\partial(rv_\phi)}{\partial r}\right\}\mathbf{e}_\theta\\
&+\left\{\frac{1}{r}\frac{\partial(rv_\theta)}{\partial r}-\frac{1}{r}\frac{\partial v_r}{\partial\theta}\right\}\mathbf{e}_\phi.
\end{aligned}\tag{2.35.27}$$

(v) Components of div **T**:
Using the definition of div **T** given in Eq. (2.33.27) and take $\mathbf{a}=\mathbf{e}_r$, we have

$$(\operatorname{div}\mathbf{T})_r=\operatorname{div}(\mathbf{T}^{\mathrm{T}}\mathbf{e}_r)-\operatorname{tr}((\nabla\mathbf{e}_r)\mathbf{T}^{\mathrm{T}}).\tag{2.35.28}$$

To evaluate the first term on the right-hand side, we note that

$$\mathbf{T}^{\mathrm{T}}\mathbf{e}_r=T_{rr}\mathbf{e}_r+T_{r\theta}\mathbf{e}_\theta+T_{r\phi}\mathbf{e}_\phi,\tag{2.35.29}$$

so that by using Eq. (2.35.26) for the divergence of a vector in spherical coordinates, we obtain,

$$\operatorname{div}(\mathbf{T}^{\mathrm{T}}\mathbf{e}_r) = \frac{1}{r^2}\frac{\partial(r^2 T_{rr})}{\partial r} + \frac{1}{r\sin\theta}\frac{\partial(T_{r\theta}\sin\theta)}{\partial\theta} + \frac{1}{r\sin\theta}\frac{\partial T_{r\phi}}{\partial\phi}. \tag{2.35.30}$$

To evaluate the second term in Eq. (2.35.28), we first used Eq. (2.35.25) to evaluate $\nabla\mathbf{e}_r$, then calculate $(\nabla\mathbf{e}_r)\mathbf{T}^{\mathrm{T}}$:

$$[\nabla\mathbf{e}_r] = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1/r & 0 \\ 0 & 0 & 1/r \end{bmatrix},\ [(\nabla\mathbf{e}_r)\mathbf{T}^{\mathrm{T}}] = \begin{bmatrix} 0 & 0 & 0 \\ T_{r\theta}/r & T_{\theta\theta}/r & T_{\phi\theta}/r \\ T_{r\phi}/r & T_{\theta\phi}/r & T_{\phi\phi}/r \end{bmatrix} \tag{2.35.31}$$

thus,

$$\operatorname{tr}((\nabla\mathbf{e}_r)\mathbf{T}^{\mathrm{T}}) = \frac{T_{\theta\theta}}{r} + \frac{T_{\phi\phi}}{r}. \tag{2.35.32}$$

Substituting Eq. (2.35.32) and Eq. (2.35.30) into Eq. (2.35.28), we obtain,

$$(\operatorname{div}\mathbf{T})_r = \frac{1}{r^2}\frac{\partial(r^2 T_{rr})}{\partial r} + \frac{1}{r\sin\theta}\frac{\partial(T_{r\theta}\sin\theta)}{\partial\theta} + \frac{1}{r\sin\theta}\frac{\partial T_{r\phi}}{\partial\phi} - \frac{T_{\theta\theta}+T_{\phi\phi}}{r}. \tag{2.35.33}$$

In a similar manner, we can obtain (see Prob. 2.75)

$$(\operatorname{div}\mathbf{T})_\theta = \frac{1}{r^3}\frac{\partial(r^3 T_{\theta r})}{\partial r} + \frac{1}{r\sin\theta}\frac{\partial(T_{\theta\theta}\sin\theta)}{\partial\theta} + \frac{1}{r\sin\theta}\frac{\partial T_{\theta\phi}}{\partial\phi} + \frac{T_{r\theta}-T_{\theta r}-T_{\phi\phi}\cot\theta}{r} \tag{2.35.34}$$

$$(\operatorname{div}\mathbf{T})_\phi = \frac{1}{r^3}\frac{\partial\left(r^3 T_{\phi r}\right)}{\partial r} + \frac{1}{r\sin\theta}\frac{\partial(T_{\phi\theta}\sin\theta)}{\partial\theta} + \frac{1}{r\sin\theta}\frac{\partial T_{\phi\phi}}{\partial\phi} + \frac{T_{r\phi}-T_{\phi r}+T_{\theta\phi}\cot\theta}{r}. \tag{2.35.35}$$

(vi) Laplacian of f:
From

$$\begin{gathered}\operatorname{div}\mathbf{v} = \frac{1}{r^2}\frac{\partial(r^2 v_r)}{\partial r} + \frac{1}{r\sin\theta}\frac{\partial v_\theta\sin\theta}{\partial\theta} + \frac{1}{r\sin\theta}\frac{\partial v_\phi}{\partial\phi}, \\ \nabla f = \frac{\partial f}{\partial r}\mathbf{e}_r + \frac{1}{r}\frac{\partial f}{\partial\theta}\mathbf{e}_\theta + \frac{1}{r\sin\theta}\frac{\partial f}{\partial\phi}\mathbf{e}_\phi,\end{gathered} \tag{2.35.36}$$

we have

$$\begin{aligned}\nabla^2 f = \operatorname{div}(\nabla f) &= \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial f}{\partial r}\right) + \frac{1}{r\sin\theta}\frac{\partial}{\partial\theta}\left(\frac{1}{r}\frac{\partial f}{\partial\theta}\sin\theta\right) + \frac{1}{r\sin\theta}\frac{\partial}{\partial\phi}\left(\frac{1}{r\sin\theta}\frac{\partial f}{\partial\phi}\right) \\ &= \frac{\partial^2 f}{\partial r^2} + \frac{2}{r}\frac{\partial f}{\partial r} + \frac{1}{r^2}\left(\frac{\partial^2 f}{\partial\theta^2}\right) + \frac{\cot\theta}{r^2}\frac{\partial f}{\partial\theta} + \frac{1}{r^2\sin^2\theta}\left(\frac{\partial^2 f}{\partial\phi^2}\right).\end{aligned} \tag{2.35.37}$$

(vii) Laplacian of a vector function $\mathbf{v}$:
It can be obtained (see Prob. 2.75)

$$\begin{aligned}\nabla(\text{div } \mathbf{v}) = &\left(\frac{1}{r^2}\frac{\partial^2 r^2 v_r}{\partial r^2} - \frac{2}{r^3}\frac{\partial r^2 v_r}{\partial r} + \frac{1}{r\sin\theta}\left(\frac{\partial^2 v_\theta \sin\theta}{\partial r \partial\theta} + \frac{\partial^2 v_\phi}{\partial r \partial\phi}\right) - \frac{1}{r^2\sin\theta}\left(\frac{\partial v_\theta \sin\theta}{\partial\theta} + \frac{\partial v_\phi}{\partial\phi}\right)\right)\mathbf{e}_r \\ &+\left(\frac{1}{r^3}\frac{\partial^2 r^2 v_r}{\partial\theta\partial r} + \frac{1}{r^2\sin\theta}\left(\frac{\partial^2 v_\theta \sin\theta}{\partial\theta^2} + \frac{\partial^2 v_\theta \sin\theta}{\partial\theta^2}\right) - \frac{1}{r^2}\left(\frac{\cos\theta}{\sin^2\theta}\right)\frac{\partial v_\theta \sin\theta}{\partial\theta} + \frac{1}{r^2}\frac{\partial}{\partial\theta}\frac{1}{\sin\theta}\frac{\partial v_\phi}{\partial\phi}\right)\mathbf{e}_\theta \\ &+\left(\frac{1}{r^3\sin\theta}\frac{\partial}{\partial\phi}\frac{\partial(r^2 v_r)}{\partial r} + \frac{1}{r^2\sin^2\theta}\frac{\partial^2(v_\theta\sin\theta)}{\partial\phi\partial\theta} + \frac{1}{r^2\sin^2\theta}\frac{\partial^2 v_\phi}{\partial^2\phi}\right)\mathbf{e}_\phi,\end{aligned} \tag{2.35.38}$$

and

$$\begin{aligned}\text{curl curl } \mathbf{v} = &\left\{\frac{1}{r^2}\left(\frac{\partial^2 r v_\theta}{\partial\theta\partial r} - \frac{\partial^2 v_r}{\partial\theta^2}\right) + \frac{\cot\theta}{r}\left(\frac{1}{r}\frac{\partial r v_\theta}{\partial r} - \frac{1}{r}\frac{\partial v_r}{\partial\theta}\right) - \left(\frac{1}{r^2\sin^2\theta}\frac{\partial^2 v_r}{\partial\phi^2} - \frac{1}{r^2\sin\theta}\frac{\partial^2 r v_\phi}{\partial\phi\partial r}\right)\right\}\mathbf{e}_r \\ &+\left\{\frac{1}{r^2\sin^2\theta}\left(\frac{\partial^2 v_\phi\sin\theta}{\partial\phi\partial\theta} - \frac{\partial^2 v_\theta}{\partial\phi^2}\right) - \frac{1}{r^2}\left(\frac{\partial r v_\theta}{\partial r} - \frac{\partial v_r}{\partial\theta}\right) - \left(\frac{1}{r}\frac{\partial^2 r v_\theta}{\partial r^2} - \frac{1}{r^2}\frac{\partial r v_\theta}{\partial r} - \frac{1}{r}\frac{\partial^2 v_r}{\partial r\partial\theta} + \frac{1}{r^2}\frac{\partial v_r}{\partial\theta}\right)\right\}\mathbf{e}_\theta \\ &+\left\{\begin{array}{l}\left(\dfrac{1}{r\sin\theta}\dfrac{\partial v_r}{\partial r\partial\phi} - \dfrac{1}{r^2}\dfrac{1}{\sin\theta}\dfrac{\partial v_r}{\partial\phi} - \dfrac{1}{r}\dfrac{\partial^2 r v_\phi}{\partial r^2} + \dfrac{1}{r^2}\dfrac{\partial r v_\phi}{\partial r}\right) + \dfrac{1}{r^2}\left(\dfrac{1}{\sin\theta}\dfrac{\partial v_r}{\partial\phi} - \dfrac{\partial r v_\phi}{\partial r}\right) \\ -\dfrac{1}{r^2}\dfrac{1}{\sin\theta}\left(-v_\phi\sin\theta + \sin\theta\dfrac{\partial^2 v_\phi}{\partial\theta^2} - \dfrac{\partial^2 v_\theta}{\partial\theta\partial\phi}\right) + \dfrac{\cos\theta}{r^2\sin^2\theta}\left(\dfrac{\partial v_\phi\sin\theta}{\partial\theta} - \dfrac{\partial v_\theta}{\partial\phi}\right)\end{array}\right\}\mathbf{e}_\phi.\end{aligned} \tag{2.35.39}$$

Thus, $\nabla^2\mathbf{v} = \nabla(\text{div } \mathbf{v}) - \text{curl curl } \mathbf{v}$ leads to:

$$(\nabla^2\mathbf{v})_r = \left(\begin{array}{l}\dfrac{1}{r^2}\dfrac{\partial^2 r^2 v_r}{\partial r^2} - \dfrac{2}{r^3}\dfrac{\partial r^2 v_r}{\partial r} + \dfrac{1}{r^2}\dfrac{\partial^2 v_r}{\partial\theta^2} + \dfrac{\cot\theta}{r^2}\dfrac{\partial v_r}{\partial\theta} + \dfrac{1}{r^2\sin^2\theta}\dfrac{\partial^2 v_r}{\partial\phi^2} - \dfrac{2}{r^2\sin\theta}\dfrac{\partial v_\theta\sin\theta}{\partial\theta} \\ -\dfrac{2}{r^2\sin\theta}\dfrac{\partial v_\phi}{\partial\phi}\end{array}\right), \tag{2.35.40}$$

$$(\nabla^2\mathbf{v})_\theta = \left(\begin{array}{l}\dfrac{1}{r^2}\dfrac{\partial}{\partial r}\left(r^2\dfrac{\partial v_\theta}{\partial r}\right) + \dfrac{1}{r^2}\dfrac{\partial}{\partial\theta}\left\{\dfrac{1}{\sin\theta}\dfrac{\partial}{\partial\theta}(v_\theta\sin\theta)\right\} + \dfrac{1}{r^2\sin^2\theta}\dfrac{\partial^2 v_\theta}{\partial\phi^2} \\ +\dfrac{2}{r^2}\dfrac{\partial v_r}{\partial\theta} - \dfrac{2}{r^2}\dfrac{\cot\theta}{\sin\theta}\dfrac{\partial v_\phi}{\partial\phi}\end{array}\right), \tag{2.35.41}$$

$$(\nabla^2\mathbf{v})_\phi = \left(\begin{array}{l}\dfrac{1}{r^2}\dfrac{\partial}{\partial r}\left(r^2\dfrac{\partial v_\phi}{\partial r}\right) + \dfrac{1}{r^2}\dfrac{\partial}{\partial\theta}\left\{\dfrac{1}{\sin\theta}\dfrac{\partial}{\partial\theta}(v_\phi\sin\theta)\right\} + \dfrac{1}{r^2\sin^2\theta}\dfrac{\partial^2 v_\phi}{\partial\phi^2} \\ +\dfrac{2}{r^2\sin\theta}\dfrac{\partial v_r}{\partial\phi} + \dfrac{2}{r^2}\dfrac{\cot\theta}{\sin\theta}\dfrac{\partial v_\theta}{\partial\phi}\end{array}\right). \tag{2.35.42}$$

CHAPTER

Stress and Integral Formulations of General Principles

4

In the previous chapter, we considered the purely kinematic description of the motion of a continuum without any consideration of the forces that cause the motion and deformation. In this chapter, we consider a means of describing the forces in the interior of a body idealized as a continuum. It is generally accepted that matter is formed of molecules, which in turn consist of atoms and subatomic particles. Therefore, the internal forces in real matter are those between these particles. In the classical continuum theory where matter is assumed to be continuously distributed, the forces acting at every point inside a body are introduced through the concept of body forces and surface forces. Body forces are those that act throughout a volume (e.g., gravity, electrostatic force) by a long-range interaction with matter or charges at a distance. Surface forces are those that act on a surface (real or imagined), separating parts of the body. We assume that it is adequate to describe the surface forces at a point on a surface through the definition of a *stress vector*, discussed in Section 4.1, which pays no attention to the curvature of the surface at the point. Such an assumption is known as *Cauchy's stress principle* and is one of the basic axioms of classical continuum mechanics.

4.1 STRESS VECTOR

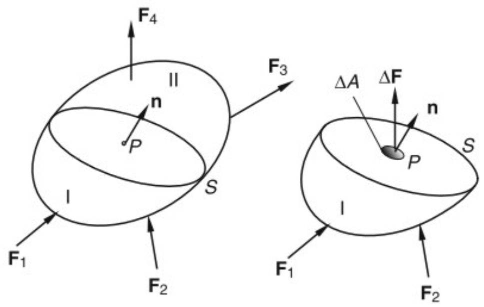

FIGURE 4.1-1

Let us consider a body depicted in Figure 4.1-1. Imagine a plane such as S, which passes through an arbitrary internal point P and which has a unit normal vector $\mathbf{n}$. The plane cuts the body into two portions. One portion

Copyright © 2010, Elsevier Ltd. All rights reserved.

lies on the side of the arrow of **n** (designated by II in the figure) and the other portion on the tail of **n** (designated by I). Considering portion I as a free body, there will be on plane S a resultant force $\Delta\mathbf{F}$ acting on a small area ΔA containing P. We define the stress vector (acting from II to I) at the point P on the plane S as the limit of the ratio $\Delta\mathbf{F}/\Delta A$ as $\Delta A \to 0$. That is, with $\mathbf{t_n}$ denoting the stress vector,

$$\mathbf{t_n} = \lim_{\Delta A \to 0} \frac{\Delta\mathbf{F}}{\Delta A}. \tag{4.1.1}$$

If portion II is considered as a free body, then by Newton's law of action and reaction, we shall have a stress vector (acting from I to II) $\mathbf{t_{-n}}$ at the same point on the same plane equal and opposite to that given by Eq. (4.1.1). That is,

$$\mathbf{t_n} = -\mathbf{t_{-n}}. \tag{4.1.2}$$

The subscript $-\mathbf{n}$ for $\mathbf{t}$ (i.e., $\mathbf{t_{-n}}$) indicates that outward normal for the portion II is in the negative direction of **n**.

Next, let S be a surface (instead of a plane) passing the point P. Let $\Delta\mathbf{F}$ be the resultant force on a small area ΔS on the surface S. The *Cauchy stress vector* at P on S is defined as

$$\mathbf{t} = \lim_{\Delta S \to 0} \frac{\Delta\mathbf{F}}{\Delta S}. \tag{4.1.3}$$

We now state the following principle, known as the *Cauchy's stress principle:* The stress vector at any given place and time has a common value on all parts of material having a common tangent plane at P and lying on the same side of it. In other words, if **n** is the unit outward normal (i.e., a vector of unit length pointing outward, away from the material) to the tangent plane, then

$$\mathbf{t} = \mathbf{t}(\mathbf{x}, t, \mathbf{n}), \tag{4.1.4}$$

where the scalar t denotes time.

In the following section, we show from Newton's second law that this dependence of the Cauchy's stress vector on the outward normal vector **n** can be expressed as

$$\mathbf{t} = \mathbf{T}(\mathbf{x}, t)\mathbf{n}, \tag{4.1.5}$$

where **T** is a linear transformation.

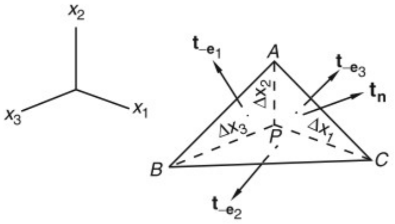
4.2 STRESS TENSOR

According to Eq. (4.1.4), the stress vector on a plane passing through a given spatial point **x** at a given time t depends only on the unit normal vector **n** to the plane. Thus, let **T** be the transformation such that

$$\mathbf{t_n} = \mathbf{Tn}. \tag{4.2.1}$$

We wish to show that this transformation is linear. Let a small tetrahedron be isolated from the body with the point P as one of its vertices (see Figure 4.2-1). The size of the tetrahedron will ultimately be made to approach zero volume so that, in the limit, the inclined plane will pass through the point P. The outward normal to the face PAB is $-\mathbf{e}_1$. Thus, the stress vector on this face is denoted by $\mathbf{t}_{-\mathbf{e}_1}$ and the force on the face is $\mathbf{t}_{-\mathbf{e}_1}\Delta A_1$, where ΔA_1 is the area of PAB. Similarly, the force acting on PBC, PAC and the inclined face ABC are $\mathbf{t}_{-\mathbf{e}_2}\Delta A_2$, $\mathbf{t}_{-\mathbf{e}_3}\Delta A_3$, and $\mathbf{t_n}\,\Delta A_n$, respectively. Thus, from Newton's second law written for the tetrahedron, we have

$$\sum \mathbf{F} = \mathbf{t}_{-\mathbf{e}_1}(\Delta A_1) + \mathbf{t}_{-\mathbf{e}_2}(\Delta A_2) + \mathbf{t}_{-\mathbf{e}_3}(\Delta A_3) + \mathbf{t_n}\Delta A_n = m\mathbf{a}. \tag{4.2.2}$$



x_2
x_3
x_1
$\mathbf{t}_{-\mathbf{e}_1}$
A
$\mathbf{t}_{-\mathbf{e}_3}$
$\mathbf{t}_{\mathbf{n}}$
Δx_2
Δx_3

C
$\mathbf{t}_{-\mathbf{e}_2}$

FIGURE 4.2-1

Since the mass m = (density)(volume) and the volume of the tetrahedron is proportional to the product of three infinitesimal lengths (in fact, the volume equals $(1/6)\Delta x_1 \Delta x_2 \Delta x_3$), when the size of the tetrahedron approaches zero, the right-hand side of Eq. (4.2.2) will approach zero faster than the terms on the left, where the stress vectors are multiplied by areas, the product of two infinitesimal lengths. Thus, in the limit, the acceleration term drops out exactly from Eq. (4.2.2). (We note that any body force, e.g., weight, that is acting will be of the same order of magnitude as that of the acceleration term and will also drop out.) Thus,

$$\sum \mathbf{F} = \mathbf{t}_{-\mathbf{e}_1}(\Delta A_1) + \mathbf{t}_{-\mathbf{e}_2}(\Delta A_2) + \mathbf{t}_{-\mathbf{e}_3}(\Delta A_3) + \mathbf{t}_{\mathbf{n}}\Delta A_n = 0. \tag{4.2.3}$$

Let the unit normal vector of the inclined plane *ABC* be

$$\mathbf{n} = n_1\mathbf{e}_1 + n_2\mathbf{e}_2 + n_3\mathbf{e}_3. \tag{4.2.4}$$

The areas ΔA_1, ΔA_2 and ΔA_3, being the projections of ΔA_n on the coordinate planes, are related to ΔA_n by

$$\Delta A_1 = n_1\Delta A_n, \quad \Delta A_2 = n_2\Delta A_n, \quad \Delta A_3 = n_3\Delta A_n. \tag{4.2.5}$$

Using Eq. (4.2.5), Eq. (4.2.3) becomes

$$\mathbf{t}_{-\mathbf{e}_1}n_1 + \mathbf{t}_{-\mathbf{e}_2}n_2 + \mathbf{t}_{-\mathbf{e}_3}n_3 + \mathbf{t}_{\mathbf{n}} = 0. \tag{4.2.6}$$

But from the law of the action and reaction,

$$\mathbf{t}_{-\mathbf{e}_1} = -\mathbf{t}_{\mathbf{e}_1}, \quad \mathbf{t}_{-\mathbf{e}_2} = -\mathbf{t}_{\mathbf{e}_2}, \quad \mathbf{t}_{-\mathbf{e}_3} = -\mathbf{t}_{\mathbf{e}_3}, \tag{4.2.7}$$

therefore, Eq. (4.2.6) becomes

$$\mathbf{t}_{\mathbf{n}} = n_1\mathbf{t}_{\mathbf{e}_1} + n_2\mathbf{t}_{\mathbf{e}_2} + n_3\mathbf{t}_{\mathbf{e}_3}. \tag{4.2.8}$$

Now, using Eq. (4.2.4) and Eq. (4.2.8), Eq. (4.2.1) becomes

$$\mathbf{T}(n_1\mathbf{e}_1 + n_2\mathbf{e}_2 + n_3\mathbf{e}_3) = n_1\mathbf{T}\mathbf{e}_1 + n_2\mathbf{T}\mathbf{e}_2 + n_3\mathbf{T}\mathbf{e}_3. \tag{4.2.9}$$

That is, the transformation **T**, defined by

$$\mathbf{t}_{\mathbf{n}} = \mathbf{T}\mathbf{n}, \tag{4.2.10}$$

is a linear transformation. It is called the *stress tensor* or the *Cauchy stress tensor*.

4.3 COMPONENTS OF STRESS TENSOR

According to Eq. (4.2.10) of the previous section, the stress vectors $\mathbf{t}_{\mathbf{e}_i}$ on the three coordinate planes (the $\mathbf{e}_i$-planes) are related to the stress tensor **T** by

$$\mathbf{t}_{\mathbf{e}_1} = \mathbf{T}\mathbf{e}_1, \quad \mathbf{t}_{\mathbf{e}_2} = \mathbf{T}\mathbf{e}_2, \quad \mathbf{t}_{\mathbf{e}_3} = \mathbf{T}\mathbf{e}_3. \tag{4.3.1}$$

By the definition of the components of a tensor [see Eq. (2.7.2)], we have

$$\mathbf{T}\mathbf{e}_i = \mathbf{T}_{mi}\mathbf{e}_m. \tag{4.3.2}$$

Thus,

$$\begin{aligned}\mathbf{t}_{\mathbf{e}_1} &= T_{11}\mathbf{e}_1 + T_{21}\mathbf{e}_2 + T_{31}\mathbf{e}_3,\\ \mathbf{t}_{\mathbf{e}_2} &= T_{12}\mathbf{e}_1 + T_{22}\mathbf{e}_2 + T_{32}\mathbf{e}_3,\\ \mathbf{t}_{\mathbf{e}_3} &= T_{13}\mathbf{e}_1 + T_{23}\mathbf{e}_2 + T_{33}\mathbf{e}_3.\end{aligned} \tag{4.3.3}$$

Since $\mathbf{t}_{\mathbf{e}_1}$ is the stress vector acting on the plane whose outward normal is $\mathbf{e}_1$, it is clear from the first equation of Eq. (4.3.3) that T_{11} is its normal component and T_{21} and T_{31} are its tangential components. Similarly, T_{22} is the normal component on the $\mathbf{e}_2$-plane and T_{12} and T_{32} are the tangential components on the same plane, and so on.

We note that for each stress component T_{ij}, the second index j indicates the plane on which the stress component acts and the first index indicates the direction of the component; e.g., T_{12} is the stress component in the direction of $\mathbf{e}_1$ acting on the plane whose outward normal is in the direction of $\mathbf{e}_2$. We also note that the positive normal stresses are also known as *tensile stresses,* and negative normal stresses are known as *compressive stresses*. *Tangential stresses* are also known as *shearing stresses*. Both T_{21} and T_{31} are shearing stress components acting on the same plane (the $\mathbf{e}_1$-plane). Thus, the resultant shearing stress on this plane is given by

$$\boldsymbol{\tau}_1 = T_{21}\mathbf{e}_2 + T_{31}\mathbf{e}_3. \tag{4.3.4}$$

The magnitude of this shearing stress is given by

$$|\boldsymbol{\tau}_1| = \sqrt{T_{21}^2 + T_{31}^2}. \tag{4.3.5}$$

Similarly, on $\mathbf{e}_2$-plane,

$$\boldsymbol{\tau}_2 = T_{12}\mathbf{e}_1 + T_{32}\mathbf{e}_3, \tag{4.3.6}$$

and on $\mathbf{e}_3$-plane,

$$\boldsymbol{\tau}_3 = T_{13}\mathbf{e}_1 + T_{23}\mathbf{e}_2. \tag{4.3.7}$$

From $\mathbf{t} = \mathbf{T}\mathbf{n}$, the components of **t** are related to those of **T** and **n** by the equation

$$t_i = T_{ij}n_j, \tag{4.3.8}$$

or, in a form more convenient for computation,

$$[\mathbf{t}] = [\mathbf{T}][\mathbf{n}]. \tag{4.3.9}$$

Thus, it is clear that if the matrix of **T** is known, the stress vector **t** on any inclined plane is uniquely determined from Eq. (4.3.9). In other words, the state of stress at a point is completely characterized by the stress tensor **T**. Also, since **T** is a second-order tensor, any one matrix of **T** determines the other matrices of **T** (see Section 2.18).

We should also note that some authors use the convention $\mathbf{t} = \mathbf{T}^{\mathrm{T}}\mathbf{n}$ so that $\mathbf{t}_{\mathbf{e}_i} = T_{ij}\mathbf{e}_j$. Under that convention, for example, T_{21} and T_{23} are tangential components of the stress vector on the plane whose normal is $\mathbf{e}_2$, and so on. These differences in meaning regarding the nondiagonal elements of $\mathbf{T}$ disappear if the stress tensor is symmetric.

4.4 SYMMETRY OF STRESS TENSOR: PRINCIPLE OF MOMENT OF MOMENTUM

By the use of the moment of momentum equation for a differential element, we shall now show that the stress tensor is generally a symmetric tensor.* Consider the free body diagram of a differential parallelepiped isolated from a body, as shown in Figure 4.4-1. Let us find the moment of all the forces about an axis passing through the center point A and parallel to the x_3-axis:

$$\begin{aligned}\sum(M_A)_3 = {} & T_{21}(\Delta x_2)(\Delta x_3)(\Delta x_1/2) + (T_{21} + \Delta T_{21})(\Delta x_2)(\Delta x_3)(\Delta x_1/2) \\ & - T_{12}(\Delta x_1)(\Delta x_3)(\Delta x_2/2) + (T_{12} + \Delta T_{12})(\Delta x_1)(\Delta x_3)(\Delta x_2/2).\end{aligned} \tag{4.4.1}$$

In writing Eq. (4.4.1), we have assumed the absence of body moments. Dropping the terms containing small quantities of higher order, we obtain

$$\sum(M_A)_3 = (T_{21} - T_{12})(\Delta x_1)(\Delta x_2)(\Delta x_3). \tag{4.4.2}$$

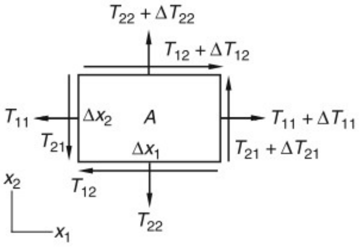

FIGURE 4.4-1

Now, whether the element is in static equilibrium or not,

$$\sum(M_A)_3 = I_{33}\alpha = 0. \tag{4.4.3}$$

This is because the angular acceleration term, $I_{33}\alpha$, is proportional to the moment of inertia I_{33}, which is given by $(1/12)(\text{density})\Delta x_1\Delta x_2\Delta x_3[(\Delta x_1)^2 + (\Delta x_2)^2]$ and is therefore a small quantity of higher order compared with the term $(T_{21}-T_{12})(\Delta x_1)(\Delta x_2)(\Delta x_3)$. Thus,

$$\sum(M_A)_3 = (T_{21} - T_{12})(\Delta x_1)(\Delta x_2)(\Delta x_3) = 0. \tag{4.4.4}$$

---

*See Prob. 4.29 for a case in which the stress tensor is not symmetric.

With similar derivations for the moments about the other two axes, we have

$$T_{12} = T_{21}, \quad T_{13} = T_{31}, \quad T_{23} = T_{32}. \tag{4.4.5}$$

These equations state that the stress tensor is symmetric, i.e., $\mathbf{T} = \mathbf{T}^{\mathrm{T}}$. Therefore, there are only six independent stress components.

Example 4.4.1

The state of stress at a certain point is $\mathbf{T} = -p\mathbf{I}$, where p is a scalar. Show that there is no shearing stress on any plane containing this point.

Solution

The stress vector on any plane passing through the point with normal $\mathbf{n}$ is

$$\mathbf{t_n} = \mathbf{Tn} = -p\mathbf{In} = -p\mathbf{n}.$$

Therefore, it is normal to the plane. This simple stress state is called a *hydrostatic state of stress*.

Example 4.4.2

With reference to a rectangular Cartesian coordinate system, the matrix of a state of stress at a certain point in a body is given by

$$[\mathbf{T}] = \begin{bmatrix} 2 & 4 & 3 \\ 4 & 0 & 0 \\ 3 & 0 & -1 \end{bmatrix} MPa.$$

(a) Find the stress vector and the magnitude of the normal stress on a plane that passes through the point and is parallel to the plane $x_1 + 2x_2 + 2x_3 - 6 = 0$.

(b) If $\mathbf{e}'_1 = \frac{1}{3}(2\mathbf{e}_1 + 2\mathbf{e}_2 + \mathbf{e}_3)$ and $\mathbf{e}'_2 = \frac{1}{\sqrt{2}}(\mathbf{e}_1 - \mathbf{e}_2)$, find T'_{12}.

Solution

(a) The plane $x_1 + 2x_2 + 2x_3 - 6 = 0$ has a unit normal given by

$$\mathbf{n} = \frac{1}{3}(\mathbf{e}_1 + 2\mathbf{e}_2 + 2\mathbf{e}_3).$$

The stress vector is obtained from Eq. (4.3.9) as

$$[\mathbf{t}] = [\mathbf{T}][\mathbf{n}] = \frac{1}{3}\begin{bmatrix} 2 & 4 & 3 \\ 4 & 0 & 0 \\ 3 & 0 & -1 \end{bmatrix}\begin{bmatrix} 1 \\ 2 \\ 2 \end{bmatrix} = \frac{1}{3}\begin{bmatrix} 16 \\ 4 \\ 1 \end{bmatrix},$$

or

$$\mathbf{t} = \frac{1}{3}(16\mathbf{e}_1 + 4\mathbf{e}_2 + \mathbf{e}_3)\ MPa.$$

The magnitude of the normal stress is, with $T_n \equiv T_{(n)(n)}$,

$$T_n = \mathbf{t} \cdot \mathbf{n} = \frac{1}{9}(16 + 8 + 2) = 2.89\ MPa.$$

(b) To find the primed components of the stress tensor, we have

$$T'_{12} = \mathbf{e}'_1 \cdot \mathbf{T}\mathbf{e}'_2 = \frac{1}{3\sqrt{2}}[2 \quad 2 \quad 1]\begin{bmatrix} 2 & 4 & 3 \\ 4 & 0 & 0 \\ 3 & 0 & -1 \end{bmatrix}\begin{bmatrix} 1 \\ -1 \\ 0 \end{bmatrix} = \frac{7}{3\sqrt{2}} = 1.65\ MPa.$$

Example 4.4.3

The distribution of stress inside a body is given by the matrix

$$[\mathbf{T}] = \begin{bmatrix} -p+\rho gy & 0 & 0 \\ 0 & -p+\rho gy & 0 \\ 0 & 0 & -p+\rho gy \end{bmatrix},$$

where p, ρ, and g are constants. Figure 4.4-2(a) shows a rectangular block inside the body.

(a) What is the distribution of the stress vector on the six faces of the block?
(b) Find the total resultant force acting on the face $y = 0$ and $x = 0$.

Solution

(a) From $\mathbf{t} = \mathbf{Tn}$, we have

$$\begin{array}{lll}
\text{On } x=0, & [\mathbf{n}] = [-1 \quad 0 \quad 0], & [\mathbf{t}] = [\,p-\rho gy \quad 0 \quad 0\,], \\
\text{On } x=a, & [\mathbf{n}] = [+1 \quad 0 \quad 0], & [\mathbf{t}] = [\,-p+\rho gy \quad 0 \quad 0\,], \\
\text{On } y=0, & [\mathbf{n}] = [0 \quad -1 \quad 0], & [\mathbf{t}] = [\,0 \quad p \quad 0\,], \\
\text{On } y=b, & [\mathbf{n}] = [0 \quad +1 \quad 0], & [\mathbf{t}] = [\,0 \quad -p+\rho gb \quad 0\,], \\
\text{On } z=0, & [\mathbf{n}] = [0 \quad 0 \quad -1], & [\mathbf{t}] = [\,0 \quad 0 \quad p-\rho gy\,], \\
\text{On } z=c, & [\mathbf{n}] = [0 \quad 0 \quad +1], & [\mathbf{t}] = [\,0 \quad 0 \quad -p+\rho gy\,].
\end{array}$$

The distribution of the stress vector on four faces of the cube is shown in Figure 4.4-2(b).

CHAPTER 1

Introduction to Serre's conjecture

1.1. Introduction

Let's start with an elliptic curve $E/\mathbf{Q}$. Nowadays, it's a familiar activity to consider the Galois representations defined by groups of division points of E. Namely, let n be a positive integer, and let $E[n]$ be the kernel of multiplication by n on $E(\overline{\mathbf{Q}})$. The group $E[n]$ is free of rank two over $\mathbf{Z}/n\mathbf{Z}$. After a choice of basis, the action of $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$ on $E[n]$ is given by a homomorphism

$$\rho_n : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{Aut}(E[n]) \approx \mathrm{GL}(2, \mathbf{Z}/n\mathbf{Z}).$$

This homomorphism is unramified at each prime p that is prime to the product of n with the conductor of E (see Exercise 15). For each such p, the element $\rho_n(\mathrm{Frob}_p)$ is a 2×2 matrix that is well defined up to conjugation. Its determinant is $p \bmod n$; its trace is $a_p \bmod n$, where a_p is the usual "trace of Frobenius" attached to E and p, i.e., the quantity $1 + p - \#E(\mathbf{F}_p)$. In his 1966 article [**107**], G. Shimura studied these representations and the number fields that they cut out for the curve $E = J_0(11)$. (This curve was also studied by Serre [**91**, pg. 254].) He noticed that for prime values $n = \ell$, the representations ρ_n tended to have large images. In [**93**], J-P. Serre proved that for any fixed elliptic curve E, not having complex multiplication, the indices

$$[\mathrm{GL}(2, \mathbf{Z}/n\mathbf{Z}) : \rho_n(\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}))]$$

are bounded independently of n. In Shimura's example, Serre proved that

$$[\mathrm{GL}(2, \mathbf{Z}/\ell\mathbf{Z}) : \rho_\ell(\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}))] = 1$$

for all $\ell \neq 5$ (see [**93**, §5.5.1]).

In this article, we will be concerned mainly with two-dimensional representations over finite fields. To that end, we restrict attention to the case where $n = \ell$ is prime. The representation ρ_ℓ is "modular" in the familiar sense that it's a representation of a group over a field in positive characteristic. The theme of this course is that it's modular in a different and deeper sense: it comes from a modular form! Indeed, according to a recent preprint of Breuil, Conrad, Diamond and Taylor (see [**7, 19, 114, 117**]), the Shimura-Taniyama conjecture is now a theorem—all elliptic curves over $\mathbf{Q}$ are modular!! Thus if N is the conductor of E, there is a weight-two newform $f = \sum_{n=1}^{\infty} c_n q^n$ ($q = e^{2\pi i z}$) on $\Gamma_0(N)$ with the property that $a_p = c_p$ for all p prime to N. Accordingly, ρ_ℓ is connected up with modular forms via the relation $\mathrm{tr}(\rho_\ell(\mathrm{Frob}_p)) \equiv c_p \pmod{\ell}$, valid for all but finitely many primes p.

The Shimura-Taniyama conjecture asserts that for each positive integer N there is a bijection between isogeny classes of elliptic curves A over $\mathbf{Q}$ of conductor N and rational newforms f on $\Gamma_0(N)$ of weight two. Given A, the Shimura-Taniyama conjecture produces a modular form $f = \sum_{n=1}^{\infty} c_n q^n$ whose Dirichlet series is equal to the L-series of A:

$$\sum_{n=1}^{\infty} \frac{c_n}{n^s} = L(f,s) \xlongequal{\qquad\qquad} L(A,s) = \sum_{n=1}^{\infty} \frac{a_n}{n^s}\ .$$

The integers a_n encode information about the number of points on A over various finite fields $\mathbf{F}_p$. If p is a prime not dividing N, then $a_p = p + 1 - \#A(\mathbf{F}_p)$; if $p \mid N$,

$$a_p = \begin{cases} -1 & \text{if } A \text{ has non-split multiplicative reduction at } p \\ 1 & \text{if } A \text{ has split multiplicative reduction at } p \\ 0 & \text{if } A \text{ has additive reduction at } p. \end{cases}$$

The integers a_n are obtained recursively from the a_p as follows:

- $a_{p^r} = \begin{cases} a_{p^{r-1}} a_p - p a_{p^{r-2}} & \text{if } p \nmid N \\ a_p^r & \text{if } p \mid N \end{cases}$
- $a_{nm} = a_n a_m, \qquad$ if $(n,m) = 1$.

The conjectures made by Serre in [**102**], which are the subject of this paper, concern representations $\rho : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \overline{\mathbf{F}}_\ell)$. We always require (usually tacitly) that our representations are continuous. The continuity condition just means that the kernel of ρ is open, so that it corresponds to a finite Galois extension K of $\mathbf{Q}$. The representation ρ then embeds $\mathrm{Gal}(K/\mathbf{Q})$ into $\mathrm{GL}(2, \overline{\mathbf{F}}_\ell)$. Since K is a finite extension of $\mathbf{Q}$, the image of ρ is contained in $\mathrm{GL}(2, \mathbf{F})$ for some finite subfield $\mathbf{F}$ of $\overline{\mathbf{F}}_\ell$.

$$\begin{tikzcd} \overline{\mathbf{Q}} \arrow[d, dash] \arrow[dd, bend left, dash, "G_{\mathbf{Q}}"] \\ K \arrow[d, dash] \\ \mathbf{Q} \end{tikzcd} \qquad\qquad \begin{tikzcd} G_{\mathbf{Q}} \arrow[d, two heads] \arrow[dr, "\rho"] & \\ \mathrm{Gal}(K/\mathbf{Q}) \arrow[r, hook] & \mathrm{GL}(2, \overline{\mathbf{F}}_\ell) \end{tikzcd}$$

For various technical reasons, the original conjectures of Serre insist that ρ be irreducible. It is nevertheless fruitful to consider the reducible case as well (see [**111**]).

The conjectures state (in particular) that each continuous irreducible ρ that satisfies a necessary parity condition "arises from" (or is associated with) a suitable modular form mod ℓ. To explain what's going on, let's start with

$$\Delta := \sum_{n=1}^{\infty} \tau(n) q^n = q \prod_{i=1}^{\infty} (1 - q^i)^{24},$$

the unique (normalized) cusp form of weight 12 on $\mathrm{SL}(2, \mathbf{Z})$. In [**92**], Serre conjectured the existence of a "strictly compatible" family of ℓ-adic representations of $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$ whose L-function is the L-function of Δ, namely

$$L(\Delta, s) = \sum_{n=1}^{\infty} \tau(n) n^{-s} = \prod_p (1 - \tau(p) p^{-s} + p^{11-2s})^{-1},$$

where the product is taken over all prime numbers p. The conjectured ℓ-adic representations were constructed soon after by Deligne [**24**]. Specifically, Deligne constructed, for each prime ℓ, a representation

$$\rho_{\ell^\infty} : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \mathbf{Z}_\ell),$$

unramified outside ℓ, such that for all primes $p \neq \ell$,

$$\operatorname{tr}(\rho_{\ell^\infty}(\mathrm{Frob}_p)) = \tau(p), \qquad \det(\rho_{\ell^\infty}(\mathrm{Frob}_p)) = p^{11}.$$

On reducing ρ_{ℓ^∞} mod ℓ, we obtain a representation

$$\rho_\ell : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \mathbf{F}_\ell)$$

with analogous properties. (Equalities are replaced by congruences mod ℓ.) In other words, the ρ_ℓ for Δ are just like the ρ_ℓ for an elliptic curve E, except that the integers a_p are replaced by the corresponding values of the τ-function. The determinant of ρ_ℓ is the 11th power of the mod ℓ cyclotomic character $\chi : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathbf{F}_\ell^*$, i.e., the character giving the action of $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$ on the group of ℓth roots of unity in $\overline{\mathbf{Q}}$ (see Section 1.5).

More generally, take a weight $k \geq 12$ and suppose that $f = \sum_n c_n q^n$ is a nonzero weight-k cusp form for $\mathrm{SL}(2, \mathbf{Z})$ that satisfies $f|T_n = c_n f$ for all $n \geq 1$, T_n being the nth Hecke operator on the space of cusp forms of weight k for $\mathrm{SL}(2, \mathbf{Z})$ (see Section 1.5). Then the complex numbers c_n $(n \geq 1)$ are algebraic integers. Moreover, the field $E := \mathbf{Q}(\ldots c_n \ldots)$ generated by the c_n is a totally real number field (of finite degree over $\mathbf{Q}$). Thus the c_n all lie in the integer ring $\mathcal{O}_E$ of E. For each ring homomorphism $\varphi : \mathcal{O}_E \to \overline{\mathbf{F}}_\ell$, one finds a representation

$$\rho = \rho_\varphi : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \overline{\mathbf{F}}_\ell),$$

unramified outside ℓ, such that

$$\operatorname{tr}(\rho(\mathrm{Frob}_p)) = \varphi(c_p), \qquad \det(\rho(\mathrm{Frob}_p)) = p^{k-1}$$

for all $p \neq \ell$. We have $\det \rho = \chi^{k-1}$. Of course, there is no guarantee that ρ is irreducible. We can (and do) suppose that ρ is semisimple by replacing it by its semisimplification. Then ρ is determined up to isomorphism by the displayed trace and determinant conditions; this follows from the Cebotarev density theorem and the Brauer-Nesbitt theorem [**21**], which states that semisimple representations are determined by their characteristic polynomials.

It is important to note that k is necessarily an even integer; otherwise the space $S_k(\mathrm{SL}(2, \mathbf{Z}))$ of weight-k cusp forms on $\mathrm{SL}(2, \mathbf{Z})$ is easily seen to be 0. Thus the determinant χ^{k-1} of ρ is an odd power of χ. In particular, $\det \rho : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathbf{F}_\ell^*$ is unramified outside ℓ and takes the value -1 on complex conjugations $c \in \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$. It's a nice exercise to check that, conversely, all continuous homomorphisms with these properties are odd powers of χ (see Exercise 1).

In the early 1970s, Serre conjectured that all homomorphisms that are "like ρ" come from cusp forms of some weight on $\mathrm{SL}(2, \mathbf{Z})$. Namely, let

$$\rho : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \overline{\mathbf{F}}_\ell)$$

be a continuous, irreducible representation that is (1) unramified outside ℓ and (2) of odd determinant, in the sense that $\det \rho(c) = -1 \in \overline{\mathbf{F}}_\ell$ for complex conjugations $c \in \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$. In a May, 1973 letter to Tate, Serre conjectured that ρ is of the form ρ_φ. This means that there is a weight $k \geq 12$, an eigenform $f \in S_k(\mathrm{SL}(2, \mathbf{Z}))$, and a homomorphism $\varphi : \mathcal{O}_E \to \overline{\mathbf{F}}_\ell$ (where $\mathcal{O}_E$ is the ring of integers of the field generated by the coefficients of f) so that ρ_φ and ρ are isomorphic.

To investigate Serre's conjecture, it is fruitful to consider the operation $\rho \mapsto \rho \otimes \chi$ on representations. This "twisting" operation preserves the set of representations that come from modular forms. Indeed, let $\theta = q\frac{d}{dq}$ be the classical differential operator $\sum a_n q^n \mapsto \sum n a_n q^n$. According to Serre and Swinnerton-Dyer [**61, 94,**

112], if f is a mod ℓ form of weight k, then θf is a mod ℓ form of weight $k+\ell+1$. Then if ρ is associated to f, $\rho\otimes\chi$ is associated with θf. According to a result of Atkin, Serre and Tate (see [**97**, Th. 3] and Section 2.1), if ρ comes from an eigenform in some space $S_k(\mathrm{SL}(2,\mathbf{Z}))$, then a suitable twist $\rho\otimes\chi^i$ of f comes from a form of weight $\leq \ell+1$.

Serre's conjecture thus has the following consequence: each two-dimensional irreducible odd representation of $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$ over $\overline{\mathbf{F}}_\ell$ that is unramified outside ℓ has a twist (by a power of χ) coming from an eigenform on $\mathrm{SL}(2,\mathbf{Z})$ of weight at most $\ell+1$. In particular, suppose that $\ell < 11$. Then the spaces $S_k(\mathrm{SL}(2,\mathbf{Z}))$ with $k \leq \ell+1$ are all 0; as a result, they contain no nonzero eigenforms! The conjecture that all ρ are modular (of level 1) thus predicts that there are *no* representations of the type contemplated if ℓ is 2, 3, 5 or 7. In support of the conjecture, the non-existence statement was proved for $\ell = 2$ by J. Tate in a July, 1973 letter to Serre [**113**]. Soon after, Serre treated the case $\ell = 3$ by methods similar to those of Tate. (See [**113**, p. 155] for a discussion and a reference to a note in Serre's Œuvres.) Quite recently, Sharon Brueggeman considered the case $\ell = 5$; she proved that the conjectured result follows from the Generalized Riemann Hypothesis (see [**8**]). In another direction, Hyunsuk Moon generalized Tate's result and proved that there are only finitely many isomorphism classes of continuous semisimple Galois representations $\rho : G_{\mathbf{Q}} \to \mathrm{GL}_4(\overline{\mathbf{F}}_2)$ unramified outside 2 such that field $K/\mathbf{Q}$ corresponding to the kernel of ρ is totally real (see [**76**]). Similar work in this direction has been carried out by Joshi [**58**], under additional local hypothesis.

Serre discussed his conjecture with Deligne, who pointed out a number of surprising consequences. In particular, suppose that one takes a ρ coming from an eigenform f' of some weight and of level $N > 1$. On general grounds, ρ has the right to be ramified at primes p dividing N as well as at the prime ℓ. Suppose that, by accident as it were, ρ turned out to be unramified at all primes $p \mid N$. Then the conjecture would predict the existence of a level-1 form f' (presumably of the same weight as f) whose mod ℓ representation was isomorphic to ρ. For example, if $N = \ell^\alpha$ is a power of ℓ, then the conjecture predicts that ρ arises from a form f' of level 1. How could one manufacture the f'?

The passage $f \rightsquigarrow f'$ comes under the rubric of "level optimization". When you take a representation ρ that comes from high level N, and it seems as though that representation comes from a lower level N', then to "optimize the level" is to cough up a form of level N' that gives ρ.

Deligne pointed out also that Serre's conjecture implies that representations ρ over $\overline{\mathbf{F}}_\ell$ are required to "lift" to λ-adic representations of $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$. In the recent articles [**80**] and [**81**], R. Ramakrishna used purely Galois cohomological techniques to prove results in this direction.

1.2. The weak conjecture of Serre

In the mid 1980s, Gerhard Frey began lecturing on a link between Fermat's Last Theorem and elliptic curves (see [**42, 43**]). (Earlier, Hellegouarch had also considered links between Fermat's Last Theorem and elliptic curves; see the MathSciNet review and Appendix of [**48**].) As is now well known, Frey proposed that if $a^\ell + b^\ell$ was a perfect ℓth power, then the elliptic curve $y^2 = x(x-a^\ell)(x+b^\ell)$ could be proved to be non-modular. Soon after, Serre pointed out that the non-modularity contemplated by Frey would follow from suitable level-optimization results concerning modular forms [**101**]. To formulate such optimization results, Serre went back to the tentative conjecture that he had made 15 years earlier and decided to study representations $\rho : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \overline{\mathbf{F}}_\ell)$ that are not necessarily unramified at ℓ. The results, of course, were the conjectures of [**102**].

An important consequence of these conjectures is the so-called "weak conjecture of Serre." As background, we recall that Hecke eigenforms on congruence subgroups of $\mathrm{SL}(2, \mathbf{Z})$ give rise to two-dimensional representations of $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$. If we set things up correctly, we get representations over $\overline{\mathbf{F}}_\ell$. More specifically, take integers $k \geq 2$ and $N \geq 1$; these are the weight and level, respectively. Let $f = \sum a_n q^n$ be a normalized Hecke eigenform in the space $S_k(\Gamma_1(N))$ of complex weight-k cusp forms on the subgroup $\Gamma_1(N)$ of $\mathrm{SL}(2, \mathbf{Z})$. Thus f is nonzero and it satisfies $f|T_n = a_n f$ for all $n \geq 1$. Further, there is a character $\varepsilon : (\mathbf{Z}/N\mathbf{Z})^* \to \mathbf{C}^*$ so that $f|\langle d \rangle = \varepsilon(d) f$ for all $d \in (\mathbf{Z}/N\mathbf{Z})^*$, where $\langle d \rangle$ is the diamond-bracket operator. Again, let $\mathcal{O}$ be the ring of integers of the field $\mathbf{Q}(\dots a_n \dots)$ generated by the a_n; this field is a number field that is either totally real or a CM field. Consider a ring homomorphism $\varphi : \mathcal{O} \to \overline{\mathbf{F}}_\ell$ as before. Associated to this set-up is a representation $\rho : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \overline{\mathbf{F}}_\ell)$ with properties that connect it up with f (and φ). First, the representation is unramified at all p not dividing ℓN. Next, for all such p, we have

$$\mathrm{tr}(\rho(\mathrm{Frob}_p)) = a_p, \qquad \det(\rho(\mathrm{Frob}_p)) = p^{k-1}\varepsilon(p);$$

the numbers a_p and $p^{k-1}\varepsilon(p)$, literally in $\mathcal{O}$, are mapped tacitly into $\overline{\mathbf{F}}_\ell$ by φ. The representation ρ is determined up to isomorphism by the trace and determinant identities that are displayed, plus the supplemental requirement that it be semisimple. We are interested mainly in the (generic) case in which ρ is irreducible; in that case, it is of course semisimple.

The construction of ρ from f, k and φ was described in [**24**]. In this article, Deligne sketches a method that manufactures for each non-archimedean prime λ of E a representation $\tilde{\rho}_\lambda : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, E_\lambda)$, where E_λ denotes the completion of E at λ. Given φ, we let $\lambda = \ker \varphi$ and find a model of $\tilde{\rho}_\lambda$ over the ring of integers $\mathcal{O}_\lambda$ of E_λ. Reducing $\tilde{\rho}_\lambda$ modulo λ, we obtain a representation over the finite field $\mathcal{O}_\lambda/\lambda\mathcal{O}_\lambda$, and φ embeds this field into $\overline{\mathbf{F}}_\ell$.

In fact, as Shimura has pointed out, the machinery of [**24**] can be avoided if one seeks only the mod λ representation attached to f (as opposed to the full λ-adic representation $\tilde{\rho}_\lambda$). As the first author pointed out in [**87**], one can use congruences among modular forms to find a form of weight two and level $N\ell^2$ that gives rise to ρ. Accordingly, one can find ρ concretely by looking within the group of ℓ-division points of a suitable abelian variety over $\mathbf{Q}$: the variety $J_1(\ell^2 N)$, which is defined in Section 2.3 and in Conrad's Appendix.

Which representations of $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$ arise in this way (as k, N, f and φ all vary)? As in the case $N = 1$ (i.e., that where $\Gamma_1(N) = \mathrm{SL}(2, \mathbf{Z})$), any ρ that comes from modular forms is an odd representation: we have $\det(\rho(c)) = -1$ when $c \in \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$ is a complex conjugation. To see this, we begin with the fact that $\varepsilon(-1) = (-1)^k$, which generalizes (1.4); this follows from the functional equation that relates $f(\frac{az+b}{cz+d})$ to $f(z)$ when $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ is an element of $\Gamma_0(N)$ (see Exercise 7). On the other hand, using the Cebotarev density theorem, we find that $\det \rho = \chi^{k-1}\varepsilon$, where χ is again the mod ℓ cyclotomic character and where ε is regarded now as a map $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \overline{\mathbf{F}}_\ell^*$ in the obvious way, namely by composing $\varepsilon : (\mathbf{Z}/N\mathbf{Z})^* \to \overline{\mathbf{F}}_\ell^*$

with the mod N cyclotomic character. The value on c of the latter incarnation of ε is the number $\varepsilon(-1) = (-1)^k$. Since $\chi(c) = -1$, we deduce that $(\det\rho)(c) = -1$, as was claimed.

Serre's weak conjecture states that, conversely, every irreducible odd representation $\rho : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \overline{\mathbf{F}}_\ell)$ is modular in the sense that it arises from some f and φ.

A concrete consequence of the conjecture is that all odd irreducible 2-dimensional Galois representations ρ come from abelian varieties over $\mathbf{Q}$. Given ρ, one should be able to find a totally real or CM number field E, an abelian variety A over $\mathbf{Q}$ of dimension $[E : \mathbf{Q}]$ that comes equipped with an action of the ring of integers $\mathcal{O}$ of E, and a ring homomorphism $\varphi : \mathcal{O} \to \overline{\mathbf{F}}_\ell$ with the following property: Let $\lambda = \ker\varphi$. *Then the representation* $A[\lambda] \otimes_{\mathcal{O}/\lambda} \overline{\mathbf{F}}_\ell$ *is isomorphic to* ρ. (In comparing $A[\lambda]$ and ρ, we use $\varphi : \mathcal{O}/\lambda \hookrightarrow \overline{\mathbf{F}}_\ell$ to promote the 2-dimensional $A[\lambda]$ into a representation over $\overline{\mathbf{F}}_\ell$.)

Much of the evidence for the weak conjecture concerns representations taking values in $\mathrm{GL}(2, \mathbf{F}_q)$ where the finite field $\mathbf{F}_q$ has small cardinality. In his original article [**102**, §5], Serre's discusses a large number of examples of such representations. Serre uses theorems of Langlands [**68**] and Tunnell [**115**] to establish his weak conjecture for odd irreducible representations with values in $\mathrm{GL}(2, \mathbf{F}_2)$ and $\mathrm{GL}(2, \mathbf{F}_3)$. Further, he reports on numerical computations of J.-F. Mestre that pertain to representations over $\mathbf{F}_4$ (and trivial determinant). Additionally, Serre remarks [**102**, p. 219] that the weak conjecture is true for those representations with values in $\mathrm{GL}(2, \overline{\mathbf{F}}_p)$ that are dihedral in the sense that their projective images (in $\mathrm{PGL}(2, \overline{\mathbf{F}}_p)$) are dihedral groups. (See also [**29**, §5] for a related argument.) This section of Serre's paper concludes with examples over $\mathbf{F}_9$ and $\mathbf{F}_7$.

More recently, representations over the fields $\mathbf{F}_4$ and $\mathbf{F}_5$ were treated, under somewhat mild hypotheses, by Shepherd-Barron and Taylor [**105**]. For example, Shepherd-Barron and Taylor show that $\rho : \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q}) \to \mathrm{GL}(2, \mathbf{F}_5)$ is isomorphic to the 5-torsion representaton of an elliptic curve over $\mathbf{Q}$ provided that $\det\rho$ is the mod 5 cyclotomic character. Because elliptic curves over $\mathbf{Q}$ are modular, it follows that ρ is modular.

1.3. The strong conjecture

Fix an odd irreducible Galois representation

$$\rho : G_{\mathbf{Q}} \to \mathrm{GL}(2, \overline{\mathbf{F}}_\ell).$$

As discussed above, the weak conjecture asserts that ρ is modular, in the sense that there exists integers N and k such that ρ comes from some $f \in S_k(\Gamma_1(N))$. The *strong conjecture* goes further and gives a recipe for integers $N(\rho)$ and $k(\rho)$, then asserts that ρ comes from $S_{k(\rho)}(\Gamma_1(N(\rho)))$. In any particular instance, the strong conjecture is, a priori, easier to verify or disprove than the weak conjecture because $S_{k(\rho)}(\Gamma_1(N(\rho)))$ is a finite-dimensional vector space that can be computed (using, e.g., the algorithm in [**73**]). The relation between the weak and strong conjectures is analogous to the relation between the assertion that an elliptic curve is modular of some level and the assertion that an elliptic curve A is modular of a specific level, the conductor of A.

For each prime p, let $I_p \subset G_{\mathbf{Q}}$ denote an inertia group at p. The optimal level is a product

$$N(\rho) = \prod_{p \neq \ell} p^{n(p)},$$

where $n(p)$ depends only on $\rho|_{I_p}$. The optimal weight $k(\rho)$ depends only on $\rho|_{I_\ell}$. The integer $n(p)$ is a conductor in additive notation. In particular, $n(p) = 0$ if and only if ρ is unramified at p.

View ρ as a homomorphism $G_{\mathbf{Q}} \to \operatorname{Aut}(V)$, where V is a two-dimensional vector space over $\overline{\mathbf{F}}_\ell$. It is natural to consider the subspace of inertia invariants:

$$V^{I_p} := \{v \in V : \rho(\sigma)v = v, \text{ all } \sigma \in I_p\}.$$

For example, $V^{I_p} = V$ if and only if ρ is unramified at p. Define

$$n(p) := \dim(V/V^{I_p}) + \operatorname{Swan}(V),$$

where the wild term $\operatorname{Swan}(V)$ is the Swan conductor

$$\operatorname{Swan}(V) := \sum_{i=1}^{\infty} \frac{1}{[G_0 : G_i]} \dim(V/V^{G_i}) \geq 0.$$

Here $G_0 = I_p$ and the $G_i \subset G_0$ are the higher ramification groups.

Suppose that ρ arises from a newform $f \in S_k(\Gamma_1(N))$. A theorem of Carayol [**12**], which was proved independently by Livné [**70**, Prop. 0.1], implies that $N(\rho) \mid N$. It is productive to study the quotient $N/N(\rho)$. Let $\mathcal{O}$ be the ring of integers of the field generated by the Fourier coefficients of f and let $\varphi : \mathcal{O} \to \overline{\mathbf{F}}_\ell$ be the map such that $\varphi(a_p) = \operatorname{tr}(\rho(\operatorname{Frob}_p))$. Let λ be a prime of $\mathcal{O}$ lying over ℓ and E_λ be the completion of $\operatorname{Frac}(\mathcal{O})$ at λ. Deligne [**24**] attached to the pair f, λ a representation

$$\rho_\lambda : G_{\mathbf{Q}} \to \mathrm{GL}(2, E_\lambda) = \operatorname{Aut}(\tilde{V})$$

where $\tilde{V}$ is a two-dimensional vector space over E_λ. The representation ρ_λ can be conjugated so that its images lies inside $\mathrm{GL}(2, \mathcal{O}_\lambda)$; the reduction of ρ_λ modulo λ is then ρ. The following diagram summarizes the set up:

$$\begin{tikzcd}
 & & \mathrm{GL}(2, E_\lambda) = \operatorname{Aut}(\tilde{V}) \\
G_{\mathbf{Q}} \arrow[r] \arrow[rru, bend left, "\rho_\lambda"] \arrow[rrd, bend right, "\rho"'] & \mathrm{GL}(2, \mathcal{O}_\lambda) \arrow[ru, hook] \arrow[rd, "\varphi"] & \\
 & & \mathrm{GL}(2, \overline{\mathbf{F}}_\ell) = \operatorname{Aut}(V)
\end{tikzcd}$$

Let $m(p)$ be the power of p dividing the conductor of ρ_λ. In [**12**], Carayol proves that $m(p) = \operatorname{ord}_p N$. As above, $m(p) = \dim(\tilde{V}/\tilde{V}^{I_p}) + (\text{wild term})$, and the wild term is the same as for ρ. The power of p dividing $N/N(\rho)$ is $\dim(\tilde{V}/\tilde{V}^{I_p}) - \dim(V/V^{I_p}) = \dim V^{I_p} - \dim \tilde{V}^{I_p}$. Though $\tilde{V}$ and V are vector spaces over different fields, we can compare the dimensions of their inertia invariant subspaces. The formula

$$\operatorname{ord}_p(N) = n(p) + (\dim V^{I_p} - \dim \tilde{V}^{I_p}) \tag{1.1}$$

indicates how this difference is the deviation of N from the optimal level locally at p. This is the description of $n(p)$ that is used in proving that if ρ is modular at all, then it is possible to refine N and k to eventually discover that ρ arises from a newform in $S_{k(\rho)}(\Gamma_1(N(\rho)))$. After much work (see [**26, 87**]) it has been shown that *for $\ell > 2$ the weak and strong conjectures are equivalent.* See [**9**] for equivalence in many cases when $\ell = 2$.

Rearranging (1.1) into

$$n(p) = \operatorname{ord}_p(N) - (\dim V^{I_p} - \dim \tilde{V}^{I_p})$$

provides us with a way to read off $N(\rho)$ from $\operatorname{ord}_p(N)$, $\dim V^{I_p}$, and $\dim \tilde{V}^{I_p}$. If $f \in S_k(\Gamma_1(N))$ gives rise to ρ and $\ell \nmid N$, then $k(\rho) \leq k$. In contrast, if we allow powers of ℓ in the level then the weight k can always be made equal to 2.

1.4. Representations arising from an elliptic curve

Equations for elliptic curves can be found in the Antwerp tables [**4**] and the tables of Cremona [**20**]. For example, consider the elliptic curve B given by the equation $y^2+y = x^3+x^2-12x+2$. This is the curve labeled **141A1** in [**20**]; it has conductor $N = 3 \cdot 47$ and discriminant $\Delta = 3^7 \cdot 47$. There is a newform $f \in S_2(\Gamma_0(141))$ attached to B. Because N is square free, the elliptic curve B is *semistable*, in the sense that B has multiplicative reduction at each prime.

The curve B is isolated in its isogeny class; equivalently, for every ℓ the representation

$$\rho_\ell : G_{\mathbf{Q}} \to \operatorname{Aut}(B[\ell]) \approx \mathrm{GL}(2, \mathbf{F}_\ell)$$

is irreducible (see Exercise 4 and Exercise 5). We will frequently consider the representations ρ_ℓ attached to B. The following proposition shows that because B is semistable, each ρ_ℓ is surjective [**93**].

Proposition 1.1. *If A is a semistable elliptic curve over $\mathbf{Q}$ and ℓ is a prime such that ρ_ℓ is irreducible, then ρ_ℓ is surjective.*

Proof. Serre proved this when ℓ is odd; see [**93**, Prop. 21], [**103**, §3.1]. If ρ_2 isn't surjective, then by [**93**, Prop. 21(b)] and Theorem 2.10 it's unramified outside 2. This contradicts [**113**]. □

To give a flavor of Serre's invariants, we describe $N(\rho_\ell)$ and $k(\rho_\ell)$ for the representations ρ_ℓ attached to B. (Note that we still have not defined $k(\rho)$.) At primes p of bad reduction, after a possible unramified quadratic extension of $\mathbf{Q}_p$, the elliptic curve B is a Tate curve. This implies that for $p \neq \ell$, the representation ρ_ℓ is unramified at p if and only if $\operatorname{ord}_p(\Delta) \equiv 0 \pmod{\ell}$; for more details, see Section 2.4.

The optimal level $N(\rho_\ell)$ is a divisor of $3 \cdot 47$; it is divisible only by primes for which ρ_ℓ is ramified, and is not divisible by ℓ. The representation ρ_ℓ is unramified at 3 if and only if $\ell \mid \operatorname{ord}_3(\Delta) = 7$, i.e., when $\ell = 7$. Furthermore, ρ_ℓ is always ramified at 47. First suppose $\ell \notin \{3, 47\}$. If in addition $\ell \neq 7$ then $N(\rho_\ell) = 3 \cdot 47$, and $k(\rho_\ell) = 2$ since $\ell \nmid 3 \cdot 47$. If $\ell = 7$ then $N(\rho_\ell) = 47$, and again $k(\rho_\ell) = 2$. The remaining cases are $\ell = 3$ and $\ell = 47$. If $\ell = 47$ then $N(\rho_\ell) = 3$, and because $\ell - 1$ is the order of the cyclotomic character, $k(\rho_\ell) \equiv 2 \pmod{47-1}$; Serre's recipe then gives $k(\rho_\ell) = 2 + (47 - 1) = 48$. Similarly, when $\ell = 3$, we have $N(\rho_\ell) = 47$ and $k(\rho_\ell) = 2 + (3 - 1) = 4$. The following table summarizes the Serre invariants:

Table 1.4. The Serre invariants of ρ_ℓ

ℓ	$N(\rho_\ell)$	$k(\rho_\ell)$
3	47	4
7	47	2
47	3	48
all other ℓ	141	2

To verify the strong conjecture of Serre for $\ell = 3, 47$, we use a standard tradeoff of level and weight, which relates eigenforms in $S_2(\Gamma_0(141); \mathbf{F}_\ell)$ to eigenforms in $S_{2+\ell-1}(\Gamma_0(141/\ell); \mathbf{F}_\ell)$ (see Section 3.1). The only exceptional prime is $\ell = 7$, for which the minimal weight $k(\rho)$ is 2. The strong conjecture of Serre predicts the existence of an eigenform $g \in S_2(\Gamma_0(47))$ that gives rise to ρ_ℓ. Our initial instinct is to look for an elliptic curve A of conductor 47 such that $A[\ell] \cong B[\ell]$, as $G_\mathbf{Q}$-modules. In fact, there are no elliptic curves of conductor 47. This is because $S_2(\Gamma_0(47))$ is four dimensional, having basis the Galois conjugates of a single eigenform $g = \sum c_n q^n$. The Fourier coefficients c_n of g generate the full ring of integers in the field K obtained from $\mathbf{Q}$ by adjoining a root of $h = x^4 - x^3 - 5x^2 + 5x - 1$. The discriminant $1957 = 19 \cdot 103$ of K equals the discriminant of h, so a root of h generates the full ring of integers. The eigenvalue c_2 satisfies $h(c_2) = 0$. Since $h \equiv (x + 2)(x^3 + 4x^2 + x + 3) \pmod 7$, there is a prime λ lying over 7 such that $\mathcal{O}/\lambda \cong \mathbf{F}_7$; the isomorphism is given by $c_2 \mapsto -2 \bmod 7$. As a check, note that $\#B(\mathbf{F}_2) = 5$ so $a_2 = 3 - 5 = -2 = \varphi(c_2)$. More generally, for $p \nmid 7 \cdot 141$, we have $\varphi(c_p) \equiv a_p \bmod 7$. This equality of traces implies that the representation $\rho_{g,\lambda}$ is isomorphic to $\rho = \rho_{A,7}$, so A is modular of level 47.

1.5. Background material

In this section, we review the cyclotomic character, Frobenius elements, modular forms, and Tate curves. We frequently write $G_\mathbf{Q}$ for $\mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$. Many of these basics facts are also summarized in [**23**].

1.5.1. The cyclotomic character

The mod ℓ *cyclotomic character* is defined by considering the group $\boldsymbol{\mu}_\ell$ of ℓth roots of unity in $\overline{\mathbf{Q}}$; the action of the Galois group $G_\mathbf{Q}$ on the cyclic group $\boldsymbol{\mu}_\ell$ gives rise to a continuous homomorphism

$$\chi_\ell : G_\mathbf{Q} \to \mathrm{Aut}(\boldsymbol{\mu}_\ell). \tag{1.2}$$

Since $\boldsymbol{\mu}_\ell$ is a cyclic group of order ℓ, its group of automorphisms is canonically the group $(\mathbf{Z}/\ell\mathbf{Z})^* = \mathbf{F}_\ell^*$. We emerge with a map $G_\mathbf{Q} \to \mathbf{F}_\ell^*$, which is the character in question.

Let A be an elliptic curve and ℓ be a prime number. The Weil pairing e_ℓ (see [**109**, III.8]) sets up an isomorphism of $G_\mathbf{Q}$-modules

$$e_\ell : \bigwedge^2 A[\ell] \xrightarrow{\cong} \boldsymbol{\mu}_\ell. \tag{1.3}$$

The determinant of the representation $\rho_{A,\ell}$ is the mod ℓ cyclotomic character χ_ℓ.

Suppose now that $c \in G_\mathbf{Q}$ is the automorphism "complex conjugation." Then the determinant of $\rho_{A,\ell}(c)$ is $\chi_\ell(c)$. Now c operates on roots of unity by the map

$\zeta \mapsto \zeta^{-1}$, since roots of unity have absolute value 1. Accordingly,

$$\det \rho_{A,\ell}(c) = -1; \tag{1.4}$$

one says that $\rho_{A,\ell}$ is *odd*. If $\ell \neq 2$, then $\rho_{A,\ell}(c)$ is conjugate over $\overline{\mathbf{F}}_\ell$ to $\left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$ (Exercise 7). If $\ell = 2$ then the characteristic polynomial of $\rho_{A,\ell}(c)$ is $(x+1)^2$ so $\rho_{A,\ell}(c)$ is conjugate over $\overline{\mathbf{F}}_\ell$ to either the identity matrix or $\left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$.

1.5.2. Frobenius elements

Let K be a number field. The Galois group $\mathrm{Gal}(K/\mathbf{Q})$ leaves the ring $\mathcal{O}_K$ of integers of K invariant, so that one obtains an induced action on the ideals of $\mathcal{O}_K$. The set of prime ideals $\mathfrak{p}$ of $\mathcal{O}_K$ lying over p (i.e., that contain p) is permuted under this action. For each $\mathfrak{p}$, the subgroup $D_\mathfrak{p}$ of $\mathrm{Gal}(K/\mathbf{Q})$ fixing $\mathfrak{p}$ is called the *decomposition group* of $\mathfrak{p}$. Meanwhile, $\mathbf{F}_\mathfrak{p} := \mathcal{O}_K/\mathfrak{p}$ is a finite extension of $\mathbf{F}_p$. The extension $\mathbf{F}_\mathfrak{p}/\mathbf{F}_p$ is necessarily Galois; its Galois group is cyclic, generated by the Frobenius automorphism $\varphi_p : x \mapsto x^p$ of $\mathbf{F}_\mathfrak{p}$. There is a natural surjective map $D_\mathfrak{p} \to \mathrm{Gal}(\mathbf{F}_\mathfrak{p}/\mathbf{F}_p)$; its injectivity is equivalent to the assertion that p is unramified in $K/\mathbf{Q}$. Therefore, whenever this assertion is true, there is a unique $\sigma_\mathfrak{p} \in D_\mathfrak{p}$ whose image in $\mathrm{Gal}(\mathbf{F}_\mathfrak{p}/\mathbf{F}_p)$ is φ_p. The automorphism $\sigma_\mathfrak{p}$ is then a well-defined element of $\mathrm{Gal}(K/\mathbf{Q})$, the Frobenius automorphism for $\mathfrak{p}$. The various $\mathfrak{p}$ are all conjugate under $\mathrm{Gal}(K/\mathbf{Q})$ and that the Frobenius automorphism for the conjugate of $\mathfrak{p}$ by g is $g\sigma_\mathfrak{p}g^{-1}$. In particular, the various $\sigma_\mathfrak{p}$ are all conjugate; this justifies the practice of writing σ_p for any one of them and stating that σ_p is well defined up to conjugation.

We next introduce the concept of Frobenius elements in $G_\mathbf{Q} = \mathrm{Gal}(\overline{\mathbf{Q}}/\mathbf{Q})$. Let p again be a prime and let $\mathfrak{p}$ now be a prime of the ring of integers of $\overline{\mathbf{Q}}$ lying over p. To $\mathfrak{p}$ we associate: (1) its residue field $\mathbf{F}_\mathfrak{p}$, which is an algebraic closure of $\mathbf{F}_p$, and (2) a decomposition subgroup $D_\mathfrak{p}$ of $G_\mathbf{Q}$. There is again a surjective map $D_\mathfrak{p} \to \mathrm{Gal}(\mathbf{F}_\mathfrak{p}/\mathbf{F}_p)$. The Frobenius automorphism φ_p topologically generates the target group. We shall use the symbol Frob_p to denote any preimage of φ_p in any $D_\mathfrak{p}$ corresponding to a prime lying over p, and refer to Frob_p as a Frobenius element for p in $G_\mathbf{Q}$. This element is doubly ill defined. The ambiguity in Frob_p results from the circumstance that $\mathfrak{p}$ needs to be chosen and from the fact that $D_\mathfrak{p} \to \mathrm{Gal}(\mathbf{F}_\mathfrak{p}/\mathbf{F}_p)$ has a large kernel, the inertia subgroup $I_\mathfrak{p}$ of $D_\mathfrak{p}$. The usefulness of $\mathrm{Frob}_\mathfrak{p}$ stems from the fact that the various $\mathfrak{p}$ are all conjugate, so that likewise the subgroups $D_\mathfrak{p}$ and $I_\mathfrak{p}$ are conjugate. Thus if ρ is a homomorphism mapping $G_\mathbf{Q}$ to some other group, the kernel of ρ contains one $I_\mathfrak{p}$ if and only if it contains all $I_\mathfrak{p}$. In this case, one says that ρ is *unramified* at p; the image of Frob_p is then an element of the target that is well defined up to conjugation.

Consider an elliptic curve A over $\mathbf{Q}$ and let ℓ be a prime number. The fixed field of $\rho_{A,\ell}$ is a finite Galois extension $K_\ell/\mathbf{Q}$ whose Galois group G_ℓ is a subgroup of $\mathrm{GL}(2, \mathbf{F}_\ell)$. A key piece of information about the extension $K_\ell/\mathbf{Q}$ is that its discriminant is divisible at most by ℓ and primes dividing the conductor of A. In other words, if $p \neq \ell$ is a prime number at which A has good reduction, then $K_\ell/\mathbf{Q}$ is unramified at ℓ (see Exercise 15); one says that the representation $\rho_{A,\ell}$ is unramified at p. Whenever this occurs, the construction described above produces a Frobenius element σ_p in G_ℓ that is well defined up to conjugation.

Fix again an elliptic curve A and a prime number ℓ, and let $\rho_{A,\ell} : G_\mathbf{Q} \to \mathrm{GL}(2, \mathbf{F}_\ell)$ be the associated representation. For each prime p not dividing ℓ at which A has good reduction the Frobenius $\sigma_p = \rho_{A,\ell}(\mathrm{Frob}_p)$ is well defined only up

CHAPTER 6

Some other conjectures

We close with some additional comments and conjectures.

6.1. Integral points on elliptic curves

The starting point for any work on integral points on elliptic curves is the following theorem of Siegel.

Theorem 6.1.1 (Siegel)**.** *Every affine model of an elliptic curve over* $\mathbf{Q}$ *has only finitely many points over* $\mathbf{Z}$.

For more recent results on integral points on elliptic curves, see for example [**170**], [**171**], [**48**], [**163**], [**178**], [**169**], [**47**], [**161**], and [**187**].

I learned from [**159**] the statement of the following question:

Question 6.1.2. *Is there is a uniform bound on the number of integral points on minimal (affine) Weierstrass equations for elliptic curves over* $\mathbf{Q}$*?*

The following conjecture of Lang (see Conjecture IX.3.5 of [**156**] and p. 140 of [**78**]) predicts a bound on the number of integral points in terms of the rank of the Mordell-Weil group.

Conjecture 6.1.3 (Lang)**.** *There is an absolute constant* C *such that if* E *is an elliptic curve over* $\mathbf{Q}$ *given by a minimal (affine) Weierstrass equation, then the number of integral points on* E *is at most* $C^{1+\mathrm{rank}(E(\mathbf{Q}))}$.

Silverman [**157**] proved Lang's Conjecture for elliptic curves over $\mathbf{Q}$ with everywhere potentially good reduction (i.e., with integral j-invariant).

See [**137**] for a good discussion of integral points on curves.

6.2. Bounds on numbers of rational points on curves

Faltings [**43**] proved Mordell's Conjecture that if C is a smooth curve of genus $g \geq 2$ defined over a number field K, then $C(K)$ is finite. The following conjectures predict bounds on the number of points.

Caporaso-Harris-Mazur Conjecture ([**22**]). *If K is a number field and $2 \leq g \in \mathbf{Z}$, then there exists a constant $B(K,g)$ such that no smooth curve of genus g defined over K has more than $B(K,g)$ K-rational points.*

Strong Caporaso-Harris-Mazur Conjecture ([**22**]). *If $2 \leq g \in \mathbf{Z}$, then there exists a constant $N(g)$ such that for every number field K there are only finitely many smooth curves of genus g defined over K with more than $N(g)$ K-rational points.*

See also [**23**], where they show that a conjecture of Lang implies the Caporaso-Harris-Mazur Conjecture.

Theorem 6.2.1 (Brumer and Mestre). *For all g,*

$$N(g) \geq 16(g+1).$$

Theorem 6.2.2 (Shioda [**152**]). *For all g,*

$$B(\mathbf{Q},g) \geq 8g+16.$$

Theorem 6.2.3 (Keller-Kulesz [**70**]).

$$B(\mathbf{Q},2) \geq 588, \qquad B(\mathbf{Q},3) \geq 176.$$

Keller and Kulesz showed that the genus 2 curve

$$y^2 = 278,271,081x^2(x^2-9)^2 - 229,833,600(x^2-1)^2$$

has at least 588 rational points, and the genus 3 curve

$$y^2 = 7,920,000(x^2+1)^4 - 136,782,591x^2(x^2-1)^2$$

has at least 176 rational points.

6.3. Conductors of elliptic curves

Let $M(N)$ denote the number of ($\mathbf{Q}$-isomorphism classes of) elliptic curves over $\mathbf{Q}$ of conductor N.

Conjecture 6.3.1 (Brumer-Silverman [**20**]). *With p prime, $M(p)$ is unbounded.*

Brumer and Silverman point out that their conjecture implies the unboundedness of both ranks of elliptic curves over $\mathbf{Q}$ (using Silverman's result bounding the number of integral points in terms of the rank, for elliptic curves with integral j-invariant, and Serre's Theorem 5.3.2 above that if N_E is prime then $\Delta_{\min}(E)$ divides p^5) and 3-ranks of ideal class groups of quadratic fields. Conjecture 6.3.1 would contradict an affirmative answer to Question 6.1.2.

6.4. Abelian varieties, Shimura varieties, and open questions

Abelian varieties are parametrized by Shimura varieties, the way elliptic curves are parametrized by modular curves. As can be seen from the work of Faltings (the Mordell Conjecture) and Wiles (Fermat's Last Theorem), one often cannot remain within the realm of elliptic curves and modular curves, and must use and understand higher dimensional abelian varieties and Shimura varieties. Many results that are known for elliptic curves are still interesting conjectures for abelian varieties. This leaves open wide areas of research for the years to come.

The Mumford-Tate Conjecture (see [**138**], [**39**]) deals with the images of ℓ-adic representations associated to varieties, and is related to the Tate Conjectures [**172**] (which in turn are related to the conjectures of Birch and Swinnerton-Dyer).

As mentioned earlier, see for example [**124**], [**111**], and [**12**] for the conjectures of Beilinson and of Bloch-Kato, which generalize the conjectures of Birch and Swinnerton-Dyer.

There are Modularity Conjectures for elliptic curves over number fields other than $\mathbf{Q}$, and for abelian varieties with real multiplication (or more generally, for abelian varieties of GL_2-type). See for example [**125**], [**58**], and [**59**] (see [**50**] and [**49**] for analogues over function fields). See also Ken Ribet's lectures on Serre's Conjectures [**136**], in this volume.

6 Energy

The internal energy E is the first term in the free energy, $F = E - TS$. This chapter describes features of E that are important for phase transitions in materials. The internal energy originates from the quantum mechanics of electrons at atoms, specifically the chemical bonds between atoms. The simplest bond is between two atoms in a diatomic molecule, which is developed first to illustrate concepts of bonding, antibonding, electronegativity, covalency, and ionicity.

Crystals have long-range translational symmetry that brings a new quantum number $\vec{k}$ for states of delocalized electrons. The concept of energy bands is presented first by extending the concepts of molecular bonding and antibonding to electron states spread over many atoms. An even simpler model of a gas of free electrons is also developed for electrons in metals.

The strength of bonding depends on the distance between atoms. The interatomic potential of a chemical bond gives rise to elastic constants that characterize how a bulk material responds to small deformations. The chapter ends with a discussion of the elastic energy generated when a particle of a new phase forms inside a parent phase, and the two phases differ in specific volume.

6.1 Atomic Schrödinger Equations and Formalism

Start with two atoms, A and B, initially far apart. The properties of their electrons are calculated independently with two single-atom Schrödinger equations

$$-\frac{\hbar^2}{2m}\nabla^2\psi_{\mathrm{A}}(\vec{r}) + V_{\mathrm{A}}(\vec{r})\,\psi_{\mathrm{A}}(\vec{r}) = \epsilon_{\mathrm{A}}\psi_{\mathrm{A}}(\vec{r}), \tag{6.1}$$

$$-\frac{\hbar^2}{2m}\nabla^2\psi_{\mathrm{B}}(\vec{r}) + V_{\mathrm{B}}(\vec{r})\,\psi_{\mathrm{B}}(\vec{r}) = \epsilon_{\mathrm{B}}\psi_{\mathrm{B}}(\vec{r}). \tag{6.2}$$

At isolated atoms, the single-electron states (denoted $|\mathrm{A}\rangle$ and $|\mathrm{B}\rangle$ in Dirac notation) have wavefunctions ψ_{A} and ψ_{B}, and energies ϵ_{A} and ϵ_{B}. The potentials $V_{\mathrm{A}}(\vec{r})$ and $V_{\mathrm{B}}(\vec{r})$ are centered at the two separated nuclei. Each Laplacian, ∇^2, acts on the coordinates of one electron, wherever it is. To be more explicit, sometimes the Laplacian is given a subscript identifying the particular electron, e.g., the kinetic energy of electron number 1 is written $-(\hbar^2/2m)\,\nabla_1^2$, and electron number 2 has the kinetic energy $-(\hbar^2/2m)\,\nabla_2^2$.

We are interested in how the states for single electrons become something new when the two nuclei are brought together close enough so the wavefunctions of their atomic states overlap slightly. In a short time, an individual electron will have amplitude at both atoms, and a molecule is formed. A single-electron wavefunction for the diatomic molecule is called a "molecular orbital." A state for one electron now needs to include the effects of both nuclei and their core electrons, since the electron spends time about both. The potential is a real challenge for several reasons, primarily because the potential for one electron depends on the presence of other electrons.[1] We begin, however, by ignoring possible changes in potential, and we assume that the total potential for the molecule is simply the sum of potentials of the isolated atoms

$$V_{\mathrm{M}}(\vec{r}) = V_{\mathrm{A}}(\vec{r}) + V_{\mathrm{B}}(\vec{r}). \tag{6.3}$$

Another assumption, a guess really, is that the molecular orbital can be constructed as a weighted sum of the atomic orbitals as

$$|\mathrm{M}\rangle = c_{\mathrm{A}}|\mathrm{A}\rangle + c_{\mathrm{B}}|\mathrm{B}\rangle, \tag{6.4}$$

$$\psi_{\mathrm{M}}(\vec{r}) = c_{\mathrm{A}}\psi_{\mathrm{A}}(\vec{r}) + c_{\mathrm{B}}\psi_{\mathrm{B}}(\vec{r}), \tag{6.5}$$

written in Dirac notation (Eq. 6.4) and with explicit wavefunctions (Eq. 6.5). It is important to remember that the molecular state $|\mathrm{M}\rangle$ accommodates one electron, so the coefficients c_{A} and c_{B} are less than 1 (the atomic states $|\mathrm{A}\rangle$ and $|\mathrm{B}\rangle$ accommodate one electron each). The wavefunctions $\psi_{\mathrm{A}}(\vec{r})$ and $\psi_{\mathrm{B}}(\vec{r})$ are centered at different nuclei, but an electron can spend time in both of them (in states $|\mathrm{A}\rangle$ and $|\mathrm{B}\rangle$) when the two nuclei are brought near each other.

Box 6.1

Dirac Notation

Many calculations in quantum mechanics involve integrations over regions containing electron wavefunctions. Working with conventional integral formalism and its coordinates leads to bulky equations where it can be hard to see the forest through the trees. Paul Dirac dispensed with the coordinates altogether with a clever and compact notation. The quantum state of an electron 1 at atom A, having the wavefunction $\psi_{\mathrm{A}}(\vec{r}_1)$, is denoted $|A\rangle$ in Dirac notation. Without coordinates, this state function is not the wavefunction, but the two are related by projecting the quantum state onto spatial coordinates (i.e., finding the presence of the state $|A\rangle$ at $\vec{r}_1$). This projection and its complex conjugate are written as

$$\psi_{\mathrm{A}}(\vec{r}_1) = \langle \vec{r}_1|\mathrm{A}\rangle, \qquad \psi^*_{\mathrm{A}}(\vec{r}_1) = \langle \mathrm{A}|\vec{r}_1\rangle. \tag{6.6}$$

A typical calculation of orthogonality or normalization takes the form

$$\int_{-\infty}^{\infty} \psi^*_{\mathrm{A}}(\vec{r}_1)\,\psi_{\mathrm{A}}(\vec{r}_1)\,\mathrm{d}^3\vec{r}_1 = \int_{-\infty}^{\infty} \langle A|\vec{r}_1\rangle\langle\vec{r}_1|\mathrm{A}\rangle\,\mathrm{d}^3\vec{r}_1 = \langle A|\int_{-\infty}^{\infty} |\vec{r}_1\rangle\langle\vec{r}_1|\mathrm{A}\rangle\,\mathrm{d}^3\vec{r}_1. \tag{6.7}$$

---

[1] This is, however, a problem already faced when calculating energies of electrons in a multi-electron atom. The effect of a second electron is to push around the first electron, but this also alters the potential and wavefunction of the second electron. Iterative methods are useful for these types of problems.

One interpretation of the integral on the RHS is that it means projecting $|\mathrm{A}\rangle$ onto spatial coordinates for electron 1 as $\langle\vec{r}_1|\mathrm{A}\rangle$, using these projections to weight $|\vec{r}_1\rangle$, and then summing (integrating) over all $\vec{r}_1$. This reconstructs the state $|\mathrm{A}\rangle$ from the $|\vec{r}_1\rangle$, so Eq. 6.7 takes the compact form[a]

$$\int_{-\infty}^{\infty} \psi_{\mathrm{A}}^*(\vec{r}_1)\psi_{\mathrm{A}}(\vec{r}_1)\,\mathrm{d}^3\vec{r}_1 = \langle\mathrm{A}|\mathrm{A}\rangle. \tag{6.8}$$

The form $\langle\ |\ \rangle$ denotes a definite integral, typically with limits over all space. The same is true of expectation values of operators. For example

$$\int_{-\infty}^{\infty} \psi_{\mathrm{A}}^*(\vec{r}_1)\frac{-\mathrm{e}^2}{r_1}\psi_{\mathrm{B}}(\vec{r}_1)\,\mathrm{d}^3\vec{r}_1 = \langle\mathrm{A}|\frac{-\mathrm{e}^2}{r_1}|\mathrm{B}\rangle, \tag{6.9}$$

or for another example:

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \psi_{\mathrm{A}}^*(\vec{r}_1)\psi_{\mathrm{B}}^*(\vec{r}_2)H'(\vec{r}_2)\psi_{\mathrm{B}}(\vec{r}_1)\psi_{\mathrm{A}}(\vec{r}_2)\,\mathrm{d}^3\vec{r}_1\,\mathrm{d}^3\vec{r}_2 = \langle\mathrm{A}|\mathrm{B}\rangle_1\langle\mathrm{B}|H'|\mathrm{A}\rangle_2, \tag{6.10}$$

where the electron subscripts on the RHS of Eqs. 6.9 and 6.10 are usually ignored.

Dirac notation allows rapid and lucid mathematical manipulations. In the end, however, calculating integrals requires thought about the best coordinate system, and typically multiple integrations over three spatial variables.

[a] The coordinates form a complete set for expressing any function of position. For complete sets we can invoke the property of "closure," defined with an integral or a sum as, for example, $\int_{-\infty}^{\infty} |\vec{r}\rangle\langle\vec{r}|\,\mathrm{d}^3\vec{r} = 1$ or $\sum_i |i\rangle\langle i| = 1$.

6.2 Molecular Orbital Theory of Diatomic Molecules

6.2.1 Molecular Schrödinger Equation

The Schrödinger equation for a single electron in the molecule is

$$H|\mathrm{M}\rangle = \epsilon|\mathrm{M}\rangle, \tag{6.11}$$

where the Hamiltonian includes a kinetic energy operator for one electron, and the potential for this electron, the $V_{\mathrm{M}}(\vec{r})$ of Eq. 6.3. Two key operations are now done to convert the RHS of the Schrödinger equation 6.11 into a real energy ϵ without the wavefunction:

1. multiply Eq. 6.11 by $\langle\mathrm{A}|$, and make a second equation by multiplying Eq. 6.11 by $\langle\mathrm{B}|$;
2. for both equations, integrate over the coordinates of the electron.

Doing both steps simultaneously with Dirac notation

$$\langle\mathrm{A}|H|\mathrm{M}\rangle = \epsilon\langle\mathrm{A}|\mathrm{M}\rangle, \tag{6.12}$$

$$\langle\mathrm{B}|H|\mathrm{M}\rangle = \epsilon\langle\mathrm{B}|\mathrm{M}\rangle. \tag{6.13}$$

Using Eq. 6.4 for $|\mathrm{M}\rangle$

$$\langle \mathrm{A}|H|\Big(c_\mathrm{A}|\mathrm{A}\rangle + c_\mathrm{B}|\mathrm{B}\rangle\Big) = \epsilon\langle \mathrm{A}|\Big(c_\mathrm{A}|\mathrm{A}\rangle + c_\mathrm{B}|\mathrm{B}\rangle\Big), \tag{6.14}$$

$$\langle \mathrm{B}|H|\Big(c_\mathrm{A}|\mathrm{A}\rangle + c_\mathrm{B}|\mathrm{B}\rangle\Big) = \epsilon\langle \mathrm{B}|\Big(c_\mathrm{A}|\mathrm{A}\rangle + c_\mathrm{B}|\mathrm{B}\rangle\Big), \tag{6.15}$$

Moving the constants c_A and c_B through the integrals

$$c_\mathrm{A}\,\langle \mathrm{A}|H|\mathrm{A}\rangle + c_\mathrm{B}\,\langle \mathrm{A}|H|\mathrm{B}\rangle = \epsilon\, c_\mathrm{A}\,\langle \mathrm{A}|\mathrm{A}\rangle + \epsilon\, c_\mathrm{B}\,\langle \mathrm{A}|\mathrm{B}\rangle, \tag{6.16}$$

$$c_\mathrm{A}\,\langle \mathrm{B}|H|\mathrm{A}\rangle + c_\mathrm{B}\,\langle \mathrm{B}|H|\mathrm{B}\rangle = \epsilon\, c_\mathrm{A}\,\langle \mathrm{B}|\mathrm{A}\rangle + \epsilon\, c_\mathrm{B}\,\langle \mathrm{B}|\mathrm{B}\rangle. \tag{6.17}$$

Definitions and Approximations

The atomic states $|\mathrm{A}\rangle$ and $|\mathrm{B}\rangle$ are normalized to accommodate one electron, so

$$\langle \mathrm{A}|\mathrm{A}\rangle = \langle \mathrm{B}|\mathrm{B}\rangle = 1. \tag{6.18}$$

Although coordinates are not included in Dirac notation, the wavefunctions $\psi_\mathrm{A}(\vec{r})$ and $\psi_\mathrm{B}(\vec{r})$ are physically centered at different nuclei. The tails of the wavefunction for $|\mathrm{A}\rangle$ overlap the tails of the wavefunction for $|\mathrm{B}\rangle$. We define the overlap integral S

$$S \equiv \langle \mathrm{A}|\mathrm{B}\rangle, \tag{6.19}$$

$$S \equiv \int_{-\infty}^{+\infty} \psi_\mathrm{A}^*(\vec{r})\;\psi_\mathrm{B}(\vec{r})\;\mathrm{d}^3\vec{r}. \tag{6.20}$$

For now, for simplicity we set $S = 0$ (expecting that S is small). A closely related approximation is that the tails of the wavefunction for $|\mathrm{A}\rangle$ overlap only weakly with the potential energy from the second nucleus at B, so we neglect energies like $\langle \mathrm{A}|V_\mathrm{B}|\mathrm{A}\rangle$. This allows the approximations

$$\langle \mathrm{A}|H|\mathrm{A}\rangle \simeq \epsilon_\mathrm{A}, \tag{6.21}$$

$$\langle \mathrm{B}|H|\mathrm{B}\rangle \simeq \epsilon_\mathrm{B}, \tag{6.22}$$

where ϵ_A and ϵ_B are the energies of electrons in states at the isolated atoms A and B. With these simplifications, Eqs. 6.16 and 6.17 become

$$c_\mathrm{A}\,\epsilon_\mathrm{A} + c_\mathrm{B}\,\langle \mathrm{A}|H|\mathrm{B}\rangle = \epsilon\, c_\mathrm{A}, \tag{6.23}$$

$$c_\mathrm{A}\,\langle \mathrm{B}|H|\mathrm{A}\rangle + c_\mathrm{B}\,\epsilon_\mathrm{B} = \epsilon\, c_\mathrm{B}. \tag{6.24}$$

The important physical quantity that remains after our manipulations and approximations is the “bond integral,” h

$$h \equiv \langle \mathrm{A}|H|\mathrm{B}\rangle, \tag{6.25}$$

$$h \equiv \int_{-\infty}^{+\infty} \psi_\mathrm{A}^*(\vec{r})\;H\;\psi_\mathrm{B}(\vec{r})\;\mathrm{d}^3\vec{r}. \tag{6.26}$$

Energies of Molecular States

Some consequences of the bond integral h are explored below, but first we complete the formal effort to obtain the electron energies in the molecule, ϵ. With Eq. 6.25 for h, the pair of Eqs. 6.23 and 6.24 is written as one compact matrix equation

$$\begin{bmatrix} \epsilon_\mathrm{A} - \epsilon & h \\ h & \epsilon_\mathrm{B} - \epsilon \end{bmatrix} \begin{bmatrix} c_\mathrm{A} \\ c_\mathrm{B} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{6.27}$$

It proves convenient to replace ϵ_A and ϵ_B with their average $\overline{\epsilon} = (\epsilon_\mathrm{A} + \epsilon_\mathrm{B})/2$ and the difference $\Delta = (\epsilon_\mathrm{B} - \epsilon_\mathrm{A})/2$ so

$$\epsilon_\mathrm{A} = \overline{\epsilon} - \Delta \quad , \quad \epsilon_\mathrm{B} = \overline{\epsilon} + \Delta, \tag{6.28}$$

$$\begin{bmatrix} \overline{\epsilon} - \Delta - \epsilon & h \\ h & \overline{\epsilon} + \Delta - \epsilon \end{bmatrix} \begin{bmatrix} c_\mathrm{A} \\ c_\mathrm{B} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{6.29}$$

The matrix equation 6.29 has a useful solution when the determinant is zero, giving the secular equation

$$(\overline{\epsilon} - \Delta - \epsilon)(\overline{\epsilon} + \Delta - \epsilon) - h^2 = 0, \tag{6.30}$$

$$(\epsilon - \overline{\epsilon})^2 = \Delta^2 + h^2, \tag{6.31}$$

$$\epsilon^\pm = \overline{\epsilon} \mp \sqrt{\Delta^2 + h^2}, \tag{6.32}$$

where the two values of ϵ are labeled as ϵ^+ and ϵ^-. Compared to the average of the atomic energies, $\overline{\epsilon}$, one molecular state has an energy higher by the amount $\sqrt{\Delta^2 + h^2}$, and the other has an energy lower by the amount $\sqrt{\Delta^2 + h^2}$. These states are naturally called "antibonding" (with higher energy ϵ^-) and "bonding" (with lower energy ϵ^+), respectively.

6.2.2 Molecular Wavefunctions of Bonding and Antibonding States

Homonuclear Molecular Orbitals

We now solve for the c_A and c_B in Eq. 6.4, from which we can obtain the electron density in the bonding and antibonding molecular states, or "molecular orbitals." For homonuclear molecular orbitals involving identical atoms, for which $\epsilon_\mathrm{B} = \epsilon_\mathrm{A}$ so $\Delta = 0$, Eq. 6.32 gives $\epsilon^\pm = \overline{\epsilon} \mp |h|$. Substituting $\epsilon^\pm$ for ϵ in Eq. 6.29

$$\begin{bmatrix} \pm|h| & h \\ h & \pm|h| \end{bmatrix} \begin{bmatrix} c_\mathrm{A}^\pm \\ c_\mathrm{B}^\pm \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{6.33}$$

The first line of Eq. 6.33 gives

$$\pm|h|\, c_\mathrm{A}^\pm + h\, c_\mathrm{B}^\pm = 0, \tag{6.34}$$

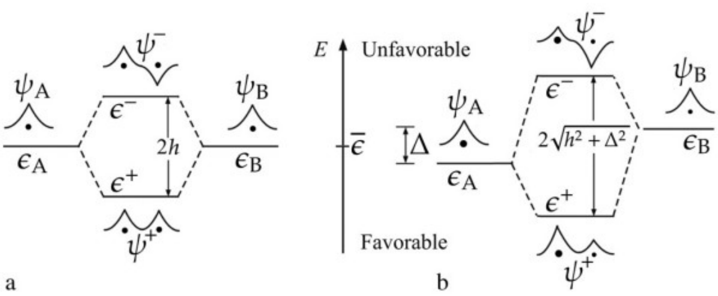

Figure 6.1 Energies and wavefunctions of molecular orbital formation in diatomic molecules with atom A on left and B on right in both panels a and b. Energy scale and definitions are in the middle. (**a**) Homonuclear molecule, such as H_2. With identical atomic energies and wavefunctions, the one-electron molecular states are symmetric. (**b**) Heteronuclear molecule, such as HF. With $\epsilon_B > \epsilon_A$, the bonding level ψ^+ is lower because it puts more of the electron in the favorable atomic wavefunction about atom A. The antibonding orbital ψ^- puts more electron in the unfavorable atomic wavefunction about atom B.

and since h is negative (bond energies are favorable)

$$c_A^{\pm} = \pm c_B^{\pm}. \tag{6.35}$$

For the bonding state with $\{\epsilon^+, c_A^+, c_B^+\}$, we obtain $c_A^+ = c_B^+$.
For the antibonding state with $\{\epsilon^-, c_A^-, c_B^-\}$, we obtain $c_A^- = -c_B^-$.

The two molecular states for single electrons, $|M^+\rangle$ and $|M^-\rangle$, are depicted in Fig. 6.1 as molecular orbital wavefunctions $\psi^+(\vec{r})$ and $\psi^-(\vec{r})$. The two panels a and b show bonding of two identical atoms (homonuclear), and bonding of two different atoms (heteronuclear). When identical atoms are brought together ($\Delta = (\epsilon_B - \epsilon_A)/2 = 0$), the bonding energy ϵ^+ and the antibonding energy ϵ^- are favored or disfavored over the isolated atoms by $\pm h$, where h is the bond integral of Eq. 6.25 (set $\Delta = 0$ in Eq. 6.32).

The $c_A^{\pm}$ and $c_B^{\pm}$ need normalization to 1 because there is one electron in either the bonding or antibonding molecular orbital

$$1 = \langle M^+|M^+\rangle = \left(c_A^+\langle A| + c_B^+\langle B|\right)\left(c_A^+|A\rangle + c_B^+|B\rangle\right), \tag{6.36}$$

$$1 = \langle M^-|M^-\rangle = \left(c_A^-\langle A| + c_B^-\langle B|\right)\left(c_A^-|A\rangle + c_B^-|B\rangle\right), \tag{6.37}$$

and with $c_A^+ = c_B^+$ and $c_A^- = -c_B^-$

$$1 = \langle M^+|M^+\rangle = c_A^{+2}\langle A|A\rangle + c_A^{+2}\langle A|B\rangle + c_A^{+2}\langle B|A\rangle + c_A^{+2}\langle B|B\rangle, \tag{6.38}$$

$$1 = \langle M^-|M^-\rangle = c_A^{-2}\langle A|A\rangle - c_A^{-2}\langle A|B\rangle - c_A^{-2}\langle B|A\rangle + c_A^{-2}\langle B|B\rangle. \tag{6.39}$$

Using the overlap integral S of Eq. 6.19 for $\langle A|B\rangle$ and $\langle B|A\rangle$

$$c_A^+ = +c_B^+ = \frac{1}{\sqrt{2}\,\sqrt{1+S}}, \tag{6.40}$$

$$c_A^- = -c_B^- = \frac{1}{\sqrt{2}\,\sqrt{1-S}}. \tag{6.41}$$

Comparing Eqs. 6.40 and 6.41, it is seen that with increasing overlap S, the bonding wavefunction needs some reduction in amplitude, and the antibonding some increase in amplitude. This can be understood from the electron density in the regions of overlap, as indicated schematically for ψ^+ and ψ^- in Fig. 6.1a. Midway between the two atoms, the wavefunction amplitude is doubled for the bonding wavefunction ψ^+, compared with the wavefunction in the tail of an atom wavefunction. It is zero in the middle of the antibonding wavefunction ψ^-. Obtaining the electron density as $\psi^*\psi$, the density for the bonding ψ^+ is increased by a factor of 2 over that for two independent atoms, whereas the density for the antibonding ψ^- is zero. Normalization of the whole wavefunction to 1 therefore decreases the total amplitude of the bonding wavefunction and increases it for the antibonding.

Heteronuclear Molecular Orbitals

The bonding energy increases with Δ, as given in Eq. 6.32 and shown in Fig. 6.1b. This Δ is a difference of atom properties, ϵ_A and ϵ_B. This difference is specified as the difference in "electronegativity," χ. The larger is χ, the more favorable are the single electron states at the atom. Our results of Eq. 6.32 show that the larger the difference in electronegativity $|\chi_A - \chi_B|$, the stronger the bonding energy. On the other hand, with increasing $|\chi_A - \chi_B|$ the antibonding state becomes even more unfavorable compared to the homonuclear molecule. As discussed further in Section 6.2.4, Fig. 6.1b illustrates what happens – the bonding level puts more electron density on the atom with the larger χ (and lower ϵ_A). The antibonding molecular orbital puts more electron density on the less favorable atom with the smaller χ. The difference between bonding and antibonding energies grows with Δ, or with increasing $|\chi_A - \chi_B|$.

6.2.3 Origin of the Bond Energy

A common argument is that the higher density of electrons in the region between the atoms, where the electron can see both nuclei with their attractive potentials, is why the bonding level is more favorable energetically. Unfortunately, this argument has a fundamental flaw. The electron density is normalized, so putting more electron density between the nuclei must remove electron density from other parts of the molecule. Indeed, Eqs. 6.40 and 6.41 show that $c_A^+ < c_A^-$, for example. Normalization removes electron density from nearest the nuclei where the potential energy is most favorable, and places it where the potential is modestly favorable. The consequence is that the antibonding level sees an increase in electron density at the nuclei, and the bonding level a decrease. The potential energy actually favors the antibonding level over the bonding level for molecular orbital theory with atomic wavefunctions.

The first step to repair this embarrassing situation is to include the electron kinetic energy. Here the disadvantage of the antibonding wavefunction is more obvious. Its node between the nuclei requires that the electron wavefunction undergoes a more rapid oscillation, increasing the kinetic energy because of a larger $\nabla^2\psi$. In contrast, the bonding wavefunction is smoother in this region between the nuclei, so it has the lower kinetic energy. This explanation of bonding is now more correct.

Molecular wavefunctions of the H_2^+ molecular ion have been calculated accurately, since there is only one electron, and the complicated electron–electron interactions are absent. Both the electron potential energy (which decreases when the electron is bunched near the nucleus) and the electron kinetic energy (which increases when the electron is confined) need to be considered in detail, for both the bonding and antibonding states. One should also consider the neglected overlap energies such as $\langle A|V_B|A\rangle$, which destabilize the antibonding state and favor the bonding state. For atomic *s*-electron wavefunctions it is found, perhaps not surprisingly, that atomic wavefunctions are inadequate even for a qualitative explanation of the chemical bond. The antibonding state is still favored slightly over the bonding state for most interatomic separations. What needs to be done is alter the shapes of $\psi_A(\vec{r})$ and $\psi_B(\vec{r})$ to minimize the energies of the bonding and antibonding states. This can be done fairly well by changing the characteristic length for the exponential decay of the atomic *s*-electron wavefunctions. By making a more rapid decay with distance of $\psi_A(\vec{r})$ and $\psi_B(\vec{r})$ for the bonding state, it is possible to place more electron density at the nuclei. The electron kinetic energy is increased a bit because the wavefunction is more confined, but the potential energy becomes much more favorable, and the bonding state does become bonding. The antibonding wavefunctions tend to lower their energy if the atomic *s*-states are expanded a bit, reducing the kinetic energy somewhat.[2] The real situation points out the risk of relying too heavily on analytical models, even for calculating bonding and antibonding states of the simplest molecule, H_2^+.

6.2.4 Ionicity and Electronegativity

For a heteronuclear molecule the two atoms differ in electronegativity, so $\Delta = (\epsilon_B - \epsilon_A)/2 \neq 0$. We expect unequal electron densities on each atom, so $|c_A| \neq |c_B|$. Expressions analogous to Eqs. 6.40 and 6.41 are obtained directly from Eqs. 6.33. Approximately[3]

$$c_A^{\pm} = \frac{1}{\sqrt{2}} \sqrt{1 \pm \frac{\delta - S}{\sqrt{1+\delta^2}}}, \tag{6.42}$$

$$c_B^{\pm} = \pm\frac{1}{\sqrt{2}} \sqrt{1 \mp \frac{\delta + S}{\sqrt{1+\delta^2}}}, \tag{6.43}$$

where the new variable

$$\delta \equiv \frac{\Delta}{|h|} \tag{6.44}$$

---

[2] A further improvement can be obtained by optimizing the atomic wavefunctions at each interatomic separation, but here the result is not changed qualitatively.

[3] When $\delta = 0$, there is a small difference between Eqs. 6.40 and 6.41 and Eqs. 6.42 and 6.43, since in Eqs. 6.42 and 6.43 some terms of order S^2 were neglected, and normalization was not done directly.

scales with the electronegativity difference of the atoms. Assuming the A-atom has the higher electronegativity as in Fig. 6.1b, electron density will transfer from B to A. We seek to write the molecular charge density $\rho = \psi^* \psi$ in the form

$$\rho(\vec{r}) = (1 + \alpha_\mathrm{i})\rho_\mathrm{A}(\vec{r}) + (1 - \alpha_\mathrm{i})\rho_\mathrm{B}(\vec{r}) + \alpha_\mathrm{c}\rho_\mathrm{bond}(\vec{r}), \tag{6.45}$$

where α_i is a fractional charge transfer caused by the ionic character of the bond (the difference in electronegativity), and α_c weights the charge density of covalent bonding that was considered in the previous section for a homonuclear molecule such as H_2.The charge redistribution upon bonding, $\rho_\mathrm{bond}(\vec{r})$, is defined with respect to the charge already present around two overlapping but independent atoms

$$\rho_\mathrm{bond}(\vec{r}) = 2\psi_\mathrm{A}(\vec{r})\psi_\mathrm{B}(\vec{r}) - S\Big[\rho_\mathrm{A}(\vec{r}) + \rho_\mathrm{B}(\vec{r})\Big], \tag{6.46}$$

where $\rho_\mathrm{A} = \psi^*_\mathrm{A}(\vec{r})\psi_\mathrm{A}(\vec{r})$ and $\rho_\mathrm{B} = \psi^*_\mathrm{B}(\vec{r})\psi_\mathrm{B}(\vec{r})$. Both ψ_A and ψ_B were assumed real in Eq. 6.46.

It turns out that

$$\alpha_\mathrm{i} = \frac{\delta}{\sqrt{1+\delta^2}}, \tag{6.47}$$

$$\alpha_\mathrm{c} = \frac{1}{\sqrt{1+\delta^2}}, \tag{6.48}$$

and $\alpha_\mathrm{i}^2 + \alpha_\mathrm{c}^2 = 1$. When $\delta = 0$, so the atoms have the same electronegativity, $\alpha_\mathrm{i} = 0$ and $\alpha_\mathrm{c} = 1$. This is a purely covalent bond.

When $\delta > 1$ and the effects of electronegativity are dominant, $\alpha_\mathrm{i} > \alpha_\mathrm{c}$, and the bond is mostly ionic. Assuming that these bonding tendencies are characteristics of atoms, or differences between atoms, it is appropriate to assign an electronegativity to each chemical element. Measures of electronegativity have been defined by different approaches, but the general trends of different electronegativity scales tend to be in agreement. It is a challenge, however, to account for bonding between different types of outer electrons of different atoms. Furthermore, there is a fundamental problem with all electronegativity scales – they predict that all pairs of chemical elements will form compounds. This is not so, and proper explanations of compound formation require concepts and physical properties that cannot be assigned to individual atoms alone.

6.3 Electronic Bands and the Tight-Binding Model

6.3.1 Translational Symmetry and Phase Factors

Translational symmetry is the fundamental difference between a molecule and a crystal, and translational symmetry has a profound effect on the spectrum of electronic energies in crystals. Neglecting surfaces, the electron density must be the same if position is shifted by a repeat distance of the crystal, i.e., a translation vector of the lattice. This does not apply, of course, to an isolated diatomic molecule.

6

e

A very special number

You have no idea how much poetry there is in the calculation of a table of logarithms.

—Carl Friedrich Gauss (1777–1855)

Prologue

As discussed in chapter 4, π is a transcendental number. Another significant transcendental number is e, which is equal to 2.71828.... The relation and importance of these two numbers is brought out eloquently by Ian Stewart (2008, 101):

> The number e is one of those strange special numbers that appear in mathematics, and have major significance. Another such number is π. These two numbers are the tip of an iceberg—there are many others. They are also arguably the most important of the special numbers because they crop up all over the mathematical landscape.

In correspondence between Gottfried Leibniz and Christian Huygens, there is mention of a constant with value 2.71828, which they represented with the letter b. It was Leonhard Euler who used e in a 1731 letter to Christian Goldbach, and then again in his 1736 book, *Mechanica.* From then on, this has been the symbol used as the standard one in mathematics. The mathematical definition of e is: the limiting value of the series represented by the expression $(1 + 1/n)^n$, as n becomes large without bound. A few values are given in Table 6.1.

Table 6.1 ***Values for (1 + 1/n)ⁿ***

n	$(1 + 1/n)^n$	*Value*
1	$(1 + 1/1)^1$	2.0
2	$(1 + 1/2)^2$	2.25
5	$(1 + 1/5)^5$	2.49
10	$(1 + 1/10)^{10}$	2.59
100	$(1 + 1/100)^{100}$	2.70
…	…	…
10,000	$(1 + 1/10{,}000)^{10{,}000}$	2.71815

Another formula used by Euler to determine the value of *e* (and there are a significant number of them) is the following one. Note that "!" means factorial, the product of an integer and all the integers below it: 4! = 4 × 3 × 2 × 1, 3! = 3 × 2 × 1, etc.

$$e = 1/0! + 1/1! + 1/2! + 1/3! + 1/4! + 1/5! + 1/6! + 1/7! \ldots$$

Equivalent to:

$$e = 1 + 1 + 1/2 + 1/6 + 1/24 + 1/120 + 1/720 + 1/5040 \ldots$$

Equivalent to:

$$e = 1 + 1 + 0.5 + 0.16 + 0.042 + 0.008 + 0.00138 + 0.000198 \ldots$$

Now, one may ask: What possible significance does such a number have? As it turns out, it forms the base of natural logarithms, which have had broad implications and applications; it appears in functions associated with the calculus; it surfaces in formulas for various kinds of curves; it crops up frequently in probability theory; it appears in the calculation of compound interest; and it has been found in natural and social phenomena such as the following:

1. radioactive decay
2. the growth of bacterial colonies
3. epidemiological patterns of all kinds
4. patterns in the accumulation of money
5. rates of change in many physical phenomena

Even though the value of 2.71828 appeared in an appendix in John Napier's 1618 book on logarithms (chapter 5), the first awareness of its mathematical significance is by English mathematician and clergyman William Oughtred (1574–1660), who defined it as the base of the *natural logarithm*. Here's what this means, recalling logarithms from the previous chapter:

> The natural logarithm of a number such as 7.389 is defined as: $\log_e$ (7.389), also written as: ln (7.389), which is approximately 2.

There is little doubt that this number has enormous significance, although the reasons why this is so remain as obscure as they are for π. This chapter deals with *e*. So many books, articles, research papers, websites, etc. have been written on this subject that it would be presumptuous and even pretentious to claim originality and even depth of coverage here (see bibliography for relevant titles). The purpose is simply to link *e* to other great ideas, showing how mathematical discovery forms a chain—a chain constructed with a handful of great ideas that appear across time and space, finding form and explanation in the writings and musings of individual mathematicians.

Mathematical connectivity

The number *e* is connected to many other concepts, structures, and patterns within mathematics, suggesting that it may be yet another kind of code for establishing interrelationships among mathematical entities. A significant property of *e* is that it is associated with various infinite series, thus linking it to the concept of mathematical infinity (to be discussed in chapter 8).

The Swiss mathematician Jacob Bernoulli (1654–1705) came up with the value of *e* by studying compound interest. He noted that a 100% increase when paid out annually results in the sum doubling year after year. However, splitting the 100% over shorter periods results in more than doubling the return at the end of the year. Bernoulli estimated what the payout would be if the interest was calculated continuously over infinitely small periods—which can be represented as an exponential function. The answer he discovered was that it grew at the annual rate of 2.71828…, which is the value of *e*. Soon after, similar findings emerged from diverse fields that involve growth or change, including epidemiology, the study of bacterial infections, and the like. Incidentally, Bernoulli's estimation of *e* involved thinking of *e* as resulting from an infinite series. As one compounds more and more interest, the value of one's investments approach a limit. Bernoulli thus defined *e* in terms of an infinite series that converges to a limit—that is, we can get closer and closer to the limit, but never quite reach it.

Euler was the first mathematician to study e in depth, coming up with the formula for an infinite series mentioned above in his 1748 book, *Introductio in analysin infinitorum* ("Introduction to Infinite Analysis"). Euler also noticed something intriguing, namely that e^x, now called an exponential function, had intriguing properties. One formula for this function is the so-called Taylor Series, formulated by British mathematician Brook Taylor in 1715:

$$e^x = 1 + x/1! + x^2/2! + x^3/3! + x^4/4! \ldots$$

Equivalent to:

$$e^x = 1 + x + x^2/2 + x^3/6 + x^4/24 \ldots$$

One of the most surprising findings regarding this function is that in differentiation none of the terms disappear, which they normally do. Rather, they repeat ad infinitum. Differentiation is an operation in the calculus. It allows us to determine the derivative of a function, which measures the slope of the graph of the function at a particular point on the graph. In other words, the derivative is a measure of change in the value of the function as the independent variable changes. This is yet another exceptional finding, implying that e^x is its own derivative and, thus, that the graph of e^x describes its own rate of change. Figure 6.1 is the graph showing how the slope rises dramatically.

So, more technically, if $f(x) = e^x$, then $dy/dx = e^x$ (where dy/dx is the symbol for differentiation). The negative exponential function, $f(x) = e^{-x}$, shows a slope

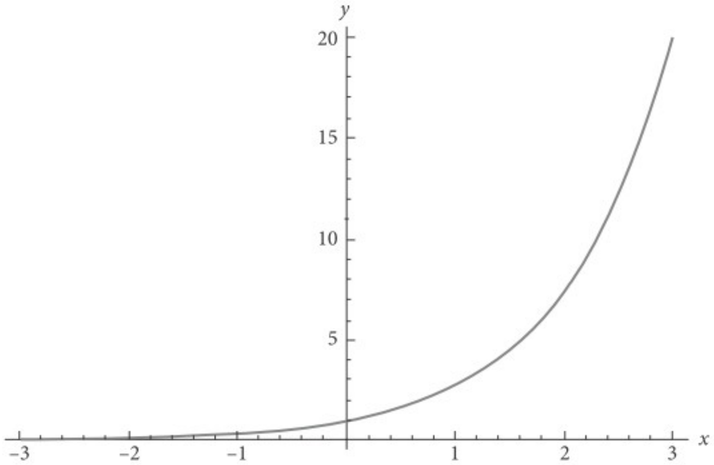

Figure 6.1 *The Exponential Function* e^x (from Wikimedia Commons)

in the opposite direction, thus visually demonstrating the relation between positive and negative exponents in the study of functions—another amazing discovery (see Figure 6.2).

Yet another serendipitous appearance of e^x is in the logarithmic spiral shown in Figure 6.3.

In this spiral, the distance from the center O is $1/e^x$ where x is the angle that results from the spiral turn. As x gets larger, $1/e^x$ becomes smaller. It was Jacob Bernoulli who discovered this remarkable property, and, given that spirals occur throughout nature, this is a rather important one. So surprised was Bernoulli by this finding that he called it a *spira mirabilis*, a miraculous spiral. Research on this figure has revealed a host of other hidden patterns. Nature is replete with logarithmic spirals having a similar mathematical structure.

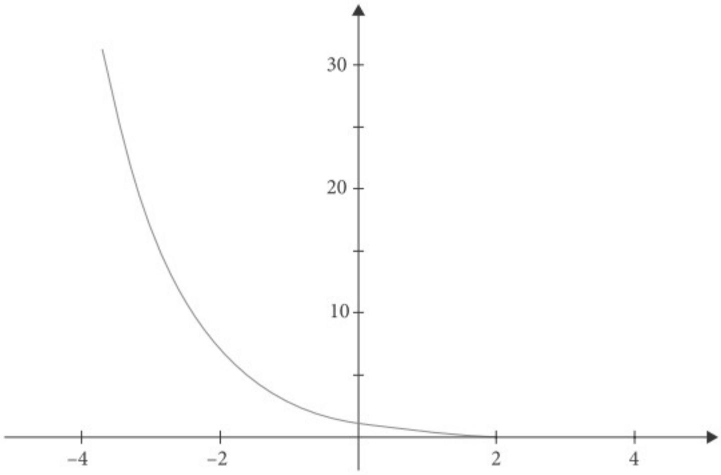

Figure 6.2 *The Exponential Function*, e^{-x} (from Wikimedia Commons)

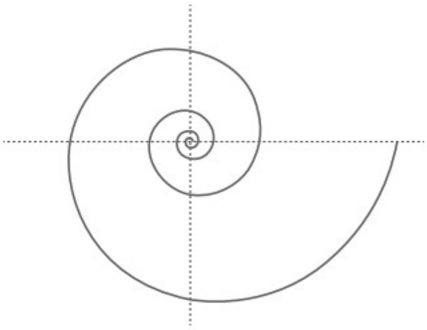

Figure 6.3 *The Logarithmic Spiral* (from Wikimedia Commons)

Bernoulli was so thrilled by his discovery that he wanted to be commemorated in death with it. As it turned out, an error was made, as Freiberger and Thomas (2014, 92) quip:

> Bernoulli was so fascinated by this self-similarity that he planned to have a logarithmic spiral engraved on his tombstone, along with the words (in Latin) 'Although changed, I shall arise the same.' Unfortunately, though, the wrong type of spiral, an Archimedean one whose loops are an equal distance apart, ended up adorning his grave. Poor Bernoulli, he must have turned (logarithmically) in his grave. Perhaps he should have gone for a simpler shape, the trusty old triangle.

The function e^x is a special one—called the *natural exponential function*. In general, an exponential function is one that has the form: $f(x) = a^x$, that is, a function in which the base is constant and the variable (x) is an exponent. Exponential functions have had many implications, not only in pure mathematics, but in in the following fields:

1. The study of radioactivity, since radioactive substances decay at an exponential rate.
2. Population analysis, since if unchecked, a population (organisms, people, cells, etc.) will grow at a rate proportional to itself.
3. In electrical engineering, since the theory of alternating current relies on the exponential function.

The connection between domains of science and exponential functions is something that is truly amazing, showing that mathematics and science are intrinsically intertwined. Indeed, mathematics is rightfully called the language of science. It has also been found that logarithmic functions occur in many areas of physics and biology. For example, the logarithm of measures of living tissue (skin area, weight), lengths of inert appendages (hair, claws), and certain physiological measures such as blood pressure all display a normal distribution. In economic theory, changes in the logarithms of exchange rates, as well as price and stock market indices also display the same type of distribution. The natural logarithm is also used by Google to give every page on the World Wide Web a score (PageRank), which is a rough measure of importance based on a logarithmic scale.

Euler's identity

Working with various exponential functions, Euler discovered an intriguing formula, known appropriately as Euler's formula, where "*i*" is an imaginary number (see chapter 7):

$$e^{i\varphi} = \cos \varphi + i \sin \varphi$$

The sine (shortened to *sin*) of an acute angle is defined in terms of a right triangle: it is the ratio of the length of the side that is opposite a given angle to the length of the longest side of the triangle (the hypotenuse). The cosine (shortened to *cos*) is the ratio of the length of the adjacent side to a given angle divided by the hypotenuse. The above formula can be plotted on the complex number plane as shown in Figure 6.4 below—complex numbers will be examined in the next chapter (Im = imaginary; Re = real):

Now, let's bring π into the picture. It is known in trigonometry that:

$$\sin \pi = 0$$

$$\cos \pi = -1$$

Let's replace φ with π in the formula above with these values:

$$e^{i\varphi} = \cos \varphi + i \sin \varphi$$

$$e^{i\pi} = \cos \pi + i \sin \pi$$

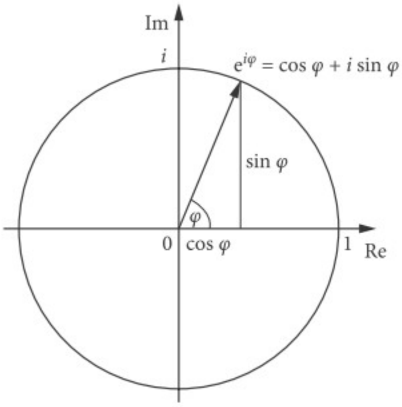

Figure 6.4 *Euler's identity* (from Wikimedia Commons)

$$e^{i\pi} = -1 + (i \times 0)$$

$$e^{i\pi} + 1 = 0$$

This is called Euler's identity. It connects some of the most significant numbers in the history of mathematics—e, i, π, 1, and 0. In 1990, the *Mathematical Intelligencer* periodical took a survey of its readers, conducted by mathematician David Wells, asking them to vote on the "most beautiful theorem in mathematics." Euler's identity came out as the winner by a large margin. It certainly is easy to see why mathematicians perceive it as having an inherent beauty, since it connects some of the most important numbers in mathematics.

There are many interesting and bizarre aspects of this equation, starting with the fact that it is really not an equation in the traditional sense, as Henshaw (2014, 58) aptly observes:

> Generally, the term "equation" implies something that it can be solved. For example, we can solve $x + 2 = 4$ and get the result $x = 2$. But Euler's identity isn't like that. There's nothing to solve for. It's just a statement of fact, like saying that $2 + 2 = 4$. And so, just as $2 + 2 = 4$ is a fact, $e^{i\pi} + 1 = 0$ is also a fact.

Epilogue

The fact that e is a descriptor of physical reality, especially in the domains of growth, decay, change, and probability once again raises the question left by Pythagoras' legacy: Why is mathematics such a powerful and unexpected language of truth? Also, as we have seen in this chapter: Why is change in natural phenomena logarithmic and described by exponential functions?

Even practical matters are governed by such mathematics. Consider the following:

> Bank A offers 100% interest on money. In one year, a sum of \$1000 becomes \$2000. Bank B pays 50% twice a year. In this case, \$1000 becomes \$1500 after six months and this becomes \$2250 after twelve months. This is clearly the better deal. Why is this so?

The formula for compound interest is the following one:

$(1 + r/n)^n$

r = annual interest rate (using 1 rather than 100%)

n = number of yearly periods

In the yearly model, $r = 1$ and $n = 1$:

$(1 + 1/1)^1 = 2.0$

In the half-yearly model, $r = 1$ and $n = 2$ (twice a year):

$(1 + 1/2)^2 = 2.25$

In the monthly model, $r = 1$, $n = 12$ (twelve times a year):

$\left(1 + 1/12\right)^{12} = 2.613$

The higher the value of n the greater the yield, and this shows why Bank B gave the better deal. Recall the formula for e at the start of this chapter:

$$\left(1 + 1/n\right)^n$$

As can be seen, the compound interest formula is based on this very formula. When the interest rate is n, the formulas become the same.

As Euler's identity seems to suggest, there may be some deeper meaning in *e*, as it relates to other numbers, of which we are not yet aware. All this suggests that mathematics is itself a conundrum. Its discoveries, such as the Pythagorean theorem, *e*, π, and so on, cannot be tied down to a specific meaning, even if they emerge in a context, including practical calculations such as those related to compound interest.

Explorations

1. A possible series for e

The number *e* has been determined by a number of series, as illustrated in this chapter. Determine if any of the following approaches *e* (2.71828); that is, if the sum of the terms might approach *e* as a limit.

$$(a)\ 1 + 1/2 + 1/3 + 1/4 + 1/5 + 1/6 + 1/7 + 1/8 \ldots$$

$$(b)\ 1 - 1/2 + 1/3 - 1/4 + 1/5 - 1/6 + 1/7 - 1/8 \ldots$$

$$(c)\ 1 \times 1/2 \times 1/3 \times 1/4 \times 1/5 \times 1/6 \times 1/7 \times 1/8 \ldots$$

2. Another series

Here is another series. It was introduced in this chapter:

$$1/0! + 1/1! + 1/2! + 1/3! + 1/4! + 1/5! + \dots$$

Note that in this case $1/0! = 1$. Does this series allow us to estimate the value of e to any degree of accuracy?

3. Plotting a function

Plot the function, $y = f(x) = x^2$ and then describe its general shape. In Table 6.2 below are some values:

Table 6.2 ***Values for f(x) = x²***

x	**0**	**1**	**−1**	**2**	**−2**	…
$f(x) = x^2$	$0^2 = 0$	$1^2 = 1$	$-1^2 = 1$	$2^2 = 4$	$-2^2 = 4$	…

4. Compound interest

The notions in this chapter are used in calculations of compound interest, as discovered by Jacob Bernoulli (above). Here is a problem that is similar to the one above.

> You are offered a new part-time job as a pizza delivery person, working only on weekends. Your boss gives you a choice in salary options as follows:
>
> *Option A*:
> $4,000 for your first year of work, and a raise of $800 for each year after the first.
>
> *Option B*:
> $2,000 for your first six months of work, and a raise of $200 every six months thereafter.
>
> Which offer is the better one?

5. The exponential function e^x

Below are a few values for e^x:

$$x = 1, e^x = 2.718$$
$$x = 2, e^x = 7.389$$
$$x = 3, e^x = 20.085$$
$$x = 4, e^x = 54.598$$

What power of x would produce the value of 1096.633? What does this imply generally about change (growth, decay, etc.) that is described by this function?

7

i

Imaginary numbers

Imaginary numbers are a fine and wonderful refuge of the divine spirit, almost an amphibian between being and non-being.

—Gottfried Leibniz (1831–1881)

Prologue

Consider the solution of the following quadratic equation, which is an equation with a variable, x in this case, which is squared:

$$x^2 + 1 = 0$$

$$x^2 = -1$$

$$x = \sqrt{-1}\left(\text{or, more precisely, } \pm\sqrt{-1}\right)$$

What kind of number is $\sqrt{-1}$? In a way that parallels the unexpected discovery of $\sqrt{2}$ by the Pythagoreans (chapter 1), when this number surfaced as a solution to a quadratic equation, mathematicians asked themselves what it could possibly mean. Not knowing what to call it, René Descartes named it, logically enough, an *imaginary number*. Euler introduced the letter "*i*" to stand for this number. Like the irrationals, the discovery of i led to new ideas and discoveries. One of these was *complex numbers*—numbers having the form

$(a + bi)$, where a and b are real numbers and i is $\sqrt{-1}$. Incredibly, complex numbers turn out to have many applications. They are used, for instance, to describe electric circuits and electromagnetic radiation and they are fundamental to quantum theory in physics. Returning to the equation above, $x^2 + 1 = 0$, if i is used like any other number, the equation has the following solution: $x = \pm i$.

In his treatise on equations, *Ars magna* (The Great Art), Italian mathematician Gerolamo Cardano (1501–1576) was among the first to come across the square root of negative numbers (Salem, Testard, and Salem 1992, 48–49). In one part, he was examining two numbers, x and y, which add up to 10 and, when multiplied, come to 40:

$$(1)\ x + y = 10$$

$$(2)\ xy = 40$$

The solution is shown below:

From (1): $y = 10 - x$
Substituting in (2): $x(10 - x) = 40$
Expanding and transposing: $-x^2 + 10x - 40 = 0$
Multiplying by -1: $x^2 - 10x + 40 = 0$
$x = 5 \pm \sqrt{-15}$

Cardano decided to abandon exploring the implications of this result calling the solution fictitious. On the other hand, Cardano's contemporary and compatriot Rafael Bombelli (1526–1572) saw such numbers as simply that—numbers that show up as the roots of some equations, formulating the first coherent theory of complex numbers in his *Algebra* of 1572. So, the values of Cardano's equation could be written as follows:

$$x = 5 \pm i\sqrt{15}$$

This chapter will look at the implications and significance of imaginary numbers, which constitute yet another of the great ideas of mathematics that have not only changed the course of mathematics but also of human history. Contemporary science and engineering would be much more limited without them.

Quadratic equations

Quadratic equations were known throughout the ancient world, from Babylon to China and India. The concept of "variable" and the use of symbols to represent numbers is traced to Greek mathematician Diophantus (c. 250 CE), who lived in Alexandria, Egypt, where he developed the techniques that later earned him the title "father of algebra." He also discussed methods of solving quadratic equations—similar methods were elaborated a few centuries later by the Hindu scholar Aryabhata (c. 476–550 CE).

It is useful here to rapidly review quadratic equations, which are defined as equations in which the power of one of the variables is 2. The general form of the quadratic equation is as follows:

$$ax^2 + bx + c = 0$$

The a and b are the numerical coefficients of x^2 and x respectively. The letter c represents the constant in the equation. Thus, for example, if $a = 3$, $b = 2$, and $c = 5$, then: $ax^2 + bx + c = 3x^2 + 2x + 5 = 0$. Consider the simple equation below, noting that in this case, $a = 1$, $b = 0$, and $c = -16$:

$$x^2 - 16 = 0$$

The solution is determined as follows:

$$x^2 - 16 = 0$$

$$x^2 = 16$$

$$x = +4 \text{ or } -4, \text{ shortened to } \pm 4$$

Now, consider the following equation:

$$x^2 + 8x + 15 = 0$$

We know that the expression $(x^2 + 8x + 16)$ represents a perfect square because it can be rewritten as $(x + 4)^2$. So, let's add 16 to both sides of the equation above, in order to produce a perfect square on the left side. This does not alter the values of the equation since the same number has been added to both sides. Note that 15 is moved to the right side, becoming -15:

$$x^2 + 8x + 16 = -15 + 16$$

$$x^2 + 8x + 16 = 1$$

$$(x + 4)^2 = 1$$

$$\surd(x+4)^2 = \surd 1$$

$$(x + 4) = 1$$

$$x = -3$$

Or:

$$-(x + 4) = 1$$

$$x = -5$$

Solution set:

$$x = \{-3, -5\}$$

The most common method for solving a quadratic equation is to use the following formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Without going into a step-by-step explanation, we plug these values in the equation above and we end up with the same solution: $x = \{-3, -5\}$.

The Babylonians were among the first to develop an algorithm for solving quadratic equations, as is evidenced by a Babylonian tablet preserved in the British Museum in which the following problem is posed (Solomon 2008, 11–12):

> The area of a square added to the side of a square comes to 0.75. What is the side of the square?

The solution unfolds as shown in Table 7.1, with corresponding contemporary algebraic notation added to show the reasoning involved.

The graphs of quadratic functions show parabolic curvature. Where the parabola touches or crosses the x-axis is where the two solutions lie. For example, the graph in Figure 7.1 shows the solution set of $x^2 - x - 2 = 0$, namely $x = \{-1, +2\}$, which are the points on the x-axis crossed by the curve:

Table 7.1 ***Babylonian Algorithm for Quadratic Equations***

Babylonian Tablet	*Contemporary Notation*
I have added the area and the side of my square: 0.75.	$x^2 + x = 0.75$
You write down 1, the coefficient.	Coefficient of x is 1
You break half of 1.	Half of 1 is 0.5
You multiply 0.5 and 0.5.	$(0.5)^2 = 0.25$
You add 0.25 and 0.75.	$0.25 + 0.75 = 1$
This is the square of 1.	$\sqrt{1} = 1$
Subtract 0.5, which you multiplied.	$1 - 0.5 = 0.5$
0.5 is the side of the square	$x = 0.5$

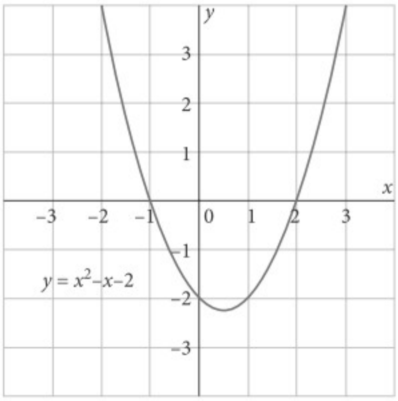

Figure 7.1 *Graph of* $y = x^2 - x - 2$ (from Wikimedia Commons)

Complex numbers

Squaring a negative number produces a positive number (chapter 3). So, what kind of number is $\sqrt{-1}$? All we can say is that it does not behave like any of the real numbers:

$$i = \sqrt{-1}$$
$$i^2 = (\sqrt{-1}) \times (\sqrt{-1}) = -1$$

The first mention of such numbers is traceable, actually, to the great twelfth-century Hindu mathematician Bhāskara (1114–1185). This was followed centuries later by Cardano and Bombelli, as mentioned above. It was Jean-Robert Argand (1768–1822) who showed how imaginary numbers and real numbers could be interconnected, followed by Carl Friedrich Gauss (1777–1855), who introduced the term, *complex number* in 1831. For example, every real number can be represented as a complex number, by simply letting the imaginary part be 0. So, for instance, 5 is:

$$a + bi = 5 + 0i = 5$$

In 1797 Gauss proved something revolutionary—namely, that complex numbers could solve any equation built from real numbers. This means that every equation has a full set of solutions among the complex numbers.

When imaginary numbers were first discovered, it was not clear how they fit into the number system or how they could be represented on the Cartesian plane. This conundrum led to the ingenious invention of a diagram by Argand that made it possible to show the relation of imaginary numbers to real ones. Figure 7.2 is the representation of $(a + bi)$ on the Argand plane (Im = imaginary number line; Re = real number line).

To add two complex numbers, say $(a + bi)$ and $(c + di)$, we add each part (real and imaginary) separately:

$$(a + bi) + (c + di) = (a + c) + (b + d)i$$

Below is an example:

$$(4 + 3i) + (5 + 6i) = (4 + 5) + (3 + 6)i = 9 + 9i$$

To multiply complex numbers we multiply them in the usual algebraic fashion:

$$(a + bi)(c + di) = ac + (ad)i + (bc)i + (bd)i^2$$

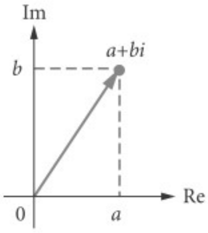

Figure 7.2 *Graph of a + bi* (from Wikimedia Commons)

Below is an example. Note that $i^2 = -1$, so $18i^2 = (18)(-1) = -18$:

$$(4+3i)(5+6i) = 20 + (24)i + (15)i + 18i^2 = 20 + (24)i + (15)i - 18 = (2+39i)$$

The other operations can also be specified in the same way, using the formulas $(a + bi)$ and $(c + di)$. The point is, as Bombelli and others suggested, that complex arithmetic is just like any type of arithmetic. The difference is, of course, the addition of i to it.

Fundamental Theorem of Algebra

The study of complex numbers led to an extraordinary discovery, known as the Fundamental Theorem of Algebra, which states that the field of complex numbers is algebraically closed—that is, there is no polynomial expression that does not have at least one complex root. It stipulates that an equation of degree n has n roots. So, for example a quadratic equation will have two roots, a cubic equation three, a quartic equation four, and so on. Let's look at a few for the sake of illustration:

Linear (one root):
$x - 5 = 0$
$x = \{5\}$

Quadratic (two roots):
$x^2 - 4 = 0$
$x = \{+2, -2\}$

Cubic (three roots):
$2x^3 + 3x^2 - 11x - 6 = 0$
$x = \{2, -1/2, -3)$

Quartic (four roots):
$3x^4 + 6x^3 - 123x^2 - 126x + 1080 = 0$
$x = \{3, 5, -4, -6\}$

This theorem was already implicit in the work of Descartes and Albert Girard (1595–1632). The first attempt to prove it is traced to French mathematician Jean d'Alembert (1717–1783) in 1746. But his proof contained some infelicities, which were corrected by Gauss, who presented his corrections in 1799. Gauss published a complete proof in 1816, building on ideas established by Euler.

The Fundamental Theorem is part of a broader theory of equations. It was Evariste Galois (1811–1832) who took a closer look at equations after the theorem was established, showing that solutions to equations could be carried out with permutations, leading to the emergence of group theory. Solutions to the quadratic, the cubic, and quartic have been found. However, no solution to the quintic (equation with a variable to the power of five) has ever emerged. Galois found that the groups of permutations associated with the quadratic, cubic, and quartic share a property that the quintic does not. This is the reason why no formula can be devised to solve the quintic.

Epilogue

The number *i* came from solving quadratic equations and had no meaning initially—much like √2 had no meaning for the Pythagoreans. After being labeled an imaginary number, it took on a mathematical life all its own, opening up a new way for expanding, classifying, and thus understanding numbers. Where were these numbers before they were discovered? As Ian Stewart (2013, 313) observes, the concept of *existence* in any treatment of mathematics raises several key questions, the most obvious one being the definition of *existence* itself:

> The deep question here is the meaning of "exist" in mathematics. In the real world, something exists if you can observe it, or, failing that, infer its necessary presence from things that can be observed. We know that gravity exists because we can observe its effects, even though no one can see gravity…However, the number two is not like that. It is not a thing, but a conceptual construct.

The irrational and the imaginary numbers did not "exist" until they cropped up in the use of the Pythagorean theorem and in solving quadratic equations respectively. Were they waiting to be discovered? This question is clearly at the core of the nature of mathematics. This "story" can be told over and over within the field—transfinite numbers, graph theory, and so on. These did not "exist" until they crystallized in the conduct of mathematics, through ingenious notational modifications, diagrammatic insights, various explorations with mathematical signs, and so on. Coming up with a theory of discovery in mathematics is an intractable task, since so many unknown factors are involved.

Consider the following question: What would happen if we add *j* and *k* to *i* in the Argand plane? The result is numbers with four parts. These were described by Irish mathematician William Rowan Hamilton (1806–1865) in

1843. He called them *quaternions.* They have led to a whole set of new rules of arithmetic shown in the multiplication table in Table 7.2.

Hamilton showed, in effect, that complex numbers were a subset of quaternions. Just as complex numbers can be shown as points on a plane, so quaternions can be considered to be points in a graph such as the one in Figure 7.3.

As it turns out, quaternions have uncovered the "existence" of many previously unknown number patterns and have had significant applications in physics. Quaternion theory has become especially significant for describing rotation in space. And it is now an essential tool in computer graphics, molecular modeling, and space flight.

Serendipity is likely to be a product of the imagination, as the late writer and semiotician Umberto Eco argued in his book *Serendipities: Language and Lunacy* (1998). The term was coined by English writer Horace Walpole who came across an ancient Persian tale, *The Three Princes of Serendip*, that suggested serendipity as a principle of life. The tale goes somewhat as follows. Three princes from Ceylon were journeying in a strange land when they came upon a man looking for his lost camel. The princes had never seen the animal, but asked the owner: Was it missing a tooth? Was it blind in one eye? Was it

Table 7.2 ***Multiplication of quaternions***

×	1	*i*	*j*	*k*
1	1	*i*	*j*	*k*
i	*i*	−1	*k*	−*j*
j	*j*	−*k*	−1	*i*
k	*k*	*j*	−*i*	−1

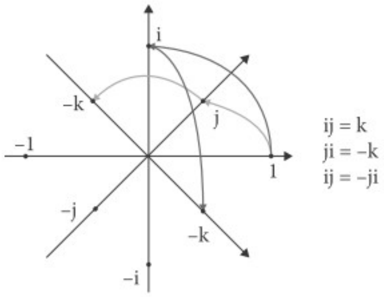

Figure 7.3 *Quaternion graph* (from Wikimedia Commons)

lame? Was it laden with butter on one side and honey on the other? Was a pregnant woman riding it? Incredibly, the answer to all their questions was "yes." The owner accused the princes of having stolen the animal since, clearly, they could not have had such precise knowledge. But the princes merely pointed out that they had observed the road, noticing several patterns in it: for example, the grass on either side was uneven, suggesting a lame gait; there were places where chewed food seemed to emerge from a gap in the animal's mouth; there were uneven patterns of footprints, the signs of awkward mounting and dismounting typical of someone who was pregnant; and there were differing accumulations of ants and flies, which congregate around butter and honey. Their questions were really prompted by inferences based on these observations. Knowing the world in which they lived, they were able to make concrete connections between the observations and what happened. Since Serendip was Ceylon's ancient name, Walpole coined the word *serendipity*, to designate how we come about our discoveries, such as mathematical and scientific ones, in a similar way.

Explorations

1. Imaginary numbers

To get a sense of what i means, figure out the following:

$$(1)\ i^3$$

$$(2)\ i^6$$

$$(3)\ i^0$$

2. A square root

Express $\sqrt{-9}$ as an imaginary number.

3. Conjugates

A conjugate number is a complex number with the opposite middle sign. So, the conjugate of the number $(a + bi)$ is $(a - bi)$, and vice versa. What happens when you multiply conjugates?

$$(a+bi)(a-bi)=?$$

4. Conjugate arithmetic

Now, apply what you discovered in exploration 3 to multiply the following:

$$(\text{a})\ (3+2i)\times(3-2i)=?$$
$$(\text{b})\ (5+3i)\times(5-3i)=?$$

5. Powers of complex numbers

Can you figure out the following?

$$(\text{a})\ (4-5i)^2$$
$$(\text{b})\ (3-3i)^3$$

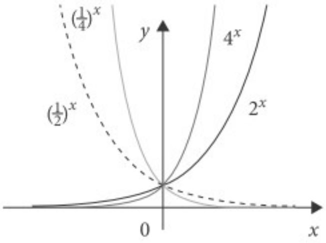

Figure 5.1 *Examples of exponential functions (from Wikimedia Commons)*

1. Equations where the variable or variables are to the power of 1 are called *first degree*: $3x + 1$; $5x + 2y$; etc.
2. Expressions where the variable or variables are to the power of 2 are named accordingly the *second degree*: $3x^2 + 1$; $5x^2 + 2y$; etc.
3. Expressions where the variable or variables are to the power of 3 are called expressions to the *third degree*: $3x^3 + 1$; $5x^3 + 2y$; etc.
4. In general, expressions where the variable is to the power of n are called expressions to the n^{th} degree.

These were known in antiquity, but the lack of an appropriate notation somewhat impeded the development of advanced algebra. The new notation provided mathematicians with a powerful descriptive tool that has had implications throughout mathematics. One of the more fascinating discoveries associated with exponents is the so-called *exponential function*. This is a function of the form $y = a^x$ (for example, $y = 2^x$). All such functions, when plotted onto the Cartesian plane have a parabolic shape as in Figure 5.1.

These functions show up in many places, from the calculation of compound interest to the measurement of anything that grows or decays, such as bacteria. They are used in radiocarbon dating, which has been of great importance to archeology.

Pascal's Triangle

After the spread of exponential arithmetic, mathematicians started looking more closely at certain types of expressions. French mathematician Blaise Pascal (1623–1662) was working with the expression $(a + b)^n$, known as a binomial (consisting of two terms), when he came across a hidden pattern in its expansion, $n = \{0, 1, 2, 3, 4, 5, \ldots\}$. Here are the first eight expansions:

$$\begin{aligned}
(a+b)^0 &= 1 \\
(a+b)^1 &= a+b \\
(a+b)^2 &= a^2+2ab+b^2 \\
(a+b)^3 &= a^3+3a^2b+3ab^2+b^3 \\
(a+b)^4 &= a^4+4a^3b+6a^2b^2+4ab^3+b^4 \\
(a+b)^5 &= a^5+5a^4b+10a^3b^2+10a^2b^3+5ab^4+b^5 \\
(a+b)^6 &= a^6+6a^5b+15a^4b^2+20a^3b^3+15a^2b^4+6ab^5+b^6 \\
(a+b)^7 &= a^7+7a^6b+21a^5b^2+35a^4b^3+35a^3b^4+21a^2b^5+7ab^6+b^7
\end{aligned}$$

In the top row, the numerical coefficient in $(a + b)^0$ is 1; in the next row down the numerical coefficients of $(a + b)^1 = a + b = 1a + 1b$ are both 1; in the next one down the numerical coefficients of $(a + b)^2 = a^2 + 2ab + b^2 = 1a^2 + 2ab + 1b^2$ are 1, 2, and 1; and so on. Extracting these coefficients from the other terms in the expressions, and leaving them in their respective rows, Pascal noted that they could be arranged into the shape of a triangle (Figure 5.2).

Now, surprisingly, the triangle itself harbors patterns that can be broken down reductively as follows:

1. Leaving aside the vertex 1 of the triangle, each row begins and ends in 1.
2. The other numbers in a row are the sum of the two numbers right above it—for example, each of the 10s in the sixth row down equals the sum of 4 and 6 above them.
3. In fact, each number in the triangle is the sum of the two directly above it.
4. It is this structure that makes it an infinite triangle, since we could continue to generate numbers within it with this simple rule ad infinitum.
5. As Sir Isaac Newton noted, the exponent in each expression in the binomial distribution indicates the row in Pascal's triangle where the numerical coefficients occur: for example, in the expansion of $(a + b)^4$,

1
1 1
1 2 1
1 3 3 1
1 4 6 4 1
1 5 10 10 5 1
1 6 15 20 15 6 1
1 7 21 35 35 21 7 1

Figure 5.2 *Pascal's Triangle*

which is $a^4 + 4a^3b + 6a^2b^2 + 4ab^3 + b^4$, the numerical coefficients (1, 4, 6, 4, 1) coincide with the fourth row of numbers in Pascal's triangle (if we do not include the top 1). Similarly, the numerical coefficients in the expansion of $(a + b)^5$, $a^5 + 5a^4b + 10a^3b^2 + 10a^2b^3 + 5ab^4 + b^5$ coincide with the fifth row of numbers in the triangle (1, 5, 10, 10, 5, 1); those in the expansion of $(a + b)^6$ with the sixth row; and so on.

6. The sum of the digits in any row, n, of the triangle is a power of 2, that is, 2^n. For instance, the sum of the digits in the fifth row is: $1 + 5 + 10 + 10 + 5 + 1 = 32$, which is 2^5 (Chamberlain 2015, 164–165).

There are many other hidden patterns in this remarkable triangle. For the sake of historical accuracy, it should be mentioned that the triangle appears in a Sanskrit text named the *Chandas Shastra,* written between 500 and 200 BCE, and in a 1303 Chinese work *Si Yuan Yu Jian* written by Zhu Shijie (1206–1320). There is no evidence to suggest that Pascal was aware of any of these texts—a fact that raises a truly deep enigma with regard to discovery. Why is it that people in different parts of the world and at different times are able to come up with similar ideas? No real answer to this question can be given—it can only be observed. To contextualize Pascal's amazing discovery, Solomon (2008, 80) makes the following relevant remarks:

> To be fair to Pascal, he did not claim to have invented the triangle. He certainly did not name it after himself. He actually referred to it as the "arithmetic triangle" and used it to calculate probabilities.

Logarithms

Exponential notation was the spark for logarithms, which have been used in many areas of mathematics, science, and statistics, leading to many discoveries. A logarithm is the actual power or exponent to which a base, usually 10, must be raised to produce a given number:

> If $n^x = a$, the logarithm of a, with n as the base, is x; symbolically, $\log_n a = x$. For example, $10^3 = 1{,}000$; therefore, $\log_{10} 1{,}000 = 3$.

To get a sense of the usefulness of logarithms, suppose we wanted to calculate the number of ancestors in any previous generation. We have 2 parents, so there are 2 ancestors in the first generation. This can be expressed as $2^1 = 2$. Each of our parents has 2 parents, and so there are $2 \times 2 = 2^2 = 4$ ancestors in the previous generation. Each of the four grandparents has 2 parents, and so there are $4 \times 2 = 2 \times 2 \times 2 = 2^3 = 8$ ancestors in the generation before. The calculation continues according to this pattern. In which generation do we have 1,024 ancestors? This can be rephrased as follows: For which value of n is $2^n = 1{,}024$? We can find the answer by multiplying 2 a number of times until we reach 1,024. But if we know that $\log_2 1{,}024 = 10$, because $2^{10} = 1{,}024$, we can get the answer much more quickly and efficiently. This tells us that in the tenth previous generation we have 1,024 ancestors. Note that in this case the base is not 10, but 2.

The invention of logarithms is traced to Scottish mathematician John Napier (1550–1617), who devised the first ones for carrying out tedious complex arithmetical operations in his 1614 work, *Mirifici logarithmorum canonis descriptio* ("Description of the Marvelous Canons of Logarithms"), coining the term *logarithm* as a combination of Greek *logos* (reason) and *arithmos* (number). In it, Napier showed how simple it is to carry out arithmetical operations with logarithms, since each number can be represented with a logarithmic value and all such values can be included in a table. For example, to multiply any two numbers:

1. Find their logarithms in the appropriate tables.
2. Add the two logarithms.
3. Look the result up in the *antilogarithm* tables (an antilogarithm is the number itself).

Napier's logarithms were based on powers of 0.999999; their translation into tables with 10 as the base was due to English mathematician Henry Briggs (1561–1630) in 1624. Briggs' improvements and refinements of Napier's techniques helped the notion of logarithms gain broad acceptance (Solomon 2008, 67).

The number of discoveries, implications, and ideas that logarithms have spawned, within and outside of mathematics, is mindboggling. One of the most widespread uses of logarithms is in so-called *log scales*. Perhaps the best-known contemporary example is the Richter scale, which is used to measure earthquake sizes, developed by Charles Richter in 1935 (see Figure 5.3). The scale shows how the magnitude of an earthquake is measured in logarithmic terms.

Other log scale phenomena include the decibel scale of sound and the pH scale of acidity. The remarkable thing to consider is that all such discoveries and uses of logarithms came about after the invention of a simple notation—exponents.

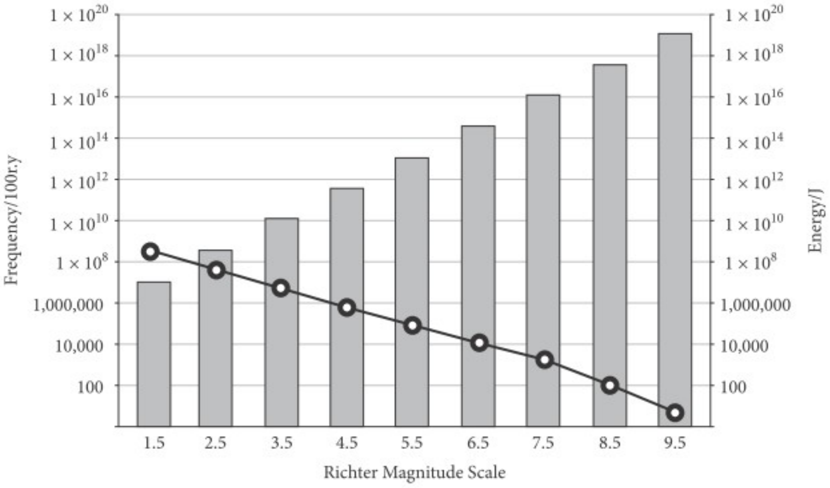

Figure 5.3 *A Richter Scale* (from Wikimedia Commons)

Notations and re-arrangements (such as the layout of Pascal's triangle) contain more hidden information about real phenomena than is initially apparent. It is upon reflecting on the hidden information that we come to extract more meaning from it than we would otherwise be likely to be able to do.

Epilogue

All of mathematics is encoded in symbolic notation. The Pythagorean equation $c^2 = a^2 + b^2$, for example, is essentially a convenient notation of saying the same thing as the sentence "the square on the hypotenuse is equal to the sum of the squares on the other two sides." In so doing, it takes the semantics in the linguistic sentence out, leaving only the structural (symbolic) outline of the information. It is this feature that makes it cognitively powerful, since we can now find many more meanings and applications for it, in addition to the original geometrical one. For example, one can now ask what integers fit the equation and, further, if there are other exponents for which the equation holds in general, $c^n = a^n + b^n$. From this deliberation on the notation itself, detached from its original geometrical meaning, has come much subsequent mathematical contemplation leading to such intriguing ideas as Fermat's Last Theorem, as we saw. In other words, notation suggests meanings that could not otherwise be contemplated.

The ancients did not have exponential notation at their disposal, so they used other devices to accomplish many of the same things as the new notation allowed so efficiently. In his book, *The Sand Reckoner*, Archimedes discussed the notion of powers in a roundabout way. However, it did not allow him to develop such techniques as exponential laws and logarithms.

Einstein's equation $E = mc^2$ has imprinted in it a lot of information about physical reality that could not be expressed in any other way. It says, in a nutshell, that the speed of light is constant and thus that it constrains physical reality. What happens if there is a universe where this formula does not hold? It would be unimaginable, even though it is possible. Above all else, we would need a notation to devise formulas for such a universe. As the philosopher Ludwig Wittgenstein (1922) put it, "Whereof one cannot speak, thereof one must be silent." As the language of Nature, mathematics breaks the silence periodically. $E = mc^2$ speaks volumes, to belabor the point somewhat.

Explorations

1. Square numbers

Here is a tricky problem, involving the exponent 2.

Find three numbers, less than or equal to 10, which when raised to the power of 2 and then added together equal 150.

2. Exponential arithmetic

Here is an age problem that requires exponential arithmetic.

> Alexander loves his grandmother. Here's how to figure out her age. It is between 50 and 100, divisible by 8. Each of the grandmother's sons has as many sons (her grandsons) as brothers. The combined number of her sons and grandsons equals her age. How old is she?

3. Generational logarithm

Above, the generation to which 1,024 ancestors belonged was computed using logarithmic method. Using the same method, to which generation do 256 ancestors belong?

4. A tough nut

This is a tough nut that became a meme on the Internet not too long ago: Can you figure out the value of x in $\sqrt{}(x + 15) + \sqrt{}x = 15$?

5. Laws of exponents

Here is a straightforward exploration what will allow you to review some of the laws of exponents discussed in this chapter. Simply provide the missing exponents in each of the following, as indicated by n in each case.

(a) $(2^n)(2^{12}) = 32{,}768$

(b) $(3^7)(2^n) = 279{,}936$

(c) $(5^n) \div (5^5) = 25$

(d) $(9^2)^n = 81$

> *And what are these fluxions? The velocities of evanescent increments? And what are these same evanescent increments? They are neither finite quantities, nor quantities infinitely small, nor yet nothing. May we not call them the ghosts of departed quantities?*
>
> George Berkeley, Bishop of Cloyne, *The Analyst* (1734) [52, p. 338]

> *...these increments must be conceived to become continuously smaller, and in this way, their ratio is represented as continuously approaching a certain limit, which is finally attained when the increment becomes absolutely nothing. This limit, which is, as it were, the final ratio of those increments, is the true object of differential calculus.*
>
> Leonhard Euler *Institutiones Calculi Differentialis* (1755) [24]

4

Differentiation

There are two classes of geometric problems treated by calculus: the determination of *tangents* is associated with derivatives, and the determination of *areas* with integrals. The standard practice in calculus texts (which we follow) is to look at derivatives first, but historically area problems were studied far more extensively and far earlier.

In Euclid and Archimedes, the notion of a line tangent to a curve was limited to circles and other *convex* curves; a line was tangent to such a curve if it touched it at exactly one point. (It is a tribute to the care that Archimedes took that he explicitly defined what it means for a curve to be convex, and set forth which properties he assumed followed from this definition [32, pp. 2–4].) A more general idea of tangent lines was given in Fermat's method for finding maxima and minima (Exercise 15 in § 4.7), which was primarily an algebraic algorithm, but supported at least in part by a concept similar to the modern one via secant lines. Descartes had a method for finding the tangent line by first finding the *normal* or perpendicular line (the *circle method* [21, pp. 125–7]) in connection with finding double roots of equations. Isaac Barrow (1630–1677), Newton's teacher and predecessor in the Lucasian Chair at Cambridge, found tangent lines via a method similar to Fermat's, using the "characteristic triangle" which we discuss below.

The approaches of Leibniz and Newton to tangents were quite different. Newton was coming at curves from a kinematic point of view; using the synthetic geometric language of Euclid, many of his tangent/derivative constructions consisted of taking a point moving toward another along a curve, and considering the chord between the two; he would then consider the positions of these chords and conclude that the "ultimate ratio" between these chords and the tangent line at the latter point was "that of equality". In general, his curve was *parametrized*: that is, it was generated by a combination of motions for two quantities, which we would label x (the abscissa) and y (the ordinate); he would consider their "fluxions" $\dot{x}$ and $\dot{y}$ (in our terms, the rates of change of the two quantities) and conclude that the tangent line has slope given by $\frac{\dot{y}}{\dot{x}}$.

Leibniz, on the other hand, thought in terms of a “characteristic triangle” whose sides were “infinitesimal” (*i.e.*, of vanishing length): this was a right triangle whose horizontal leg was the “differential” dx, the vertical leg was dy, and the hypotenuse was ds. These were to represent the infinitesimal increments of the abscissa, ordinate, and of the position along the curve. He would quite happily use the similarity between this triangle and various more conventional ones to deduce results about the tangent and related items. Our modern view combines some of Newton’s kinematic vision with Leibniz’s differential notation, rejecting the idea of actually taking a ratio of the form $\frac{dy}{dx}$ as Leibniz might do, but considering the limiting value of the ratio. However, Leibniz’s notation has survived in all aspects of calculus.

The first quotation at the head of this chapter is a famous passage from a pamphlet published in 1734 by George Berkeley (1685–1753), the Bishop of Cloyne. Berkeley attacked the reasoning behind the calculus of Newton, Leibniz and their colleagues to counter attacks on religious thinking as inexact; his point was that (even though the results *work*) the logical basis for the calculus was no more rigorous (no, less so) than the theological thinking of the time. His criticisms found their target; Newton among others tried to firm up the foundations of their thinking; the quotation from Euler is an indication of the ways this was attempted. But rigorous formulations of the basic ideas of limits, continuity and derivatives really only came in the nineteenth century.

The first careful formulations of the idea of derivative were given by Bernhard Bolzano (1781–1848) in 1817 and Augustin-Louis Cauchy (1789–1857) in 1821; we have already mentioned several times that Bolzano’s work, while somewhat earlier, was not generally known. Cauchy’s definition of the derivative is much the same as ours.

There was a presumption in the seventeenth through mid-nineteenth centuries that all continuous functions can be differentiated, with perhaps a few exceptional points (such as interface points for functions defined in pieces). In fact, Joseph Louis Lagrange (1736–1813) built a whole theory of functions around this assumption (using power series—see Chapter 6) [38]. At the end of this chapter, we will construct an example that shows this assumption can fail spectacularly. The first such example was probably given by Bolzano in 1834, but went unnoticed; however, when Karl Weierstrass (1815–1897) constructed such an example in the 1860s, it had an effect analogous to the discovery of the irrationality of $\sqrt{2}$ in Hellenic times, and was a major push toward the development of a far more careful formulation of the ideas of continuity, limits and derivatives.

4.1 Slope, Speed and Tangents

The **graph** (or **locus**) of an equation in x and y is the collection of points in the plane whose coordinates (x, y) satisfy the equation. The simplest equations involve sums of terms which are constant multiples of x or y, or just constants

$$Ax + By = C; \tag{4.1}$$

these are called **linear equations**, because their graphs are straight lines. When A and B are both nonzero, then the line crosses each coordinate axis at a unique point: it crosses the x-axis (which is the set of points where $y = 0$) at the point $(\frac{C}{A}, 0)$ and the y-axis (where $x = 0$) at $(0, \frac{C}{B})$; $\frac{C}{A}$ (*resp.*, $\frac{C}{B}$) is called the $\boldsymbol{x}$**-intercept** (*resp.*, $\boldsymbol{y}$**-intercept**) of the line.

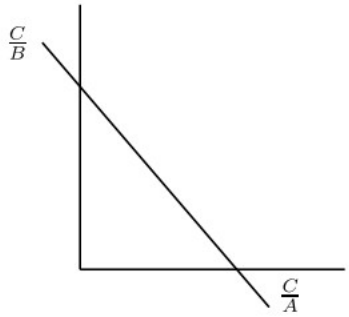

Figure 4.1. $Ax + By = C$

Of course, an equation can be manipulated algebraically, either by multiplying both sides by the same nonzero number or adding the same term to both sides, without changing the graph: in this way (provided $B \neq 0$) we can rewrite equation (4.1) as the definition of a polynomial function of degree 1

$$y = f(x) := mx + b \tag{4.2}$$

where $m = -\frac{A}{B}$ and $b = \frac{C}{B}$. Technically, such a function is not called "linear" (even though its graph is a straight line) unless $b = 0$; in general it is called an **affine function**. The coefficients of this polynomial have geometric interpretations. You can see immediately that b is the y-intercept of the graph. The various lines going through the point $(0, b)$ (or any other given point, for that matter) are distinguished by their "tilt", which is determined by the first-order coefficient m. Geometrically, if we compare the point $(0, b)$ (corresponding to $f(x)$ at $x = 0$) and the point corresponding to another, higher value of x, we see that the value $f(a) = ma + b$ at $x = a$ is precisely ma units higher than that at $x = 0$ (assuming $m > 0$; otherwise we adopt the convention that going "up" (*resp.*, "right") a *negative* number of units is the same as going "down" (*resp.*, "left") by its absolute value). Thus, m represents the ratio between the change, or **increment** $\triangle y$ in the output $y = f(x)$ and the increment $\triangle x$ in the input x as we go from $x = 0$ to any other value of x. In fact, if we start at *any* input value $x = x_1$ (with corresponding output value $y_1 = f(x_1)$) and go to any *other* input $x = x_2$ (with $y = y_2 = f(x_2)$), the increment in x is

$$\triangle x := x_2 - x_1$$

and the corresponding increment in $y = f(x)$ is

$$\triangle y := y_2 - y_1 = f(x_2) - f(x_1)$$

(sometimes also denoted "$\triangle f$") so (when f is affine, given by equation (4.2))

$$\triangle y = (mx_1 + b) - (mx_2 + b) = m(x_2 - x_1) = m\triangle x$$

and thus we have

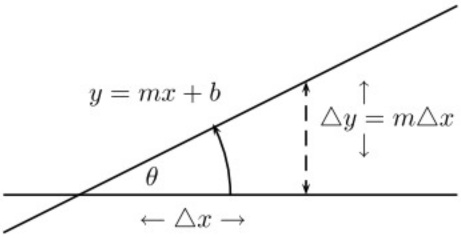
$$m = \frac{\triangle y}{\triangle x}$$

for *any* pair of *distinct* inputs $x_1 \neq x_2$. The fraction on the right is pronounced "*delta y over delta x*", but another colloquial expression for it is "*rise over run*", reflecting the fact that $\triangle y$ corresponds to vertical displacement and $\triangle x$ to horizontal displacement along the line.

The value $m = \frac{\triangle y}{\triangle x}$ is called the **slope** of the line $y = mx + b$; geometrically,

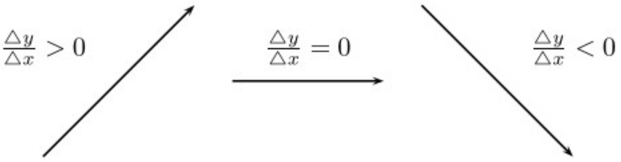
$$m = \frac{\triangle y}{\triangle x} = \tan\theta \tag{4.3}$$

where θ is the angle between the line and any horizontal line (Figure 4.2): *positive* slope means the line tilts *up* to the right while *negative* slope means it tilts *down* to the right; a horizontal line is the graph of a constant function, with slope zero (Figure 4.3). It also follows that two lines are parallel precisely if they have the same slope (Exercise 7).



$y = mx + b$
$\triangle y = m\triangle x$
θ
$\leftarrow \triangle x \rightarrow$

Figure 4.2. $m = \tan\theta$



$\frac{\triangle y}{\triangle x} > 0$
$\frac{\triangle y}{\triangle x} = 0$
$\frac{\triangle y}{\triangle x} < 0$

Figure 4.3. Sign of slope

The fact that $\frac{\triangle y}{\triangle x}$ is the same for any pair of points when y is an affine function of x can be used to write down the equation of the line through any pair of distinct points. For example, for $(x_1, y_1) = (-1, 3)$ and $(x_2, y_2) = (2, -3)$, the increments are

$$\begin{aligned} \triangle y &= y_2 - y_1 = (-3) - (3) = -6, \\ \triangle x &= x_2 - x_1 = 2 - (-1) \quad = 3, \end{aligned}$$

so the affine function $f(x) := mx + b$ with $f(-1) = 3$ and $f(2) = -3$ has

$$m = \frac{\triangle y}{\triangle x} = \frac{-6}{3} = -2;$$

then the fact that $f(-1) = 3$ means

$$-2(-1) + b = 3$$

or

$$b = 1$$

so the equation of the given line is

$$y = -2x + 1.$$

(You should check that $(x_2, y_2) = (2, -3)$ also lies on this line.)

The slope $\frac{\triangle y}{\triangle x}$ can also be interpreted as the **rate of change** of $y = f(x)$ between $x = x_1$ and $x = x_2$: in our example, a (horizontal) change in x of 3 units leads to a (vertical) change in $y = -2x + 1$ of -6 units, so y changes -2 units for every unit of change in x.

A little thought, fortified by some calculation (Exercise 8), shows that affine functions (including constants) are the *only* functions with domain $(-\infty, \infty)$ for which $\frac{\triangle y}{\triangle x}$ is the same for any pair of points. For example if we carried out the corresponding calculations for

$$f(x) = 3x^2 - 2$$

with $x_1 = -1$ and $x_2 = 2$, we would get $y_1 = 3(-1)^2 - 2 = 1$, $y_2 = 3(2)^2 - 2 = 10$, so

$$\frac{\triangle y}{\triangle x} = \frac{9}{3} = 3$$

while if we changed x_2 to $x_2 = 1$, we would have $y_2 = 3(1)^2 - 2 = 1$, so

$$\begin{aligned} \triangle y &= y_2 - y_1 = 1 - 1 &&= 0, \\ \triangle x &= x_2 - x_1 = 1 - (-1) &&= 2, \end{aligned}$$

and

$$\frac{\triangle y}{\triangle x} = 0;$$

similarly, if $x_1 = 1$ and $x_2 = 2$, then

$$\begin{aligned} \triangle y &= 10 - 1 = 9, \\ \triangle x &= 2 - 1 \ \ = 1, \end{aligned}$$

so

$$\frac{\triangle y}{\triangle x} = 9.$$

How, then, do we formulate the rate of change of a non-affine function? First, we have to be more specific: clearly $y = 3x^2 - 2$ is *increasing* when x is close to $x = 2$ but *decreasing* when x is near $x = -1$, so we need to specify *where* we want to find the rate of change. Second, the quantity $\frac{\triangle y}{\triangle x}$ represents a kind of *average* rate of change: we can only say that, for example, between $x = -1$ and $x = 2$ the function $y = 3x^2 - 2$ has a net increase of 9 units for a 3-unit increase in x, giving an average rate of change of 3 units increment in y per unit increment in x, while between $x = -1$ and $x = 1$ the function has no *net* change (of course, it does not stay constant in between—it just happens to return to its initial value), so the *average* rate of change between $x = -1$ and $x = 1$ is zero.

If we try to formulate "how fast" a function is changing *at a particular point*, we need to resort to limits. The idea is that if, say, we want to know how fast $y = 3x^2 - 2$ is changing *at* $x = 1$, we work from the assumption that the *average* rate of change over a *small* interval containing $x = 1$ should approximate the "true" or **instantaneous rate of change** at $x = 1$, and the smaller the interval, the better the approximation. This leads to the notion of a derivative.

Definition 4.1.1. *Suppose the function f is defined for all input values near $x = a$. The* ***derivative*** *of $y = f(x)$ at $x = a$ is the limit defined as follows:*

- *for each input x near $x = a$, set*

$$\begin{aligned}\triangle x &= x - a,\\ \triangle y &= f(x) - f(a)\,,\end{aligned}$$

- *the derivative is then the limit*

$$\lim_{x\to a}\frac{\triangle y}{\triangle x} = \lim_{x\to a}\frac{f(x)-f(a)}{x-a}.$$

While this idea was there in Newton's work, in the form of "ultimate ratios", it was not stated so clearly, particularly not in terms of functions (this notion, in fact, came later). The first statement of the derivative of a *function* in the terms above appears to have been by Jean le Rond D'Alembert (1717–1783) in an article in an encyclopedia (1754). Edwards [21, p. 295] has a translated quotation of d'Alembert's statement. Augustin-Louis Cauchy (1789–1857) gave a *rigorous* definition of derivative, more or less as above, in 1823 and used it along with his rigorous formulations of the notions of limit and integral to develop a careful theory of basic calculus.

Note that in this process, $\frac{\triangle y}{\triangle x}$ *does not make sense* when $x = a$. Also, notice that we could equally well have formulated this in terms of $\triangle x$ instead of x, using $x = a + \triangle x$:

$$\frac{\triangle y}{\triangle x} = \frac{f(a+\triangle x) - f(a)}{\triangle x}$$

and taken the limit as $\triangle x \to 0$.[1] Of course, as $\triangle x \to 0$, so[2] does $\triangle y$. A standard notational convention in calculus, which we shall see again in Chapter 5, says that when a quantity is defined in terms of increments of certain variables (like $\frac{\triangle y}{\triangle x}$), then the limiting value as all of these go to zero is denoted by replacing the Greek letter Δ (denoting a concrete small increment, calculated from two distinct but close points) with the corresponding English[3] letter d. Thus, a standard notation for the derivative is

$$\frac{dy}{dx} := \lim_{\triangle x\to 0}\frac{\triangle y}{\triangle x}.$$

Note that the expression $\frac{dy}{dx}$ is *not* the ratio between two quantities called "dx" and "dy"; rather we look at the *whole expression* as the limit of the ratio $\frac{\triangle y}{\triangle x}$. If we want to explicitly indicate *where* the derivative is being taken, we write

$$\left.\frac{dy}{dx}\right|_{x=a} = \lim_{x\to a}\frac{\triangle y}{\triangle x};$$

---

[1] It is common to replace the slightly awkward symbol $\triangle x$ with h in the definition of derivative, so one frequently sees the definition of the derivative written in the (clearly equivalent) form $f'(a) = \lim_{h\to 0}\frac{f(a+h)-f(a)}{h}$.

[2] at least if f is continuous

[3] or French, in the case of Cauchy

also, when $y = f(x)$, we sometimes use "f" in place of "y"

$$\left.\frac{dy}{dx}\right|_{x=a} = \left.\frac{df}{dx}\right|_{x=a} = \frac{df}{dx}.$$

An entirely different notation (due to Lagrange), which indicates in a more graceful way the function being differentiated and the place where the differentiation is being performed, is

$$\left.\frac{df}{dx}\right|_{x=a} = f'(a)\,,$$

and finally, we sometimes write y' in place of $f'(a)$ when $y = f(x)$.

Let us examine this definition in case $f(x) = 3x^2 - 2$ and $a = 1$. We will think in terms of $\triangle x$. We have

$$\begin{aligned}\triangle y = \triangle f &= f(1+\triangle x) - f(1) = [3(1+\triangle x)^2 - 2] - [1] \\ &= 6\triangle x + 3\triangle x^2\end{aligned}$$

so

$$\frac{\triangle y}{\triangle x} = \frac{\triangle f}{\triangle x} = \frac{6\triangle x + 3\triangle x^2}{\triangle x} = \frac{(6+\triangle x)\triangle x}{\triangle x} = 6 + \triangle x$$

and clearly

$$y' = f'(1) = \frac{df}{dx} = \frac{dy}{dx} = \lim_{\triangle x \to 0} \frac{\triangle y}{\triangle x} = \lim_{\triangle x \to 0}(6 + \triangle x) = 6.$$

There is a geometric way of thinking about the process of differentiation. When we have two distinct points (x_1, y_1) and (x_2, y_2) on the graph of $y = f(x)$, the line joining them is sometimes called a **secant line**; the slope of this line is the ratio $\frac{\triangle y}{\triangle x}$ of increments calculated using this pair of points (Figure 4.4). To calculate the derivative $f'(a)$, we nail down the point (x_1, y_1) at $x_1 = a$ (and $y_1 = f(a)$) and consider the secant line joining this to the variable point $x_2 = a + \triangle x$ (and $y_2 = f(a + \triangle x) = y_1 + \triangle y$); now consider the limit as $\triangle x \to 0$ (*i.e.*, $x_2 \to x_1$). All the secant lines we consider in this process go through the point $(x_1, y_1) = (a, f(a))$, but as x_2 changes they rotate around that point: it is geometrically clear that as $\triangle x \to 0$ this rotation brings them ever closer to a limiting position, with slope $\frac{dy}{dx}$: this defines the "tangent line" (to the graph) at the point (Figure 4.5).

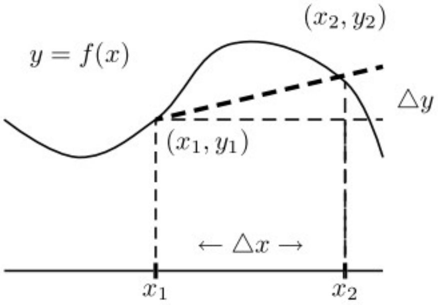


Figure 4.4. Secant Line

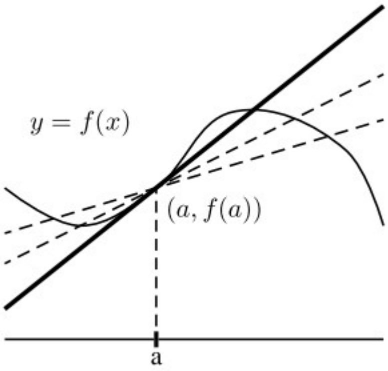

Figure 4.5. Tangent Line

Definition 4.1.2. *Suppose the function f is defined for all x near $x = a$. The line* ***tangent*** *to the graph $y = f(x)$ at $x = a$ is the limit of the secant lines through $(x_1, y_1) = (a, f(a))$ and nearby points (x_2, y_2) on the graph as $\triangle x = x_2 - x_1 \to 0$; the tangent line is the line through $(a, f(a))$ with slope $m = f'(a)$.*

From this description, we can deduce that the equation of the tangent line at $(a, f(a))$ is

$$y - f(a) = f'(a)\,(x - a)$$

or

$$y = f(a) + f'(a)\,(x - a). \tag{4.4}$$

The function defined by equation (4.4) (whose graph is the tangent line) plays a very important role in the application of derivatives to the analysis of f. We will clarify later (Lemma 6.1.1 and Proposition 6.1.2) that this is the affine function which best approximates the behavior of f near $x = a$. We will call this function by several names: it is the **tangent map** or **affine approximation** to $f(x)$ at $x = a$; we denote it by

$$T_a f(x) := f(a) + f'(a)\,(x - a).$$

In all of this discussion, we have ignored a crucial point: does every function *have* a derivative, or equivalently, does every curve have a tangent line? After all, these are defined as limits, and we have already seen that whenever we work with limits we should first make sure they exist. The following shows that not every function can be differentiated.

Remark 4.1.3. *In order for (the limit defining) the derivative $f'(a)$ to exist, the function f must be continuous at $x = a$.*

This is simply a consequence of the definition of the derivative: we are interested in the limit of the fraction $\frac{\triangle y}{\triangle x}$ as $\triangle x \to 0$, and if $\triangle y$ does *not* go to zero, this *must* diverge (why?). But saying $\triangle y \to 0$ is the same as saying $f(a + \triangle x) - f(a) \to 0$, and this is precisely the same as

$$f(a) = \lim_{x \to a} f(x)$$

(Exercise 9).

We say f is **differentiable** at $x = a$ if the limit defining $f'(a)$ exists; the remark tells us that *every differentiable function is continuous*. Thus for example the function

$$f(x) := \begin{cases} \frac{|x|}{x} & \text{for } x \neq 0, \\ 0 & \text{for } x = 0 \end{cases}$$

is *not* differentiable at $x = 0$. We have seen that $f(x) = 3x^2 - 2$ *is* differentiable at $x = 1$, and in the next section we shall establish that most of our "everyday" functions are differentiable wherever they are defined. But there is one glaring exception: the absolute value

$$f(x) = |x|.$$

First, look at the graph of the absolute value (Figure 4.6): for $x \geq 0$, we have $f(x) = x$, a line through the origin with slope $+1$, but for $x \leq 0$, $f(x) = -x$ is a line of slope -1. Certainly near any point $x = a$ *different from* $x = a$, the function looks just like the function $y = x$ (*resp.*, $y = -x$) if $a > 0$ (*resp.*, $a < 0$), so it is differentiable with derivative $y' = \pm 1$. But what is the tangent line at the origin? *All* secants through $(x_1, y_1) = (0, 0)$ and (x_2, y_2) with $x_2 > 0$ (and hence $y_2 = x_2$) have slope $+1$ while *all* secants with $x_2 < 0$ (so $y_2 = -x_2$) have slope -1. Thus, in the definition of $\frac{dy}{dx}$ as the limit of $\frac{\triangle y}{\triangle x}$, we have distinct one-sided limits

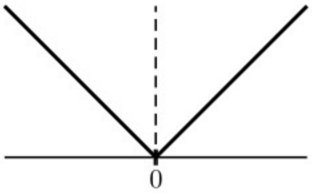

Figure 4.6. $y = |x|$

$$\lim_{\triangle x \to 0^+} \frac{\triangle y}{\triangle x} = \lim_{\triangle x \to 0^+} +1 = +1,$$
$$\lim_{\triangle x \to 0^-} \frac{\triangle y}{\triangle x} = \lim_{\triangle x \to 0^-} -1 = -1.$$

Thus, the (two-sided) *limit* does *not* exist: *the absolute value function $y = |x|$ is continuous, but NOT differentiable at $x = 0$.*

We shall deal with other examples of functions defined in pieces in the next section.

Exercises for § 4.1

Answers to Exercises 1–2ace, 3a, 4aceg, 5acf, 6acd, 10ade, 11c, 12a are given in Appendix B.

Practice problems:

1. Find the slope of each line below:

(a) $y = 3x + 5$
(b) $x = 3y + 5$
(c) $x + y = 0$
(d) $3x + 2y = 5$
(e) $3x = 2y + 5$
(f) $2y = 3x + 5$

> *. . . these were the days of Cavalieri and Roberval, when an area was looked upon as the same thing as an infinite number of line segments, a very helpful if dangerous definition.*

Integration

We have spent a good deal of time and energy studying differentiation; we now turn to the complementary notion of integration. Integration arises in connection with the calculation of areas, volumes, and length of curves, as well as averaging processes and related problems, particularly in probability and statistics.

The study of areas and volumes goes back to the Greeks; in the exercises for the first section of this chapter we will explore the results given by Euclid and Archimedes concerning the area of a circle. Both sources did much more, using versions of the method of exhaustion. For example, Archimedes found the area under a parabola, and volumes of cones, spheres, cylinders, and even paraboloids and hyperboloids. In the eleventh century the Islamic scholar Alhazen (*ca.*965–1039) extended some of these results, for example finding the volume obtained when a parabola is rotated about its base (rather than its axis). In the early seventeenth century Johannes Kepler (1571–1630) and Bonaventura Cavalieri (1598–1647) found formulas for other areas and volumes by heuristic methods. More general methods, closer to ones we now recognize as rigorous, were developed by Pierre de Fermat (1601–1665), Evangelista Torricelli (1608–1647), Gilles Roberval (1602–1675) and Blaise Pascal (1623–1662) in Europe, and John Wallis (1616–1703) and Isaac Barrow (1630–1677) in England.

Then, in the 1660s, the stunning result, known as the *Fundamental Theorem of Calculus*, was discovered: the process of finding areas (integration) is the inverse of the operation of finding tangents (differentiation). This was observed in a special case by Torricelli [52, p. 253] and in more general terms (but in a geometric language that to a modern reader is rather obscure) by James Gregory (1638–1675)—a brilliant Scots mathematician whose early death diminished his historical influence—and Isaac Barrow—Newton's teacher and predecessor in the Lucasian Chair of Mathematics at Cambridge. The full power of this observation was harnessed by Newton and Leibniz (independently) and is at the heart of much of the power of the calculus.

After this breakthrough, calculus developed at a breathtaking pace; by 1700, many of the results and techniques of what we call first-year calculus (and much more) had already been developed by the English and Continental schools. The eighteenth century saw a further blossoming of the field, particularly through power series methods in the hands of the masters Leonard Euler (1707–1783) and Joseph Louis Lagrange (1736–1813). During this period, integration was seen (as it is by many beginning calculus students now) primarily as *antidifferentiation*, and its foundation in the theory of area was somewhat eclipsed.

Then in the early nineteenth century, in connection with problems concerning the wave equation and heat equation, the foundations of integration were re-examined. Augustin-Louis Cauchy (1789–1857) gave a careful formulation of the definite integral (making more rigorous Leibniz's view of a definite integral as a sum of infinitesimals) and used his formulation to discuss integrals in the complex domain, as well as convergence of series. Euler had done some investigating of approximation of integrals by finite sums, but for him this was a property of antiderivatives; for Cauchy it was the definition: in fact, the Fundamental Theorem of Calculus was obtained by him as a consequence of his definition. Cauchy dealt primarily with integrals of continuous functions, but the emerging study of Fourier series required going beyond the assumption of continuity. Cauchy's definition was further refined by Bernhard Riemann (1826–1866) in 1854 to a form close to what we use today, although the recognition that some of his results required the notion of uniform continuity really came later, from Karl Weierstrass (1815–1897). Riemann also gave necessary and sufficient conditions for his integral to exist for a given function; we explore this in the last section of this chapter.

The notion of the integral continued to be extended: **??**Stieltjes18561894 introduced the idea of integrating with respect to a mass distribution in 1894, and a revolutionary new theory of integration was produced by Henri Lebesgue (1875–1941) in his doctoral thesis (1902); the description of the Lebesgue integral is beyond the scope of this book, but in its ability to handle really wild functions and its introduction of new ideas it has had a profound effect on the development of analysis in the last century; even more abstract and general formulations of the integral proliferated throughout that century.

5.1 Area and the Definition of the Integral

The idea of area, like that of velocity, begins with common-sense intuition but ends up requiring sophisticated limit processes to work in any but the simplest situations.

Our basic premise is that area is *additive*: if a region S consists of two pieces S_1 and S_2 which can share boundary points, but not interior points (*i.e.*, , they don't *overlap*) then the area $A(S)$ of the whole region should be the sum of the areas of the pieces:

$$A(S) = A(S_1) + A(S_2)\,. \tag{5.1}$$

We use this in two ways: *subdivision* and *tiling*. Starting with a standard square (sides of length 1) as our unit of area ($A = 1$), we can subdivide it into n^2 subsquares with sides of length $1/n$, so each of these subsquares must have area $1/n^2$. Now, a rectangle whose sides have rational length,[1] say width $w = p/n$ and length $\ell = q/n$, can be tiled by q rows consisting of p squares each with side $1/n$, so we obtain the area formula

---

[1] with common denominator n

$$A = \ell w$$

for (rational) rectangles; it is natural to extrapolate this formula to rectangles with rational or irrational sides.

It is also possible to use these kinds of subdivision and tiling arguments to deduce the area formula for triangles and other polygons. However, this approach collapses when we attempt to calculate the area of regions with curved sides.

To understand this more general situation, we investigate the area of the plane region (see Figure 5.1) S bounded below by the x-axis, on the left and right by two vertical lines ($x = a$ and $x = b$) and above by the graph of a function $y = f(x)$, which we assume is nonnegative and continuous on the interval $x \in [a, b]$:

$$S = \{(x, y) \,|\, a \le x \le b,\ 0 \le y \le f(x)\}\,.$$

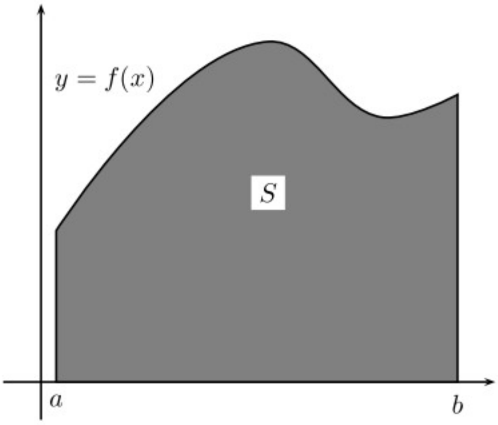

Figure 5.1. Area under a graph

We will illustrate our general discussion using the example

$$f(x) = x^3,\ a = 1,\ b = 2.$$

The idea is to locate the number $A(S)$ (giving the area of S) by a process of approximation analogous to our approximation of $\sqrt{2}$ in § 2.2. Our estimates use the *monotonicity* of area: the area of any subregion is less than the area of the whole:

$$S_1 \subset S_2 \Rightarrow A(S_1) \le A(S_2)\,. \tag{5.2}$$

(This actually follows from additivity of area: see Exercise 3.)

To obtain *lower* bounds for $A(S)$, we fit nonoverlapping rectangles *inside* S (Figure 5.3). Start by subdividing the interval $[a, b]$ into adjacent subintervals: this is specified by a finite list of division points, together with the two endpoints, numbered left-to-right and starting with index 0:

$$a = p_0 < p_1 < \cdots < p_n = b.$$

We refer to the collection

$$\mathcal{P} = \{p_0, p_1, \dots, p_n\}$$

as a **partition** of $[a, b]$. The **component intervals** of $\mathcal{P}$

$$I_j = [p_{j-1}, p_j] \quad j = 1, \dots, n$$

are also numbered left to right; the length of the j^{th} component interval is

$$\triangle x_j = \|I_j\| = p_j - p_{j-1} \quad j = 1, \dots, n.$$

As an example, we consider, for $n = 2, 3, \dots$, the partition $\mathcal{P}_n$ of the interval $[1, 2]$ into n intervals, *all of the same length*—that is, the points p_i, $i = 0, \dots, n$ are equally spaced in $[1, 2]$, so

$$\triangle x_j = \frac{2-1}{n} = \frac{1}{n}$$

for $j = 1, \dots, n$, and we easily see that

$$p_j = 1 + \frac{j}{n}, \quad i = 0, \dots, n$$

or

$$\mathcal{P}_n = \left\{1, 1 + \frac{1}{n}, 1 + \frac{2}{n}, \dots, 1 + \frac{n-1}{n}, 2\right\}.$$

Now, we use each component interval I_j (sitting on the x-axis) as the base of a rectangle of height h_j (and width $w_j = \triangle x_j$). This rectangle is contained inside S precisely if h_j is a lower bound for $f(x)$ on I_j, so the *tallest* rectangle with base I_j that fits inside S (Figure 5.2) has height

$$h_j = h_j^- := \inf_{x \in I_j} f(x)$$

and hence area

$$\triangle A_j^- = h_j^- w_j = \left[\inf_{x \in I_j} f(x)\right] \triangle x_j.$$

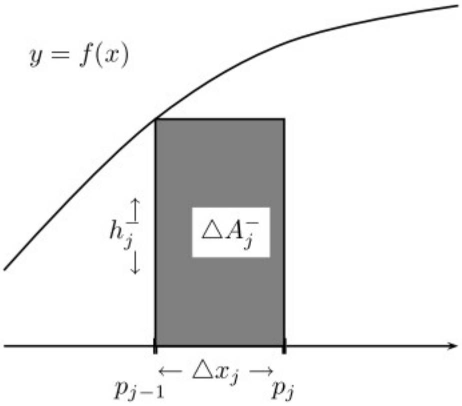

Figure 5.2. Inside Rectangle over $I_j = [p_{j-1}, p_j]$

Thus, starting from the component intervals of the partition $\mathcal{P}$, the largest union of rectangles we can fit inside S (Figure 5.3) has total area

$$\sum_{j=1}^{n} \triangle A_j^- = \sum_{j=1}^{n} \left[\inf_{x\in I_j} f(x)\right] \triangle x_j.$$

The expression on the right is called the **lower sum** for f associated to the partition $\mathcal{P}$ of $[a,b]$; we write

$$\mathcal{L}(\mathcal{P},f) = \sum_{j=1}^{n} \inf_{I_j} f \triangle x_j.$$

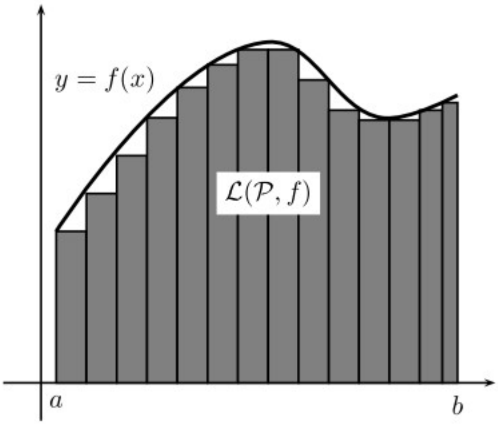

Figure 5.3. $\mathcal{L}(\mathcal{P},f)$

Monotonicity of area then says that, for every partition $\mathcal{P}$,

$$\mathcal{L}(\mathcal{P},f) \leq A(S).$$

In our example, $f(x)=x^3$ is strictly increasing over $[1,2]$, so for each j,

$$\begin{aligned} h_j^- &= \inf_{x\in I_j} x^3 = p_{j-1}^3 \\ &= \left(1+\frac{j-1}{n}\right)^3 \end{aligned}$$

and the lower sum for x^3 associated to the partition $\mathcal{P}_n$ of $[1,2]$ into n equal parts is

$$\begin{aligned} \mathcal{L}(\mathcal{P}_n, x^3) &= \sum_{j=1}^{n} \left[1+\frac{(j-1)}{n}\right]^3 \cdot \frac{1}{n} \\ &= \frac{1}{n} \sum_{i=j-1=0}^{n-1} \left[1+\frac{i}{n}\right]^3 \\ &= \frac{1}{n} \sum_{i=0}^{n-1} \left[1+3\frac{i}{n}+3\frac{i^2}{n^2}+\frac{i^3}{n^3}\right]. \end{aligned}$$

This formidable looking summation can be evaluated using the following summation formulas (Exercise 5):

$$\sum_{k=1}^{n} 1 = n, \tag{5.3}$$

$$\sum_{k=1}^{n} k = \frac{n(n+1)}{2}, \tag{5.4}$$

$$\sum_{k=1}^{n} k^2 = \frac{n(n+1)(2n+1)}{6}, \tag{5.5}$$

$$\sum_{k=1}^{n} k^3 = \frac{n^2(n+1)^2}{4} = \left(\sum_{k=1}^{n} k\right)^2. \tag{5.6}$$

Using these (and noting that we are applying them with n replaced by $n-1$ in all but the first sum, since the terms for $i=0$ drop out), we can write

$$\begin{aligned}\mathcal{L}(\mathcal{P}_n, x^3) &= \frac{1}{n}\left[n + \frac{3}{n}\frac{(n-1)(n)}{2} + \frac{3}{n^2}\frac{(n-1)(n)(2n-1)}{6} + \frac{1}{n^3}\frac{(n-1)^2(n)^2}{4}\right] \\ &= 1 + \frac{3}{2}\left(\frac{n-1}{n}\right) + \frac{3}{6}\left(\frac{(n-1)(2n-1)}{n^2}\right) + \frac{1}{4}\left(\frac{(n-1)^2}{n^2}\right). \end{aligned} \tag{5.7}$$

To obtain an *upper* bound for $A(S)$, we use a similar construction to enclose S inside a union of rectangles built on the same bases. Given $I_j = [p_{j-1}, p_j]$ a component of the partition $\mathcal{P} = \{p_0, \ldots, p_n\}$ of $[a, b]$, the rectangle with base I_j and height h_j contains all the points $(x, y) \in S$ with $x \in I_j$ precisely if h_j is an upper bound for $f(x)$ on I_j; the *shortest* such rectangle has height[2]

$$h_j = h_j^+ :== \sup_{I_j} f.$$

This rectangle has area

$$\triangle A_j^+ = \sup_{I_j} f \triangle x_j.$$

The total area of these rectangles (Figure 5.4) gives an upper bound for $A(S)$,

$$A(S) \leq \sum_{j=1}^{n} \triangle A_j^+ = \sum_{j=1}^{n} \sup_{I_j} f \triangle x_j.$$

The sum on the right is called the **upper sum** for f associated to the partition $\mathcal{P}$, and denoted

$$\mathcal{U}(\mathcal{P}, f) = \sum_{j=1}^{n} \sup_{I_j} f \triangle x_j.$$

---

[2] The supremum here exists since f is continuous on I_j, hence bounded by the Extreme Value Theorem (Theorem 3.3.4).

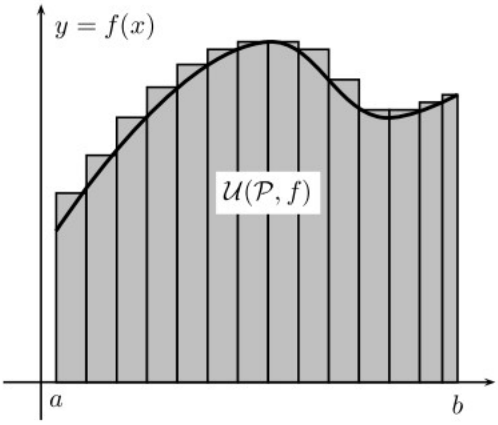

Figure 5.4. $\mathcal{U}(\mathcal{P}, f)$

In our example again, since $f(x) = x^3$ is strictly increasing on $[1, 2]$, we have

$$h_j^+ = \sup_{x \in I_j} x^3 = p_j^3$$

so that the upper sum is

$$\begin{aligned}\mathcal{U}(\mathcal{P}_n, x^3) &= \frac{1}{n} \cdot \sum_{j=1}^{n} \left[1 + 3\frac{j}{n} + 3\frac{j^2}{n^2} + \frac{j^3}{n^3}\right] \\ &= 1 + \frac{3}{2}\left(\frac{n+1}{n}\right) + \frac{3}{6}\left(\frac{(n+1)(2n+1)}{n^2}\right) + \frac{1}{4}\left(\frac{(n+1)^2}{n^2}\right). \quad (5.8)\end{aligned}$$

We see, then, that the area $A(S)$ of the plane region

$$S = \{(x, y) \,|\, a \leq x \leq b,\ 0 \leq y \leq f(x)\}$$

is bounded by the lower and upper sums associated to any partition $\mathcal{P}$ of $[a, b]$:

$$\sum_{j=1}^{n} \inf_{I_j} f \triangle x_j = \mathcal{L}(\mathcal{P}, f) \leq A(S) \leq \mathcal{U}(\mathcal{P}, f) = \sum_{j=1}^{n} \sup_{I_j} f \triangle x_j.$$

We note in particular that the "trivial partition" $\mathcal{P}_0 = \{a, b\}$ has one component interval ($I_1 = [a, b]$) with $\triangle x_1 = b - a$, leading to the estimate

$$\inf_{a \leq x \leq b} f(x)\,(b-a) = \mathcal{L}(\mathcal{P}_0, f) \leq A(S) \leq \mathcal{U}(\mathcal{P}_0, f) = \sup_{a \leq x \leq b} f(x)\,(b-a).$$

Any other partition $\mathcal{P} = \{a = p_0 < p_1 < \cdots < p_n = b\}$ can be obtained from $\mathcal{P}_0$ by adding the new division points $p_1, \ldots, p_{n-1}$ to $\mathcal{P}_0$, or equivalently by subdividing the component $[a, b]$ of $\mathcal{P}_0$ into several adjacent intervals, to form the component intervals of $\mathcal{P}$. For each component interval I_j of $\mathcal{P}$, we clearly have

$$\inf_{I_j} f \geq \inf_{[a,b]} f \text{ and } \sup_{I_j} f \leq \sup_{[a,b]} f$$

and, since

$$\sum_{j=1}^{n} \triangle x_j = b - a,$$

we can conclude that

$$\begin{aligned}
\mathcal{L}(\mathcal{P}, f) &= \sum_{j=1}^{n} \inf_{I_j} f \triangle x_j \\
&\geq \sum_{j=1}^{n} \inf_{[a,b]} f \triangle x_j = \inf_{I_j} f \sum_{j=1}^{n} \triangle x_j = (\inf_{I_j} f)(b-a) \\
&= \mathcal{L}(\mathcal{P}_0, f)
\end{aligned}$$

and, similarly,

$$\mathcal{U}(\mathcal{P}, f) = \sum_{j=1}^{n} \sup_{I_j} f \triangle x_j \leq (\sup_{[a,b]} f)(b-a) = \mathcal{U}(\mathcal{P}_0, f).$$

An analogous argument (Exercise 6) shows that adding new division points to *any* partition $\mathcal{P}$ leads to a new partition $\mathcal{P}'$ whose lower and upper sums are bounded by those of $\mathcal{P}$. We call $\mathcal{P}'$ a **refinement** of $\mathcal{P}$ if, as sets of points,

$$\mathcal{P} \subset \mathcal{P}';$$

that is, every partition point of $\mathcal{P}$ is also a partition point of $\mathcal{P}'$ (or, in different terms, if every component interval of $\mathcal{P}'$ is entirely contained in a single component interval of $\mathcal{P}$). We have

Remark 5.1.1. *If $\mathcal{P}'$ is a refinement of $\mathcal{P}$, then*

$$\mathcal{L}(\mathcal{P}, f) \leq \mathcal{L}(\mathcal{P}', f)$$

and

$$\mathcal{U}(\mathcal{P}, f) \geq \mathcal{U}(\mathcal{P}', f).$$

So far, we have been proceeding as if the area $A(S)$ were a well-defined number satisfying the estimates

$$\mathcal{L}(\mathcal{P}, f) \leq A(S) \leq \mathcal{U}(\mathcal{P}, f) \tag{5.9}$$

for every partition $\mathcal{P}$ of $[a, b]$. But all we *really* know are the lower and upper sums $\mathcal{L}(\mathcal{P}, f)$ and $\mathcal{U}(\mathcal{P}, f)$; we would like to *define* the area $A(S)$ as the number satisfying all the inequalities above. For such a definition to make sense, we need two conditions. First, there must be *at least one* number satisfying all of these inequalities. This boils down to the requirement that *every* lower sum is less than (or equal to) *every* upper sum, even for different partitions. When this holds, we are able to conclude that

$$\sup_{\mathcal{P}} \mathcal{L}(\mathcal{P}, f) \leq \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P}, f),$$

(where the supremum and infimum are taken over all possible finite partitions $\mathcal{P}$ of $[a, b]$) and any number between these two automatically satisfies all the inequalities. But then, for these inequalities to actually *define* a number $A(S)$, we need to insure that *only one* number works—that is, we really need the *equality*

$$\sup_{\mathcal{P}} \mathcal{L}(\mathcal{P}, f) = \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P}, f).$$

The first condition can be established using Remark 5.1.1. Given two partitions $\mathcal{P}_1$ and $\mathcal{P}_2$, we can form their **mutual refinement** $\mathcal{P}$ by taking all division points from either partition; that is, as sets of points,

$$\mathcal{P} = \mathcal{P}_1 \cup \mathcal{P}_2.$$

Now, $\mathcal{P}_i \subset \mathcal{P}$ ($\mathcal{P}$ is a refinement of $\mathcal{P}_i$) for $i = 1, 2$, and hence

$$\mathcal{L}(\mathcal{P}_i, f) \leq \mathcal{L}(\mathcal{P}, f) \leq \mathcal{U}(\mathcal{P}, f) \leq \mathcal{U}(\mathcal{P}_i, f), \quad i = 1, 2. \tag{5.10}$$

In particular, for arbitrary partitions $\mathcal{P}_1$ and $\mathcal{P}_2$,

$$\mathcal{L}(\mathcal{P}_1, f) \leq \mathcal{U}(\mathcal{P}_2, f).$$

But then the upper sum of *any* partition is an upper bound for *all* lower sums, and hence for their least upper bound

$$\sup_{\mathcal{P}} \mathcal{L}(\mathcal{P}, f) \leq \mathcal{U}(\mathcal{P}_2, f),$$

and the *left* side is a lower bound for *all* upper sums, hence for their greatest lower bound:

$$\sup_{\mathcal{P}} \mathcal{L}(\mathcal{P}, f) \leq \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P}, f).$$

We state this formally, for future use:

Remark 5.1.2. *For any two partitions $\mathcal{P}_1$ and $\mathcal{P}_2$,*

$$\mathcal{L}(\mathcal{P}_1, f) \leq \mathcal{U}(\mathcal{P}_2, f)$$

and hence

$$\sup_{\mathcal{P}} \mathcal{L}(\mathcal{P}, f) \leq \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P}, f).$$

So there is always *some* number bounded below by all lower sums and above by all upper sums. Its uniqueness takes further work. Before proceeding, we will enlarge our context. Note that in the construction of lower and upper sums, as well as in the proofs of the various inequalities so far, we have used the assumption that f is continuous *only* to establish that f is bounded on $[a, b]$ (so that the numbers involved in defining $\mathcal{L}(\mathcal{P}, f)$ and $\mathcal{U}(\mathcal{P}, f)$ are all well-defined). Go back over these arguments to convince yourself that everything so far works if we just assume that f is *bounded* (but not necessarily continuous) on $[a, b]$. That is, if there exists $M \in \mathbb{R}$ such that

$$0 \leq f(x) \leq M$$

for all $x \in [a,b]$, then for every partition $\mathcal{P}$ of $[a,b]$ we can define the upper and lower sums

$$\mathcal{L}(\mathcal{P},f) = \sum_{j=1}^{n} \inf_{I_j} f \triangle x_j,$$
$$\mathcal{U}(\mathcal{P},f) = \sum_{j=1}^{n} \sup_{I_j} f \triangle x_j,$$

and these satisfy the inequality

$$\mathcal{L}(\mathcal{P}_1,f) \leq \mathcal{U}(\mathcal{P}_2,f)$$

for any pair of partitions $\mathcal{P}_1$ and $\mathcal{P}_2$. It follows that

$$\sup_{\mathcal{P}} \mathcal{L}(\mathcal{P},f) \leq \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P},f).$$

So for any bounded nonnegative function f, we will say that the set of points in the plane

$$S = \{(x,y) \mid a \leq x \leq b,\ 0 \leq y \leq f(x)\}$$

has a well-defined area if

$$\sup_{\mathcal{P}} \mathcal{L}(\mathcal{P},f) = \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P},f)$$

—that is, only one number can satisfy equation (5.9)—and in that case the **area** $A(S)$ is precisely this (well-defined) number.

In general, it is a daunting task to try to maximize (*resp*., minimize) the lower (*resp*., upper) sums over *all* partitions. In our example, however, we can get at this indirectly. You can verify directly from equation (5.7) and equation (5.8) that

$$\lim_{n\to\infty} \mathcal{L}(\mathcal{P}_n,x^3) = \lim_{n\to\infty} \mathcal{U}(\mathcal{P}_n,x^3) = 1 + \frac{3}{2} + \frac{6}{6} + \frac{1}{4} = 3\frac{3}{4}.$$

But since we know that *every* lower sum is less than *every* upper sum, we see that

$$\begin{aligned} 3\frac{3}{4} &= \lim_{n\to\infty} \mathcal{L}(\mathcal{P}_n,x^3) \\ &\leq \sup_{\mathcal{P}} \mathcal{L}(\mathcal{P},x^3) \leq \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P},x^3) \\ &\leq \lim_{n\to\infty} \mathcal{U}(\mathcal{P}_n,x^3) = 3\frac{3}{4} \end{aligned}$$

and so the area of $\{(x,y) \mid 0 \leq y \leq x^3,\ 1 \leq x \leq 2\}$ is well-defined and equals $3\frac{3}{4}$.

We note briefly that once we drop continuity of f, the area of S *need not* be well-defined. For example, the function

$$f(x) = \begin{cases} 1 & \text{if } x \text{ is rational,} \\ 0 & \text{if } x \text{ is irrational} \end{cases}$$

has, for *every* nontrivial interval I_j,

$$\inf_{I_j} f = 0, \quad \sup_{I_j} f = 1$$

so that for *any* finite partition $\mathcal{P}$ of a nontrivial interval $[a, b]$ ($a < b$),

$$\mathcal{L}(\mathcal{P}, f) = 0 < b - a = \mathcal{U}(\mathcal{P}, f)$$

and hence the area under the graph of f is *not* well defined in the sense above.[3] We shall return to this phenomenon later.

Actually, we can extend the context further. Our calculations were motivated by the problem of finding the area of the region S below the graph of f, and we needed f to be nonnegative on $[a, b]$ to even define S. But the calculations *themselves* make formal sense even when f takes negative values, and lead to a useful object.

So we formulate the more general concept of the **definite integral** of f over $[a, b]$ as follows:

Definition 5.1.3. *Suppose f is bounded on the closed interval $[a, b]$. For every partition of $[a, b]$,*

$$\mathcal{P} = \{a = p_0 < p_1 < \cdots < p_n = b\}$$

with component intervals

$$I_j = [p_{j-1}, p_j] \quad j = 1, \ldots, n$$

*of length $\|I_j\| = p_j - p_{j-1} = \triangle x_j$, define the **lower sum** (resp., **upper sum**) associated to $\mathcal{P}$*

$$\mathcal{L}(\mathcal{P}, f) = \sum_{j=1}^{n} \inf_{I_j} f \triangle x_j,$$

$$\mathcal{U}(\mathcal{P}, f) = \sum_{j=1}^{n} \sup_{I_j} f \triangle x_j.$$

*Then f is **(Riemann) integrable** over $[a, b]$ if*

$$\sup_{\mathcal{P}} \mathcal{L}(\mathcal{P}, f) = \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P}, f)$$

*(the supremum and infimum are taken over all finite partitions $\mathcal{P}$ of $[a, b]$). In this case, we call the number above the **definite (Riemann) integral** of f over $[a, b]$,[4] denoted by*

$$\int_a^b f(x)\, dx = \sup_{\mathcal{P}} \mathcal{L}(\mathcal{P}, f) = \inf_{\mathcal{P}} \mathcal{U}(\mathcal{P}, f).$$

This is, as it stands, a highly abstract definition, and with few exceptions it would be foolhardy to try to calculate the integral (or even verify integrability) directly from the definition. In the next section, we will continue in an abstract vein to deduce some consequences of this definition which will help us better handle the concept. In particular, we will find a large class of functions which are guaranteed to be integrable. Then, in § 5.3, we will establish the Fundamental Theorem of Calculus, which leads to a practical way of calculating the integrals of many functions, a process we will explore at length in §§5.4–5.6.

---

[3] The Lebesgue theory does handle this example.

[4] or "from a to b"

Exercises for § 5.1

Answers to Exercises 1, 2ac are given in Appendix B.

Practice problems:

1. Let $S = \left\{(x, y) \,|\, 1 \leq x \leq 2,\ 0 \leq y \leq x^2\right\}$ be the region bounded below by the x-axis, above by the graph $y = x^2$ of the function $f(x) = x^2$ and on the sides by the lines $x = 1$ and $x = 2$. Let $\mathcal{P}_1 = \left\{1, \frac{3}{2}, 2\right\}$ be the partition of $[1, 2]$ into two equal parts, and $\mathcal{P}_2 = \left\{1, \frac{4}{3}, \frac{5}{3}, 2\right\}$ the partition of $[1, 2]$ into three equal parts.
   (a) Calculate the upper and lower sums $\mathcal{L}(\mathcal{P}_1, f)$ and $\mathcal{U}(\mathcal{P}_1, f)$. (*Hint:* The function f is strictly increasing on $[1, 2]$.)
   (b) Calculate the upper and lower sums $\mathcal{L}(\mathcal{P}_2, f)$ and $\mathcal{U}(\mathcal{P}_2, f)$.
   (c) Let $\mathcal{P}$ be the mutual refinement of $\mathcal{P}_1$ and $\mathcal{P}_2$. Calculate $\mathcal{L}(\mathcal{P}, f)$ and $\mathcal{U}(\mathcal{P}, f)$ and verify equation (5.10) in this case.
   (d) Let $\mathcal{P}' = \{1, 1.2, 1.6, 2\}$. Calculate the upper and lower sums $\mathcal{L}(\mathcal{P}', f)$ and $\mathcal{U}(\mathcal{P}', f)$

2. For each function f and interval $[a, b]$ below, (i) write down a formula for the points x_i of the partition $\mathcal{P}_n$ of $[a, b]$ into n equal pieces; (ii) write an expression for $\mathcal{L}(\mathcal{P}_n, f)$ and $\mathcal{U}(\mathcal{P}_n, f)$ as an explicit sum; (iii) express each sum as a combination of sums of the form $A(n) + B(n) \sum_{i=1}^{n} i + C(n) \sum_{i=1}^{n} i^2$; (iv) use Equations (5.3)–(5.5) to write these as functions of n alone; (v) find the limits of these as $n \to \infty$ (*Hint:* Your answer for lower and upper sums should be the same; then the argument we used in the text for $f(x) = x^3$ shows that this limit equals the definite integral $\int_a^b f(x)\, dx$.)
   (a) $f(x) = x$, $[a, b] = [0, 1]$
   (b) $f(x) = x^2 + 1$, $[a, b] = [0, 1]$
   (c) $f(x) = 2x^2 - 1$, $[a, b] = [-2, 0]$
   (d) $f(x) = 1 - x^2$, $[a, b] = [-2, 2]$ (*Hint:* Consider the sums over $[-2, 0]$ and $[0, 2]$ separately.)

Theory problems:

3. Suppose we know that the area of a union of disjoint regions equals the sum of the areas of the pieces (equation (5.1)). Use this to show that the area of a subregion is at most equal to the area of the whole region (equation (5.2)).

4. Starting with the assumption that the area of a square of side 1 inch is 1 square inch, and the additive property of area (equation (5.1)), derive
   (a) The formula for the area of a rectangle with length and width an *integer* number of inches;

Part II

Euclidean Geometry

The goal of this book is to provide an introduction to both Euclidean and non-Euclidean (hyperbolic) geometry. The two geometries share many features, but they have fundamental and radical differences. Neutral geometry is the part of the path they have in common and that is what we have been studying so far, but we have now come to the fork in the path. That fork comes when you try to answer this question:

> Given a line ℓ and a point P that is not on ℓ, how many lines pass through P and are parallel to ℓ?

Using just the axioms of neutral geometry, we can prove that there is always at least one such parallel. We can also prove that if there is more than one parallel, then there must be infinitely many. But that is the extent of what the neutral axioms can say. The neutral axioms are not enough to determine whether there is one parallel or many. A single axiom is what separates Euclidean and non-Euclidean geometry: the final axiom of Euclidean geometry calls for exactly one parallel, the final axiom of non-Euclidean geometry calls for more than one parallel.

The next several chapters are devoted to Euclidean geometry. Euclidean geometry is very old, and so there is a lot of it. We only cover the fundamentals in this book, but there are many excellent books that do much more, such as *Geometry Revisited* [CG67] by Coxeter and Greitzer.

11

The Axiom on Parallels

Euclidean geometry is distinguished from neutral geometry by one axiom, one that describes the nature of parallel lines. There are many formulations of the parallel axiom for Euclidean geometry, but the one that gets right to the heart of the matter is *Playfair's axiom*, named after the Scottish mathematician John Playfair.

> *(Playfair's axiom) Let ℓ be a line, and let P be a point that is not on ℓ. Then there is exactly one line through P that is parallel to ℓ.*

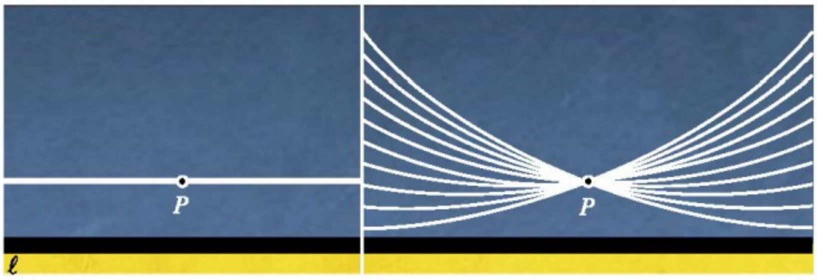

Figure 1. On the left, Euclidean geometry: a single line through P parallel to ℓ. On the right, more than one line through P parallel to ℓ.

In this chapter, we look at a small collection of theorems that are almost immediate consequences of Playfair's axiom, and as such are at the very core of Euclidean geometry. The first of these is Euclid's fifth postulate. This is the controversial postulate in the *Elements*, but also the one that guarantees the same parallel behavior that Playfair's axiom provides. Euclid's fifth is a little unwieldy, particularly when compared to Playfair's axiom, but it is the historical impetus for much of what followed. So let's use Playfair's axiom to prove Euclid's fifth postulate.

Theorem 11.1 *(Euclid's fifth postulate) If lines ℓ_1 and ℓ_2 are crossed by a transversal t, and the sum of adjacent interior angles on one side of t measure less than* 180°, *then ℓ_1 and ℓ_2 intersect on that side of t.*

Proof First some labels.

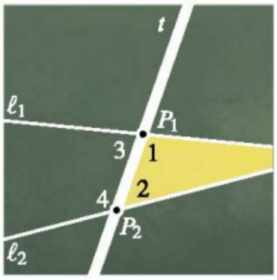

Figure 2. The labels.

Start with lines ℓ_1 and ℓ_2 crossed by transversal t. Label P_1 and P_2, the points of intersection of t with ℓ_1 and ℓ_2 respectively. On one side of t, the two adjacent interior angles should add up to less than 180°. Label the one at P_1 as $\angle 1$ and the one at P_2 at $\angle 2$. Label the supplement of $\angle 1$ as $\angle 3$ and label the supplement of $\angle 2$ as $\angle 4$.

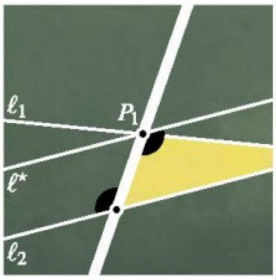

Figure 3. Constructing the unique parallel.

This theorem asserts that the lines intersect, and says where the intersection occurs. We will tackle those two statements in that order. Note that $\angle 1$ and $\angle 4$ are alternate interior angles, but they are not congruent: if they were, their supplements $\angle 2$ and $\angle 3$ would be too, and then

$$(\angle 1) + (\angle 2) = (\angle 1) + (\angle 3) = 180^\circ.$$

There is, however, another line ℓ^* through P_1 that forms an angle congruent to $\angle 4$ (because of the angle construction axiom), and by the alternate interior angle theorem, ℓ^* must be parallel to ℓ_2. Because of Playfair's axiom, ℓ^* is the only parallel to ℓ_2 through P_1. Therefore ℓ_1 intersects ℓ_2.

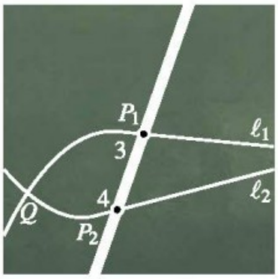

Figure 4. An impossible triangle on the wrong side of t.

The second part of the proof is to figure out on which side of t that ℓ_1 and ℓ_2 cross. Let's see what would happen if they intersected at a point Q on the wrong side of t, the side with $\angle 3$ and $\angle 4$. Then ΔP_1P_2Q would have two interior angles, $\angle 3$ and $\angle 4$, whose measures add up to more than 180°. This would violate the Saccheri-Legendre theorem. So ℓ_1 and ℓ_2 cannot intersect on the side of t with $\angle 3$ and $\angle 4$ and so they must intersect on the side with $\angle 1$ and $\angle 2$.

□

One of the truly useful theorems of neutral geometry is the alternate interior angle theorem. In fact, we just used it in the last proof. You may recall from high school geometry that the converse of the theorem is often even more useful. The problem is that the converse of the alternate interior angle theorem can't be proved using just the axioms of neutral geometry. It depends on the Euclidean behavior of parallel lines.

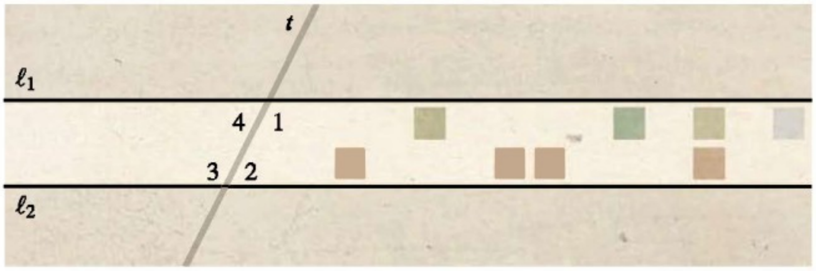

Figure 5. The converse of the alternate interior angle theorem: if $\ell_1 \parallel \ell_2$, then $\angle 1 \simeq \angle 3$ and $\angle 2 \simeq \angle 4$.

Theorem 11.2 *(Converse of the alternate interior angle theorem) If ℓ_1 and ℓ_2 are parallel, then the pairs of alternate interior angles formed by a transversal t are congruent.*

Proof Consider two parallel lines crossed by a transversal. Label adjacent interior angles: $\angle 1$ and $\angle 2$, and $\angle 3$ and $\angle 4$, so that $\angle 1$ and $\angle 4$ are supplementary and $\angle 2$ and $\angle 3$ are supplementary. That means that the pairs of alternate interior angles are $\angle 1$ and $\angle 3$, and $\angle 2$ and $\angle 4$. Now, we just have to do a little arithmetic. From the two pairs of supplementary angles:

(*i*): $(\angle 1) + (\angle 4) = 180°$
(*ii*): $(\angle 2) + (\angle 3) = 180°$.

Adding all four angles together,

$$(\angle 1) + (\angle 2) + (\angle 3) + (\angle 4) = 360°.$$

Now we turn to Euclid's fifth postulate, or rather its contrapositive. The lines ℓ_1 and ℓ_2 are parallel, which means that they do not intersect on either side of t. Therefore Euclid's fifth says that on neither side of t may the sum of adjacent interior angles be less than 180°:

- $(\angle 1) + (\angle 2) \geq 180°$
- $(\angle 3) + (\angle 4) \geq 180°$.

If either sum was greater than 180°, though, the sum of all four angles would have to be more than 360°. We saw above that is not the case, so the inequalities are actually equalities:

(*iii*): $(\angle 1) + (\angle 2) = 180°$
(*iv*): $(\angle 3) + (\angle 4) = 180°$.

Now we have two systems of equations with four unknowns, and it is basic algebra from here. Subtract *(iv)* from *(i)* to get

$$(\angle 1) - (\angle 3) = 0 \implies (\angle 1) = (\angle 3).$$

Subtract *(i)* from *(iii)* to get

$$(\angle 2) - (\angle 4) = 0 \implies (\angle 2) = (\angle 4).$$

Therefore the alternate interior angles are congruent. □

One of the key theorems we proved in the neutral geometry section was the Saccheri-Legendre theorem: that the angle sum of a triangle is at most 180°. That is all you can say

with the axioms of neutral geometry, but in a world with Playfair's axiom and the converse of the alternate interior angle theorem, we can make a more bold statement about angle sums of triangles.

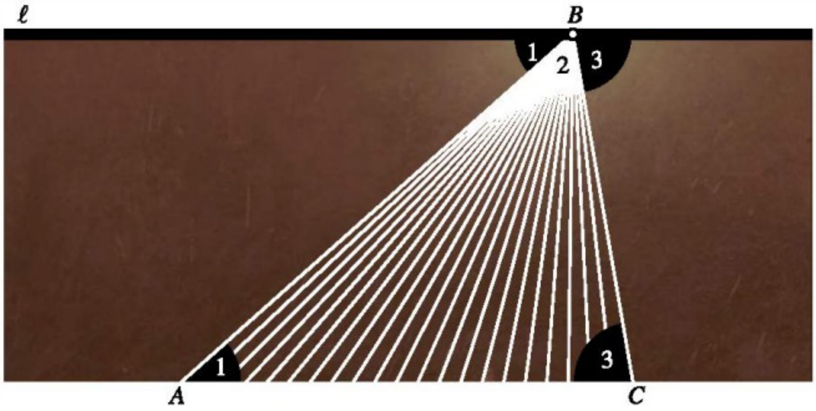

Figure 6. Use the converse of the alternate interior angle theorem to find the angle sum of a triangle.

Theorem 11.3 *The angle sum of a triangle is* 180°.

Proof Given $\triangle ABC$, by Playfair's axiom, there is a unique line ℓ through B that is parallel to $\overline{AC}$. That line and the rays $\overrightarrow{BA}$ and $\overrightarrow{BC}$ form three angles, $\angle 1$, $\angle 2$, and $\angle 3$ as shown in figure 6. By the converse of the alternate interior angle theorem, two pairs of alternate interior angles are congruent: $\angle 1 \simeq \angle A$ and $\angle 3 \simeq \angle C$. Therefore, the angle sum of $\triangle ABC$ is

$$s(\triangle ABC) = (\angle A) + (\angle B) + (\angle C) = (\angle 1) + (\angle 2) + (\angle 3) = 180^\circ. \qquad \square$$

So, the three angles in an equilateral triangle all measure 60° and the measures of the two acute angles in a right triangle must add up to 90°.

In the last chapter on quadrilaterals we talked a little bit about the uncertain status of rectangles in neutral geometry, saying that it is easy to make a convex quadrilateral with three right angles, but that once you have done that, there is no guarantee that the fourth angle will be a right angle. Here it is now in the Euclidean context:

Theorem 11.4 *Let $\angle ABC$ be a right angle. Let r_A and r_C be rays so that r_A has endpoint A, is on the same side of $\overline{AB}$ as C, and is perpendicular to $\overline{AB}$; r_C has endpoint C, is on the same side of $\overline{BC}$ as A, and is perpendicular to $\overline{BC}$. Then r_A and r_C intersect at a point D, and the angle formed at this intersection, $\angle ADC$, is a right angle. Therefore $\square ABCD$ is a rectangle.*

Proof First we need to make sure that r_A and r_C intersect. Let ℓ_A and ℓ_C be the lines containing r_A and r_C respectively. By the alternate interior angle theorem, the right angles at A and B imply that ℓ_A and $\overline{BC}$ are parallel. So $\overline{BC}$ is the one line parallel to ℓ_A through C, and that implies that ℓ_C cannot be parallel to ℓ_A: it has to intersect ℓ_A. Let's call that point of intersection D. This

theorem claims that it is the rays, not the lines, that intersect. Therefore we need to rule out the possibility that the intersection of ℓ_A and ℓ_C might happen on one (or both) of the opposite rays. Since ℓ_A is parallel to $\overline{BC}$, all the points of ℓ_A are on the same side of $\overline{BC}$ as A. None of the points of r_C^{op} is on that side of BC, so D cannot be on r_C^{op}. Likewise, all the points of ℓ_C are on the same side of $\overline{AB}$ as C. None of the points of r_A^{op} is on that side of AB, so D cannot be on r_A^{op}.

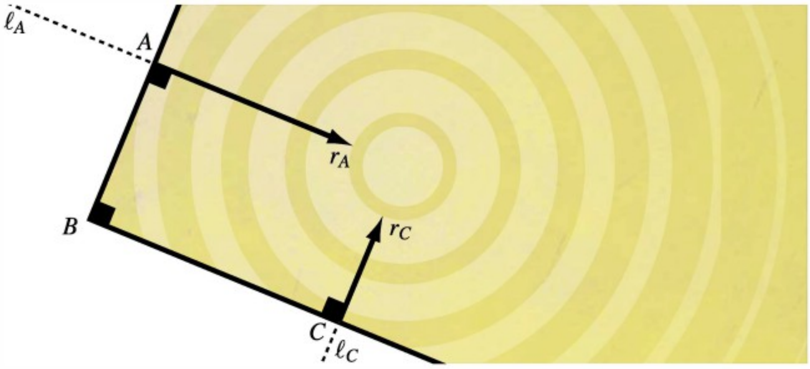

Figure 7. Constructing a rectangle.

So now $\square ABCD$ has three right angles, $\angle A$, $\angle B$, and $\angle C$. It is actually a convex quadrilateral too (verifying this is left as an exercise), so the diagonal AC divides $\square ABCD$ into two triangles $\triangle ABC$ and $\triangle ADC$ (see figure 8). Then, since the angle sum of a triangle is 180°,

$$
\begin{gathered}
s(\triangle ABC) + s(\triangle ADC) = 180^\circ + 180^\circ \\
(\angle CAB) + (\angle B) + (\angle ACB) + (\angle CAD) + (\angle D) + (\angle ACD) = 360^\circ \\
(\angle A) + (\angle B) + (\angle C) + (\angle D) = 360^\circ \\
90^\circ + 90^\circ + 90^\circ + (\angle D) = 360^\circ \\
(\angle D) = 90^\circ.
\end{gathered}
$$

Therefore $\angle D$ is a right angle. □

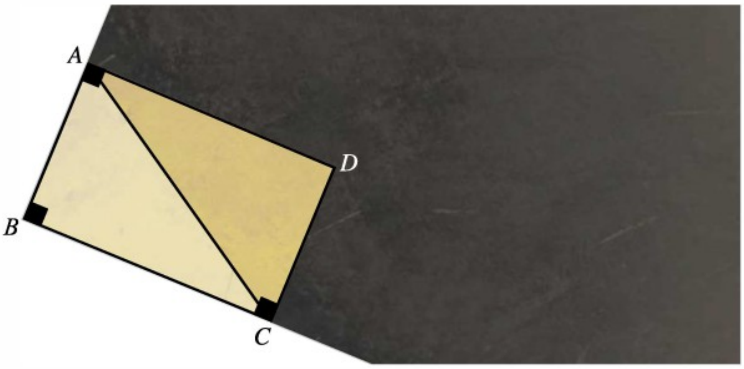

Figure 8. Verifying that the fourth angle is right.

Exercise 11.1 Fill in the gap in the proof by explaining why $\square ABCD$ must be convex.

We see then that, yes, rectangles exist in Euclidean geometry. Two essential properties of rectangles are provided in the following (easy) exercises.

Exercise 11.2 Let $\square ABCD$ be a rectangle. Prove that $\overline{AB}$ is parallel to $\overline{CD}$ and $\overline{AD}$ is parallel to $\overline{BC}$.

Exercise 11.3 Let $\square ABCD$ be a rectangle. Prove that $AB \simeq CD$ and $AD \simeq BC$ and $AC \simeq BD$.

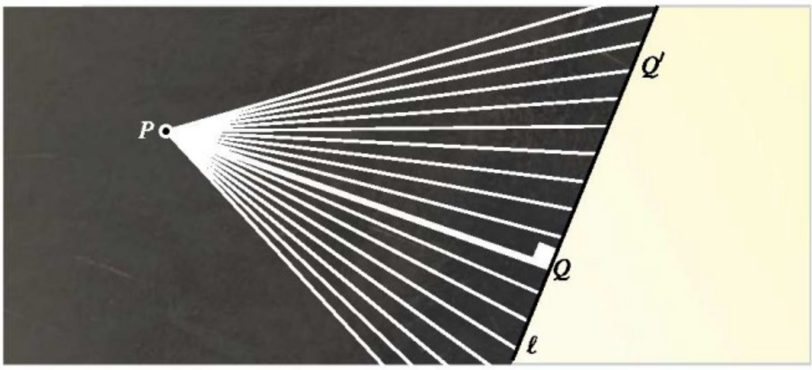

Figure 9. The distance from P to ℓ is measured along the segment from P to ℓ that is perpendicular to ℓ.

For the last result of this section, we return to parallel lines. One of the things that we will see when we study non-Euclidean geometry is that parallel lines tend to diverge from each other. That doesn't happen in Euclidean geometry. This is one of the key differences between the two geometries. Let's make this more precise. Suppose that P is a point that is not on a line ℓ. Define the distance from P to ℓ to be the minimum distance from P to a point on ℓ:

$$d(P,\ell) = \min\left\{ |PQ| \;\middle|\; Q \text{ is on } \ell \right\}.$$

Exercise 11.4 Prove that the minimum actually occurs when Q is the foot of the perpendicular to ℓ through P (this can be proved using solely the axioms of neutral geometry).

For a pair of parallel lines, that distance as measured along perpendiculars does not change.

Theorem 11.5 *If ℓ and ℓ' are parallel lines, then the distance from a point on ℓ to ℓ' is constant. In other words, if P and Q are points on ℓ, then*

$$d(P,\ell') = d(Q,\ell').$$

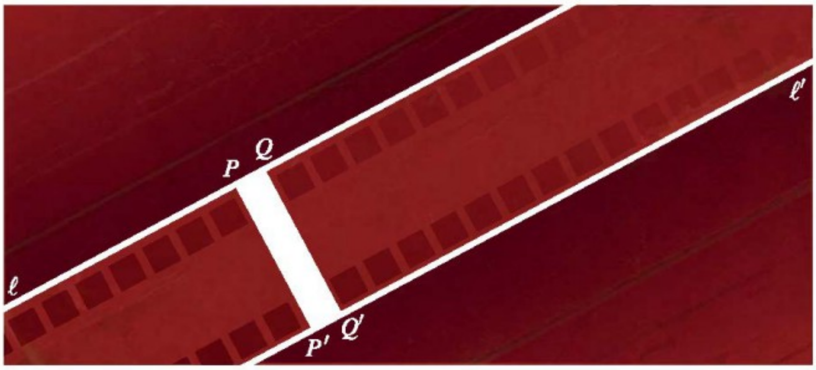

Figure 10. Perpendicular segments PP' and QQ' between parallel lines have the same length. That is, parallel lines are equidistant.

Proof Let P' and Q' be the feet of the perpendiculars on ℓ' from P and Q respectively. That way, by the previous exercise,

$$d(P,\ell') = |PP'| \text{ and } d(Q,\ell') = |QQ'|.$$

Then $\angle PP'Q'$ and $\angle QQ'P'$ are right angles. By the converse of the alternate interior angle theorem, $\angle P$ and $\angle Q$ are right angles too, so $\square PQQ'P'$ is a rectangle. According to exercise 11.2, PP' and QQ', which are opposite sides of a rectangle, are congruent. □

11.1 Exercises

11.5. Let ℓ be a line and P a point not on ℓ. Using only the results of neutral geometry, prove that there is at least one line through P that is parallel to ℓ.

11.6. Suppose that ℓ_1, ℓ_2, and ℓ_3 are three distinct lines such that ℓ_1 and ℓ_2 are parallel, and ℓ_2 and ℓ_3 are parallel. Prove that ℓ_1 and ℓ_3 are parallel.

11.7. Suppose that ℓ_1 and ℓ_2 are parallel lines, and that t is a line that intersects (but is distinct from) ℓ_1. Prove that t intersects ℓ_2.

11.8. Given three distinct parallel lines, prove that there is a labeling of them as ℓ_1, ℓ_2, and ℓ_3 so that

- no point of ℓ_1 lies between a point of ℓ_2 and a point of ℓ_3
- every point of ℓ_2 lies between a point of ℓ_1 and of ℓ_3
- no point of ℓ_3 lies between a point of ℓ_1 and a point of ℓ_2.

In this case, we can say that ℓ_2 is *between* ℓ_1 and ℓ_3.

11.9. This exercise is an extension of the previous one. Given n distinct parallel lines, prove that there is an ordering of them as $\ell_1, \ell_2, \ldots, \ell_n$ so that if $i < j < k$ then ℓ_j is between ℓ_i and ℓ_k.

11.10. Find the angle sum of a convex n-gon as a function of n.

11.11. What is the measure of an interior angle of a regular n-gon (as a function of n)?

11.12. Consider a convex quadrilateral $\square ABCD$. Prove that the two diagonals of $\square ABCD$ bisect each other if and only if $\square ABCD$ is a parallelogram.

11.13. Show that a parallelogram $\square ABCD$ is a rectangle if and only if $AC \simeq BD$.

11.14. Suppose that the diagonals of a convex quadrilateral $\square ABCD$ intersect one another at a point P and that

$$AP \simeq BP \simeq CP \simeq DP.$$

Prove that $\square ABCD$ is a rectangle.

11.15. Suppose that the diagonals of a convex quadrilateral bisect one another at right angles. Prove that the quadrilateral must be a rhombus.

11.16. Let $\triangle ABC$ be isosceles with $AB \simeq AC$, and let a be the midpoint of BC. Let b and c be points on the line through A that is parallel to BC so that $b * A * c$ and so that $bA \simeq cA \simeq Ba$. Prove that $\triangle ABC \simeq \triangle abc$.

11.17. Verify that the Cartesian model (as developed through the exercises in chapters 1–3) satisfies Playfair's axiom.

12

Parallel Projection

In the course of this chapter, we will need to use a few properties of parallelograms. It is rather common to confuse the properties of a parallelogram with its definition, so first, recall the definition of a parallelogram.

Definition 12.1 A *parallelogram* is a simple quadrilateral whose opposite sides are parallel.

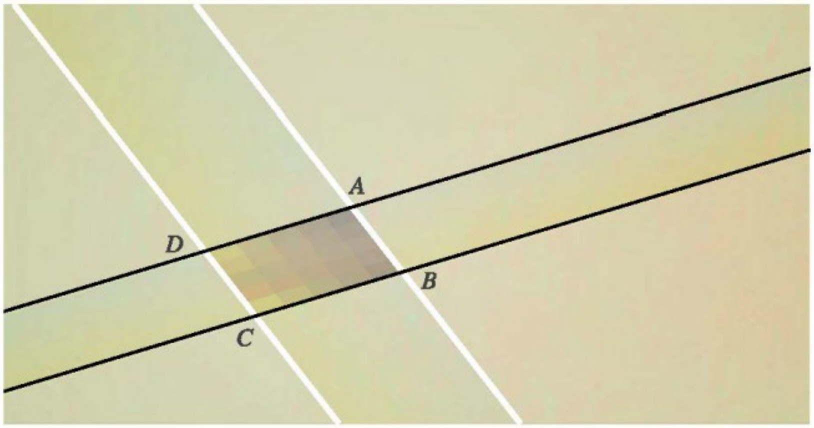

Figure 1. A parallelogram.

Now on to the properties of parallelograms that we will need for this chapter.

Exercise 12.1 Prove that in a parallelogram, the two pairs of opposite sides are congruent and the two pairs of opposite angles are congruent.

Exercise 12.2 Prove that if a convex quadrilateral has one pair of opposite sides that are both parallel and congruent, then it is a parallelogram.

Exercise 12.3 Let $\square ABB'A'$ be a simple quadrilateral. Verify that if AA' and BB' are parallel, but AB and $A'B'$ are not, then AA' and BB' cannot be congruent.

12.1 Parallel projection

The purpose of this chapter is to introduce a mechanism called *parallel projection*, a particular kind of mapping from the points on one line to the points on another. Parallel projection is the piece of machinery that you have to have in place to understand similarity, which is in turn essential for much of what we will be doing in the next chapters. The primary goal at this point is to understand how distances between points may be distorted by the parallel projection mapping. Once that is figured out, we will be able to turn our attention to the geometry of similarity.

Definition 12.2 A *parallel projection* from one line ℓ to another ℓ' is a map $\Phi : \ell \to \ell'$ that assigns to each point P on ℓ a point $\Phi(P)$ on ℓ' so that all the lines connecting a point and its image are parallel to one another.

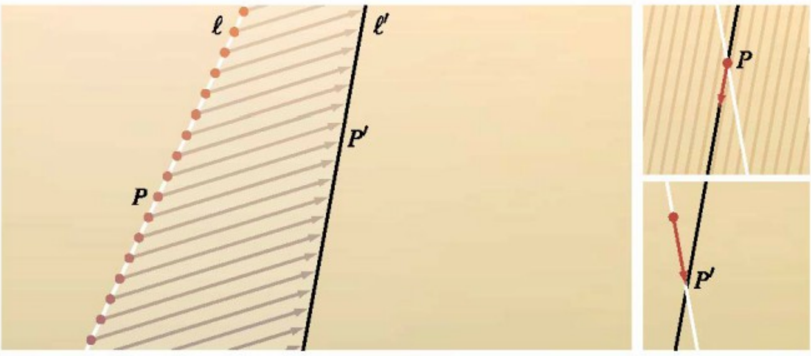

Figure 2. The path from a point P on ℓ to a point P' on ℓ' defines a parallel projection as long as neither P nor P' is the intersection of ℓ and ℓ' (as shown at right).

It is easy to construct parallel projections. Any point P on ℓ and its image $\Phi(P)$ on ℓ' completely determines the projection: for any other point Q on ℓ there is a unique line that passes through Q and is parallel to $\overline{P\,\Phi(P)}$. Wherever the line intersects ℓ' will have to be $\Phi(Q)$. There are only two cases where this construction will not work: if P is the intersection of ℓ and ℓ', then the lines of projection run parallel to ℓ' and so fail to provide a point of intersection; and if $\Phi(P)$ is the intersection of ℓ and ℓ', then the lines of projection actually coincide rather than being parallel.

Theorem 12.3 *A parallel projection is both one-to-one and onto.*

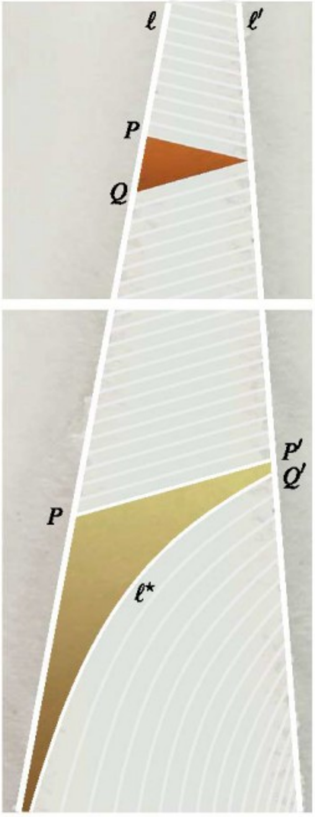

Figure 3. Using proofs by contradiction, we can show that parallel projection is both one-to-one (top) and onto (bottom).

Proof Let $\Phi : \ell \to \ell'$ be a parallel projection. First let's see why Φ is one-to-one. Suppose that it is not. That is, suppose that P and Q are two distinct points on ℓ but that $\Phi(P) = \Phi(Q)$. Then the two projecting lines $\overline{P\,\Phi(P)}$ and $\overline{Q\,\Phi(Q)}$, which ought to be parallel, actually share a point. This can't happen.

Now let's see why Φ is onto. Suppose that Q' is a point on ℓ' that is not in the image of Φ. To get a sense of how Φ is casting points from ℓ to ℓ', consider a point P on ℓ and its image $P' = \Phi(P)$ on ℓ'. By Playfair's axiom, there is a unique line ℓ^* that passes through Q' and is parallel to $\overline{PP'}$. If ℓ^* intersects ℓ at a point Q, then $\Phi(Q) = Q'$, contradicting the initial supposition that Q' is not in the image of Φ. If ℓ^* does not intersect ℓ, then both ℓ and $\overline{PP'}$ are lines that pass through P and are parallel to ℓ^*, in violation of Playfair's axiom. In either case, we arrive at a contradiction. Therefore, an arbitrary point Q' of ℓ must be in the image of Φ, and so Φ is onto. $\square$

Now that we have established that parallel projection is a bijection, it helps to use a naming convention to makes things more readable. I will use a prime mark $'$ to indicate the parallel projection of a point, so $\Phi(P) = P'$, $\Phi(Q) = Q'$, and so on.

12.2 Parallel projection, order, and congruence

So far we have seen that parallel projection establishes a correspondence between the points of one line and the points of another. What about the order of the points? Can points get shuffled up in the process of a parallel projection? No.

Theorem 12.4 *Let $\Phi : \ell \to \ell'$ be a parallel projection. If A, B, and C are points on ℓ and $A * B * C$, then $A' * B' * C'$.*

Proof Because B is between A and C, A and C must be on opposite sides of $\overline{BB'}$. But, $\overline{AA'}$ does not intersect $\overline{BB'}$, so A' has to be on the same side of $\overline{BB'}$ as A; and $\overline{CC'}$ does not

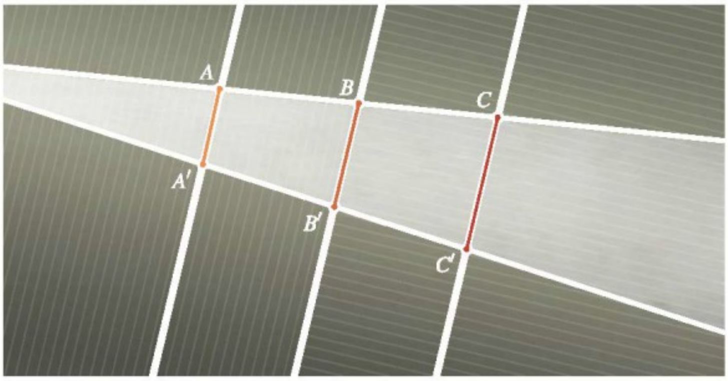

Figure 4. Parallel projection keeps points in order.

intersect $\overline{BB'}$, so C' has to be on the same side of $\overline{BB'}$ as C. Therefore A' and C' have to be on opposite sides of $\overline{BB'}$, and so the intersection of $\overline{BB'}$ and $A'C'$, which is B', must be between A' and C'. □

Now what about congruence?

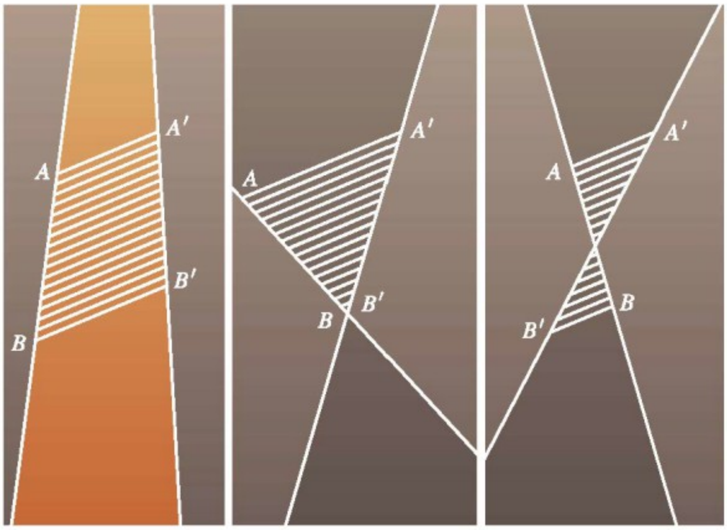

Figure 5. There are three positions for A and B relative to the image line: both on the same side, one on the image line, or one on each side. Likewise, there are three positions for a and b. There are nine cases in all.

Theorem 12.5 *Let $\Phi : \ell \to \ell'$ be a parallel projection. If a, b, A, and B are points on ℓ and if $ab \simeq AB$, then $a'b' \simeq A'B'$.*

Proof There are several cases, depending on the positions of ab and AB relative to ℓ'. They could lie on the same side of ℓ', they could lie on opposite sides of ℓ', one or both could straddle

ℓ', or one or both could have an endpoint on ℓ'. Each case must be handled differently. We will look at the case where both segments are on the same side of ℓ'. The others are left as exercises. There are still two cases to consider, depending on whether or not ℓ and ℓ' are parallel.

Case 1: when ℓ and ℓ' are parallel (see figure 6). This is the simpler case, but it helps illuminate the more general case. Because aa' is parallel to bb' and ab is parallel to $a'b'$, $\square aa'b'b$ is a parallelogram; AA' is parallel to BB' and AB is parallel to $A'B'$ so $\square AA'B'B$ is also a parallelogram. Because the opposite sides of a parallelogram are congruent (exercise 12.1), $a'b' \simeq ab$ and $AB \simeq A'B'$. Since $ab \simeq AB$, $a'b' \simeq A'B'$.

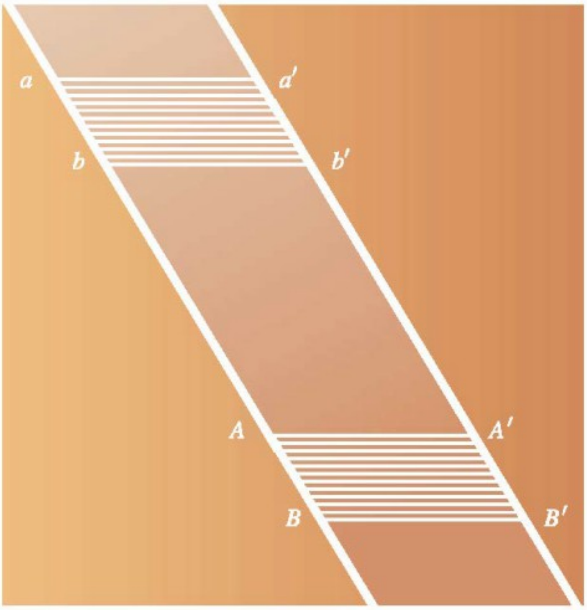

Figure 6. Case 1, when the two lines are parallel.

Case 2: when ℓ and ℓ' are not parallel (see figure 7). This is the more likely case, in which $\square aa'b'b$ and $\square AA'B'B$ will not be parallelograms. We can takes a similar approach to case 1, though, by building some parallelograms into the problem. Because ℓ and ℓ' are not parallel, the segments aa' and bb' cannot have the same length (exercise 12.3), and the segments AA' and BB' cannot have the same length. Let's assume that aa' is shorter than bb' and that AA' is shorter than BB'. If this is not the case, then it is just a matter of switching some labels to make it so. Then

- there is a point c between b and b' so that $bc \simeq aa'$, and
- there is a point C between B and B' so that $BC \simeq AA'$.

This creates four shapes of interest: the quadrilaterals $\square a'abc$ and $\square A'ABC$ that are parallelograms (exercise 12.2), and the triangles $\Delta a'b'c$ and $\Delta A'B'C$. The key here is to prove that $\Delta a'b'c \simeq \Delta A'B'C$.

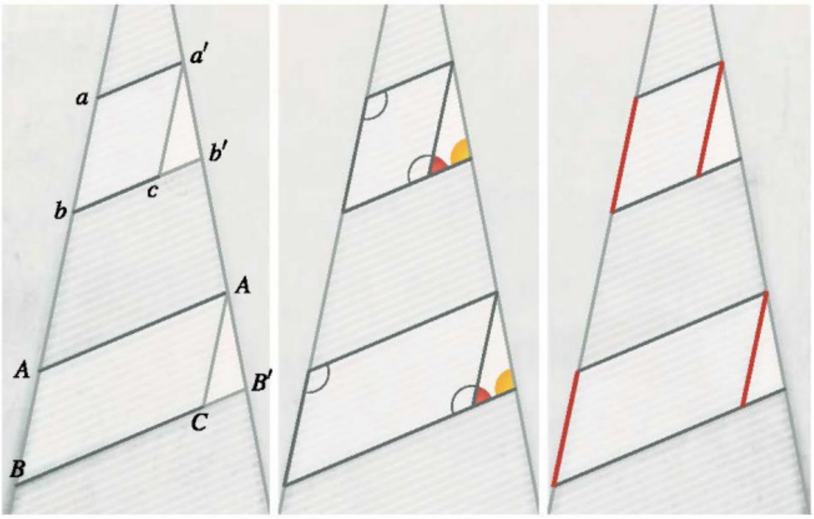

Figure 7. The non-parallel case. (l) First construct parallelograms. (c) The two angles and (r) the sides needed for AAS to show that $\Delta a'b'c' \simeq \Delta A'B'C'$.

- **A:** $\angle b' \simeq \angle B'$. The lines $\overline{cb'}$ and $\overline{CB'}$ are parallel (they are two of the projecting lines) and they are crossed by the transversal ℓ'. By the converse of the alternate interior angle theorem, $\angle a'b'c$ and $\angle A'B'C$ are congruent.
- **A:** $\angle c \simeq \angle C$. The opposite angles of the two parallelograms are congruent. Therefore $\angle a'cb \simeq \angle a'ab$ and $\angle A'AB \simeq \angle A'CB$. But $\overline{aa'}$ and $\overline{AA'}$ are parallel lines cut by the transversal ℓ, so $\angle a'ab \simeq \angle A'AB$, so $\angle a'cb \simeq \angle A'CB$, and so their supplements $\angle a'cb'$ and $\angle A'CB'$ are also congruent.
- **S:** $a'c \simeq A'C$. The opposite sides of the two parallelograms are congruent too. Therefore $a'c \simeq ab$ and $AB \simeq A'C$, and since $ab \simeq AB$, we get $a'c \simeq A'C$.

By AAS, then, $\Delta a'b'c \simeq \Delta A'B'C$. The corresponding sides $a'b'$ and $A'B'$ have to be congruent.

□

Exercise 12.4 Fill in some gaps:

(1) Prove the theorem in the case when both a and A lie on ℓ' (at the intersection of ℓ and ℓ').
(2) Prove the theorem in the case when a and A lie on opposite sides of ℓ' from b and B.

12.3 Parallel projection and distance

That brings us to the question at the very heart of parallel projection. If Φ is a parallel projection and A and B are two points on ℓ, how do the lengths $|AB|$ and $|A'B'|$ compare? In case 1 of the last proof, AB and $A'B'$ ended up being congruent, but that was because ℓ and ℓ' were parallel. In general, AB and $A'B'$ do not have to be congruent. But it turns out that in the process of parallel projecting from one line to another, all distances are scaled by a constant multiple.

Theorem 12.6 *If $\Phi : \ell \to \ell'$ is a parallel projection, then there is a constant k such that*

$$|A'B'| = k|AB|$$

for all points A and B on ℓ.

It is helpful to get a little perspective on this before the proof. First note that the previous theorem gives us a way to narrow the scope of the problem. Fix a point O on ℓ and let r be one of the two rays along ℓ with O as its endpoint. The segment construction axiom says that every segment AB on ℓ is congruent to a segment OP where P is some point on r. We have just seen that parallel projection maps congruent segments to congruent segments. So if Φ scales all segments of the form OP by a factor of k, then it must scale all the segments of ℓ by the same factor.

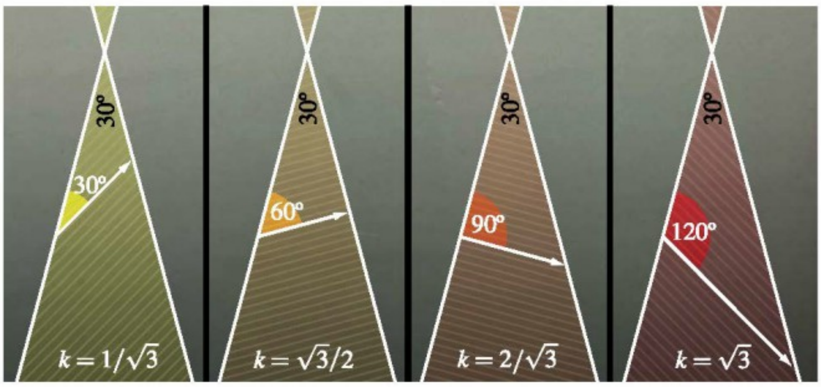

Figure 8. Some parallel projections and their scaling constants.

Second, we can extend that by considering what happens when we parallel project end-to-end congruent copies of a segment. For this, let me introduce another convenient notation convention: for the rest of this argument, let P_d denote the point on r that is a distance d from O. Now, pick a positive real value x, and let

$$k = |O'P'_x|/|OP_x|,$$

so that Φ scales the segment OP_x by a factor of k. Eventually we will have to show that Φ scales all segments by that factor, but for now let's restrict our attention to the segments OP_{nx}, where n is a positive integer. Between O and P_{nx} are P_x, P_{2x}, … $P_{(n-1)x}$ in order:

$$O * P_x * P_{2x} * \cdots * P_{(n-1)x} * P_{nx}.$$

We have seen that parallel projection preserves the order of points, so

$$O' * P'_x * P'_{2x} * \cdots * P'_{(n-1)x} * P'_{nx}.$$

Each segment $P_{ix}P_{(i+1)x}$ is congruent to OP_x and consequently each parallel projection $P'_{ix}P'_{(i+1)x}$ is congruent to $O'P'_x$. Add their lengths:

$$\begin{aligned}|O'P'_{nx}| &= |O'P'_x| + |P'_xP'_{2x}| + |P'_{2x}P'_{3x}| + \cdots + |P'_{(n-1)x}P'_{nx}| \\ &= kx + kx + kx + \cdots + kx \quad (n \text{ times}) \\ &= k \cdot nx\end{aligned}$$

and so Φ scales OP_{nx} by a factor of k.

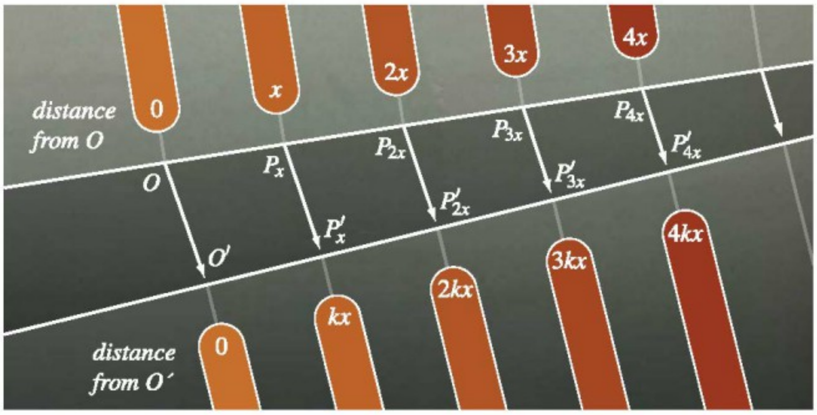

Figure 9. Scaling of segments of length kx, where k is an integer.

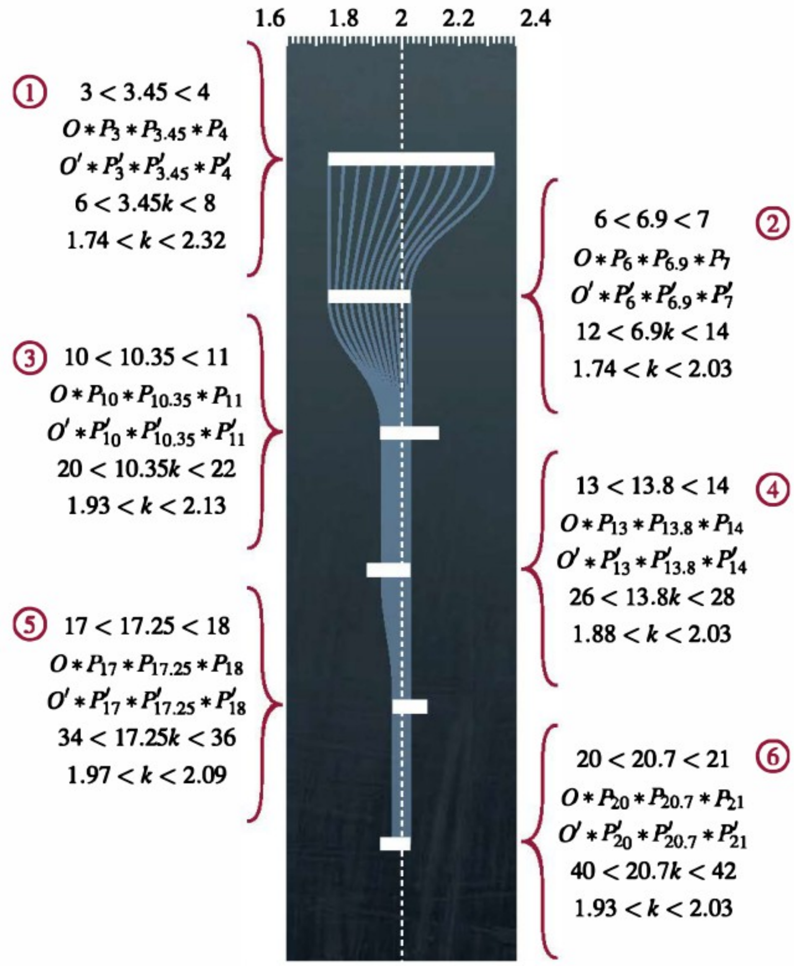
Sadly, no matter what x is, the points P_{nx} account for an inconsequential portion of the set of all points of r. However, if OP_x and OP_y were to have two different scaling factors we could use this end-to-end copying to magnify the difference between them. Third, then, consider an example that demonstrates how this works, and which shows how this ultimately prevents there being two different scaling factors. In this example, let's suppose that $|O'P'_1| = 2$, so all integer length segments on ℓ are scaled by a factor of 2. Let's take a look at what this means for $P_{3.45}$. Let k be the scaling factor for $OP_{3.45}$. Figure 10 shows how the first few end-to-end copies of $OP_{3.45}$ begin to limit the possible values of k.

Fourth, note that the floor function, $f(x) = \lfloor x \rfloor$, assigns to each real number x the largest integer that is less than or equal to it. The ceiling function, $f(x) = \lceil x \rceil$, assigns to each real number x the smallest integer that is greater than or equal to it.

It is finally time to prove that parallel projection scales distance.

Proof Let $k = |O'P'_1|$ so that k is the scaling factor for the segment of length 1 (and consequently for all integer length segments). Now take a point P_x on ℓ and let k' be the scaling factor for the segment OP_x. We want to show that $k' = k$ and we can do that by following the same strategy as in the example above, by capturing k' in an increasingly narrow band around k by looking at the parallel projection of P_{nx} as n increases. Start by working back and forth between



① $3 < 3.45 < 4$
$O * P_3 * P_{3.45} * P_4$
$O' * P'_3 * P'_{3.45} * P'_4$
$6 < 3.45k < 8$
$1.74 < k < 2.32$

$6 < 6.9 < 7$ ②
$O * P_6 * P_{6.9} * P_7$
$O' * P'_6 * P'_{6.9} * P'_7$
$12 < 6.9k < 14$
$1.74 < k < 2.03$

③ $10 < 10.35 < 11$
$O * P_{10} * P_{10.35} * P_{11}$
$O' * P'_{10} * P'_{10.35} * P'_{11}$
$20 < 10.35k < 22$
$1.93 < k < 2.13$

$13 < 13.8 < 14$ ④
$O * P_{13} * P_{13.8} * P_{14}$
$O' * P'_{13} * P'_{13.8} * P'_{14}$
$26 < 13.8k < 28$
$1.88 < k < 2.03$

⑤ $17 < 17.25 < 18$
$O * P_{17} * P_{17.25} * P_{18}$
$O' * P'_{17} * P'_{17.25} * P'_{18}$
$34 < 17.25k < 36$
$1.97 < k < 2.09$

$20 < 20.7 < 21$ ⑥
$O * P_{20} * P_{20.7} * P_{21}$
$O' * P'_{20} * P'_{20.7} * P'_{21}$
$40 < 20.7k < 42$
$1.93 < k < 2.03$

Figure 10. An example. Projecting end-to-end congruent copies of a segment of length 3.45 by a parallel projection that scales all integer length segments by a factor of two.

inequalities of real numbers and orders of points:

$$\lfloor nx \rfloor \leq nx \leq \lceil nx \rceil$$
$$O * P_{\lfloor nx \rfloor} * P_{nx} * P_{\lceil nx \rceil}$$
$$O' * P'_{\lfloor nx \rfloor} * P'_{nx} * P'_{\lceil nx \rceil}$$
$$k\lfloor nx \rfloor \leq k' nx \leq k\lceil nx \rceil.$$

(The notation here is a bit casual—if nx is an integer, then $\lfloor nx \rfloor = nx$, so $P_{\lfloor nx \rfloor}$ is not actually between O and P_{nx}. This does not cause any problems for the proof.) Because $(nx - 1) \leq \lfloor nx \rfloor$

and $\lceil nx \rceil \leq (nx + 1)$ we can move to a less precise but more manageable set of inequalities:

$$k(nx - 1) \leq k'nx \leq k(nx + 1).$$

Divide by nx to get

$$k\left(\frac{nx - 1}{nx}\right) \leq k' \leq k\left(\frac{nx + 1}{nx}\right).$$

As n increases, the ratios $(nx - 1)/(nx)$ and $(nx + 1)/(nx)$ both approach 1. In the limit as n goes to infinity, they are 1. Since the inequalities have to be true for all n, the only possible value for k', then, is k. □

12.4 Exercises

12.5. Suppose that Φ is a parallel projection from ℓ to ℓ'. If ℓ and ℓ' intersect at P, prove that $\Phi(P) = P$.

12.6. Prove that if ℓ and ℓ' are parallel, then the scaling factor of a parallel projection between them must be one, but that if ℓ and ℓ' are not parallel, then there is a parallel projection with every possible scaling factor k where $0 < k < \infty$.

12.7. Let $\Phi : \ell \to \ell'$ be a parallel projection. Show that the inverse map $\Phi^{-1} : \ell' \to \ell$ is also a parallel projection.

12.8. Let $\Phi_1 : \ell \to \ell'$ and $\Phi_2 : \ell' \to \ell''$ be parallel projections. Is the composition $\Phi_2 \circ \Phi_1 : \ell \to \ell''$ necessarily a parallel projection?

12.9. In chapter 6, we constructed a distance function, and one of the keys to the construction was locating the points on a ray that were a distance of $m/2^n$ from its endpoint. In Euclidean geometry, there is a construction that locates all the points on a ray that are any rational distance m/n from its endpoint. Take two non-opposite rays r and r' with a common endpoint O. Along r, lay out m congruent copies of a segment of length 1, ending at the point P_m. Along r', lay out n congruent copies of a segment of length 1, ending at the point Q_n. Mark the point Q_1 on r' that is a distance 1 from O. Verify that the line that passes through Q_1 and is parallel to $P_m Q_n$ intersects r a distance of m/n from O.

Part III

Euclidean Transformations

In the third part of this book, we will look at Euclidean geometry from a different perspective, that of Euclidean transformations. It is a point of view that has been most closely associated with Felix Klein, that the way to study some property (such as congruence) is to study the maps that preserve it. The first chapter sets the scene with a quick development of analytic geometry. Then it is on to Euclidean isometries, bijections of the Euclidean plane that preserve distance. Over several chapters we will study the isometries, and ultimately we will classify all Euclidean isometries into four types: reflections, rotations, translations, and glide reflections. Then it is time to loosen the restriction a bit to consider bijections that preserve congruence, but not necessarily distance. Finally, we will look at inversion, a type of bijection of the punctured plane (the Euclidean plane minus a point). As luck would have it, inversion provides a convenient bridge into non-Euclidean geometry.

21

Analytic Geometry

This chapter is a quick development of analytic geometry and trigonometry in the language of Euclidean geometry. I feel an obligation to provide this bridge between traditional Euclidean geometry (as we have developed it) and more contemporary analytic geometry, but you should already be comfortable with this material, so feel free to skim through it.

21.1 Analytic geometry

At the heart of analytic geometry, there is a correspondence between points and coordinates, ordered pairs of real numbers. The Cartesian approach to the correspondence is a familiar one that goes something like this. Begin with two perpendicular lines (the choice is arbitrary). These are the x- and y-axes. Their intersection is the origin O. We will want to measure signed distances from O along the axes, which means we need to assign a positive direction to them. Once directions have been chosen, each axis will be divided into two rays that share O as their common vertex: a positive axis consisting of points whose signed distance from O is positive, and a negative axis consisting of points whose signed distance from O is negative. From a geometric point of view, the choice of directions is arbitrary, but there is an established convention: the axes are assigned positive directions so that the positive y-axis is a 90° counterclockwise turn from the positive x-axis. Geometry provides no way to distinguish which direction is the counterclockwise direction, so it is a convention that must be communicated by way of illustrations (and clocks).

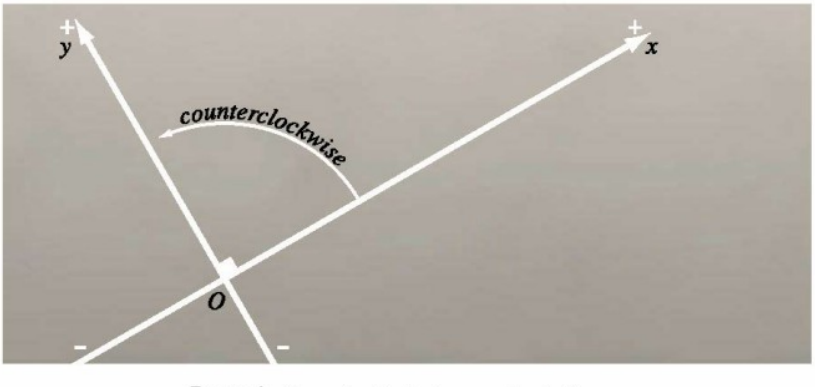


Figure 1. A counterclockwise coordinate frame.

A point P on the x-axis is assigned the coordinates $(p, 0)$, where p is the signed distance from O to P. A point Q on the y-axis is assigned the coordinates $(0, q)$ where q is the signed distance from O to Q. Most points will not lie on either axis. For their coordinates, we must consider their projections onto the axes. If R is such a point, then we draw the lines that pass through R and are perpendicular to the axes. If the points where the perpendiculars cross the axes have coordinates $(a, 0)$ and $(0, b)$, then the coordinates of R are (a, b). With this correspondence, every point corresponds to a unique coordinate pair, and every coordinate pair corresponds to a unique point.

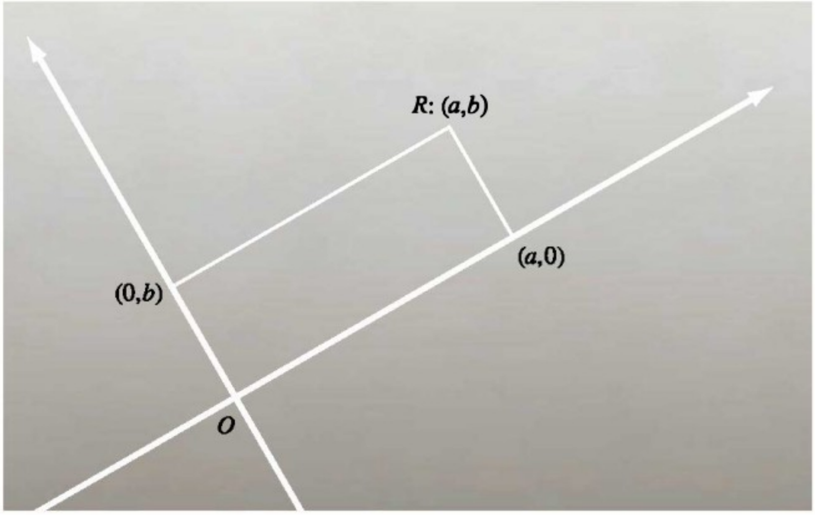

Figure 2. Assigning coordinates to a point.

The next step is to figure out how to calculate the distance between points in terms of their coordinates. This is essential for everything that we are going to do. Let's begin with two special cases.

Lemma 21.1 *(Horizontal and vertical distance) For points that share an x-coordinate, $P_1 = (x, y_1)$ and $P_2 = (x, y_2)$, $|P_1P_2| = |y_1 - y_2|$. For points that share a y-coordinate, $P_3 = (x_3, y)$ and $P_4 = (x_4, y)$, $|P_3P_4| = |x_3 - x_4|$.*

Proof We will just prove the second statement. Label two more points, $Q_1 = (x_1, 0)$ and $Q_2 = (x_2, 0)$. Then $\square P_1P_2Q_2Q_1$ is a rectangle, so its opposite sides P_1P_2 and Q_1Q_2 have to be the same length. This is where we make the direct connection between coordinates and distance: the coordinates along each axis were chosen to reflect their signed distance from the origin O. To be thorough, there are several cases to consider:

$$\begin{aligned}
O * Q_1 * Q_2 &: \quad |Q_1Q_2| = |OQ_2| - |OQ_1| = x_2 - x_1 = |x_1 - x_2| \\
O * Q_2 * Q_1 &: \quad |Q_1Q_2| = |OQ_1| - |OQ_2| = x_1 - x_2 = |x_1 - x_2| \\
Q_1 * O * Q_2 &: \quad |Q_1Q_2| = |OQ_1| + |OQ_2| = -x_1 + x_2 = |x_1 - x_2|
\end{aligned}$$

$$\begin{aligned}
Q_2 * O * Q_1: &\quad |Q_1Q_2| = |OQ_2| + |OQ_1| = -x_2 + x_1 = |x_1 - x_2| \\
Q_1 * Q_2 * O: &\quad |Q_1Q_2| = |OQ_1| - |OQ_2| = -x_1 - (-x_2) = |x_1 - x_2| \\
Q_2 * Q_1 * O: &\quad |Q_1Q_2| = |OQ_2| - |OQ_1| = -x_2 - (-x_1) = |x_1 - x_2|.
\end{aligned}$$

In all cases, $|P_1P_2| = |Q_1Q_2| = |x_1 - x_2|$. □

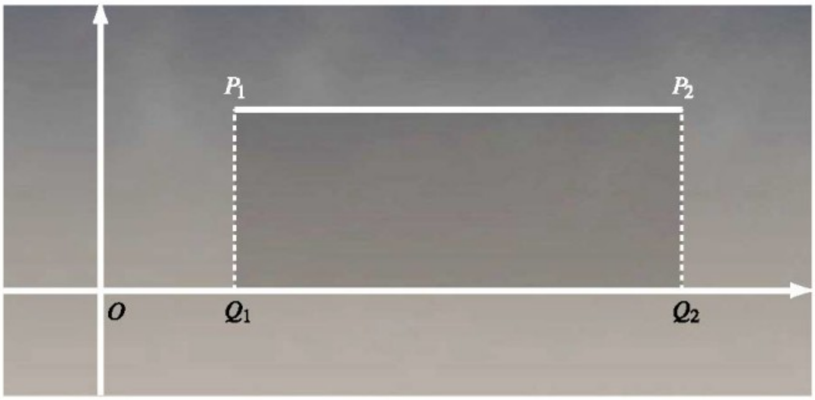

Figure 3. Measuring the distance between points on a horizontal line.

The general distance formula is now an easy consequence of the Pythagorean theorem.

Theorem 21.2 *(The distance formula) For two points $P = (x_1, y_1)$ and $Q = (x_2, y_2)$,*

$$|PQ| = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}.$$

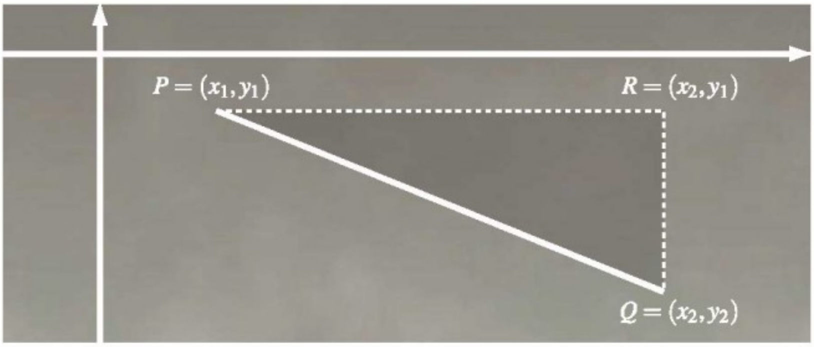

Figure 4. The distance formula is a consequence of the Pythagorean theorem.

Proof If P and Q share either x-coordinates or y-coordinates, then the formula reduces to the special case in the previous lemma (because $\sqrt{a^2} = |a|$). If not, mark one more point: $R = (x_2, y_1)$, the intersection of the horizontal line through P and the vertical line through Q.

Then $|PR| = |x_1 - x_2|$, $|RQ| = |y_1 - y_2|$, and $\triangle PRQ$ is a right triangle. By the Pythagorean theorem,

$$|PQ|^2 = |PR|^2 + |QR|^2 = (x_1 - x_2)^2 + (y_1 - y_2)^2.$$

Take the square root to get the formula. ☐

Corollary 21.3 *(Equation of a circle) The equation of a circle $\mathcal{C}$ with center at $P = (h, k)$ and radius r is*

$$(x - h)^2 + (y - k)^2 = r^2.$$

Proof By definition, the points of $\mathcal{C}$ are those points that are a distance of r from P. Therefore (x, y) is on $\mathcal{C}$ if and only if

$$\sqrt{(x - h)^2 + (y - k)^2} = r.$$

Square both sides of the equation to get the standard form. ☐

Now let's try to find equations that will describe lines. The key is the idea that a line describes the shortest path between points. That is captured more formally in the triangle inequality, which you should recall states that $|AB| + |BC| \geq |AC|$, but that the equality only happens when $A * B * C$.

Theorem 21.4 *Given two distinct points $P_1 = (x_1, y_1)$ and $P_2 = (x_2, y_2)$ on a line ℓ, a third point $P = (x, y)$ lies on ℓ if and only if its coordinates can be written in the form*

$$x = x_1 + t(x_2 - x_1) \quad \textit{and} \quad y = y_1 + t(y_2 - y_1)$$

for some $t \in \mathbb{R}$.

Proof The orderings of P, P_1, and P_2 on the line create several cases. Let's consider only the case where t is between 0 and 1 and P is between P_1 and P_2. It is representative of the other two cases.

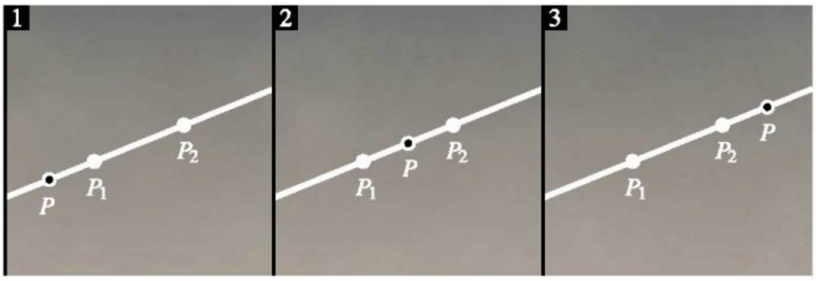

Figure 5. Finding the equation for an arbitrary point P on a line through P_1 and P_2. There are three cases depending upon the order of the points P, P_1, and P_2 on that line.

$\Longrightarrow$ First, let us show that if $P = (x_1 + t(x_2 - x_1), y_1 + t(y_2 - y_1))$ for some value of t between 0 and 1, then P is between P_1 and P_2. We can directly calculate $|P_1P|$ and $|PP_2|$:

$$\begin{aligned}
|P_1P| &= [(x - x_1)^2 + (y - y_1)^2]^{1/2} \\
&= [(x_1 + t(x_2 - x_1) - x_1)^2 + (y_1 + t(y_2 - y_1) - y_1)^2]^{1/2} \\
&= [(tx_2 - tx_1)^2 + (ty_2 - ty_1)^2]^{1/2} \\
&= t[(x_2 - x_1)^2 + (y_2 - y_1)^2]^{1/2} \\
&= t|P_1P_2|. \\
|PP_2| &= [(x_2 - x)^2 + (y_2 - y)^2]^{1/2} \\
&= [(x_2 - (x_1 + t(x_2 - x_1)))^2 + (y_2 - (y_1 + t(y_2 - y_1)))^2]^{1/2} \\
&= [((1 - t)x_2 - (1 - t)x_1)^2 + ((1 - t)y_2 - (1 - t)y_1)^2]^{1/2} \\
&= (1 - t)[(x_2 - x_1)^2 + (y_2 - y_1)^2]^{1/2} \\
&= (1 - t)|P_1P_2|.
\end{aligned}$$

According to the triangle inequality, P is between P_1 and P_2, since

$$|P_1P| + |PP_2| = t|P_1P_2| + (1 - t)|P_1P_2| = |P_1P_2|.$$

$\Longleftarrow$ Conversely, let us show that if P is between P_1 and P_2, then the coordinates of P can be written in the parametric form $(x_1 + t(x_2 - x_1), y_1 + t(y_2 - y_1))$ for some value of t between 0 and 1. P is the only point in the plane that is a distance $d_1 = |P_1P|$ from P_1 and a distance $d_2 = |PP_2|$ from P_2. Because of the uniqueness, we just need to find a point in parametric form that is also those distances from P_1 and P_2. The point that we are looking for is the one where $t = d_1/(d_1 + d_2)$. The two calculations, that the distance from this point to P_1 is d_1, and that the distance from this point to P_2 is d_2, are both straightforward, so are left as exercises.

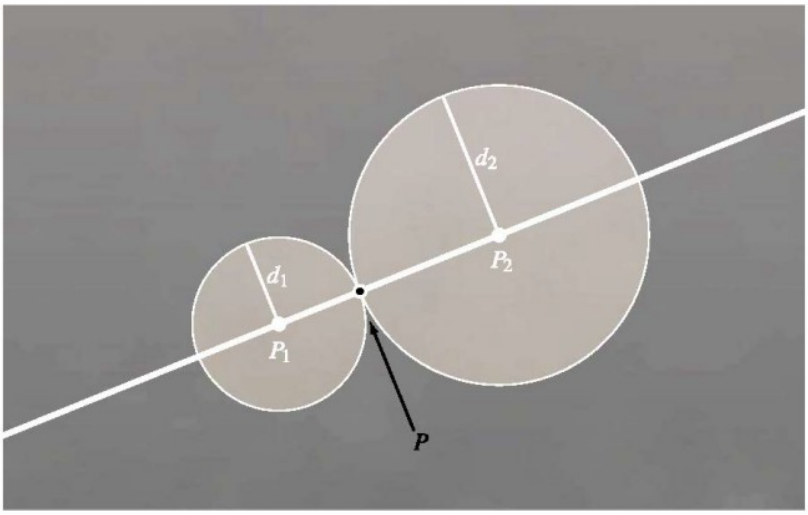

Figure 6. A point P is between P_1 and P_2 if the triangle inequality is an equality. Furthermore, P is the only point that is a distance d_1 from P_1 and a distance d_2 from P_2. □

Exercise 21.1 Complete the calculation in the last proof: using the parametrized form for $r(t)$ given there, show that $r(d_1/(d_1+d_2))$ gives the coordinates of a point that is a distance d_1 from P_1 and d_2 from P_2.

From the parametric form it is easy to get to standard form, and from there to point-slope form, slope-intercept form, and so on. The latter steps are usually done in a pre-calculus course, so I will only go one step further.

Theorem 21.5 *The coordinates (x, y) of the points of a line satisfy an equation of the form $Ax + By = C$ where A, B, and C are real numbers.*

Proof Suppose that (x_1, y_1) and (x_2, y_2) are distinct points on the line. As we saw in the last theorem, the other points on the line have coordinates (x, y) that satisfy the equations

$$\begin{aligned} x &= x_1 + t(x_2 - x_1) \\ y &= y_1 + t(y_2 - y_1). \end{aligned}$$

Now it is just a matter of combining the equations to eliminate the parameter t.

$$\begin{aligned} x - x_1 &= t(x_2 - x_1) \\ y - y_1 &= t(y_2 - y_1). \end{aligned}$$

It is tempting to divide the second equation by the first. That eliminates t and also serves as a definition of the slope of a line (in particular, it shows that the slope is constant). But we cannot divide by zero. Instead, multiply:

$$\begin{aligned} (x - x_1)(y_2 - y_1) &= t(x_2 - x_1)(y_2 - y_1) \\ (y - y_1)(x_2 - x_1) &= t(y_2 - y_1)(x_2 - x_1). \end{aligned}$$

Set the equations equal and simplify:

$$\begin{aligned} (x - x_1)(y_2 - y_1) &= (y - y_1)(x_2 - x_1) \\ x(y_2 - y_1) - x_1(y_2 - y_1) &= y(x_2 - x_1) - y_1(x_2 - x_1) \\ x(y_2 - y_1) - y(x_2 - x_1) &= x_1(y_2 - y_1) - y_1(x_2 - x_1). \end{aligned}$$

This equation has the proper form, with

$$A = (y_2 - y_1), \quad B = -(x_2 - x_1), \quad \text{and } C = x_1(y_2 - y_1) - y_1(x_2 - x_1). \qquad \square$$

Exercise 21.2 Suppose that A, B, and C are real numbers. Show that if A and B are not both zero, then the equation $Ax + By = C$ describes a line.

21.2 The unit circle approach to trigonometry

At the end of chapter 13 on similarity, we defined the six trigonometric functions in terms of the angles of a right triangle, which means that they were restricted to values in the interval $(0, \pi/2)$. There is also a unit circle approach that extends the definitions beyond that narrow window. This is standard fare, so what follows is a brief recap. A point with two positive coordinates (x, y) on the unit circle corresponds to a right triangle whose vertices are $(0, 0)$, $(x, 0)$, and (x, y). If θ is the measure of the angle at the origin, then $\cos\theta = x$ and $\sin\theta = y$ (because the hypotenuse has length one). Now just continue that: any ray from the origin forms an angle θ measured in the counterclockwise direction from the x-axis. The ray intersects the unit circle at a point (x, y) and we define

$$\cos(\theta) = x, \quad \sin(\theta) = y.$$

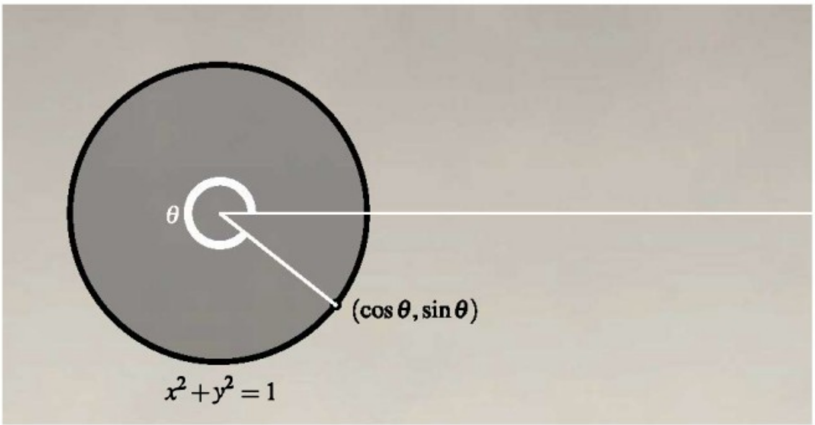

Figure 7. Coordinates on the unit circle correspond to the cosine and sine functions.

Allowing for proper and reflex angles, that extends the domains of sine and cosine to $[0, 2\pi)$, but we can go farther. We can allow the ray to spin around the circle more than once (for θ values greater than 2π) or in the clockwise direction (for negative θ). By imposing periodicity:

$$\cos(\theta + 2n\pi) = \cos(\theta), \quad \sin(\theta + 2n\pi) = \sin(\theta), \quad n \text{ an integer.}$$

The other four trigonometric functions (tangent, cotangent, secant, cosecant) are defined similarly as the ratios

$$\tan(\theta) = y/x, \quad \cot(\theta) = x/y, \quad \sec(\theta) = 1/x, \quad \csc(\theta) = 1/y.$$

There are many relationships among the trigonometric functions, some obvious and some subtle. Let's get the obvious ones out of the way. From the definitions of the functions, we get the reciprocal identities

$$\sec\theta = \frac{1}{\cos\theta}, \quad \csc\theta = \frac{1}{\sin\theta}, \quad \cot\theta = \frac{1}{\tan\theta},$$

and identities that relate tangent and cotangent to sine and cosine:

$$\tan\theta = \frac{\sin\theta}{\cos\theta}, \quad \cot\theta = \frac{\cos\theta}{\sin\theta}.$$

Figure 8. We can use an equilateral triangle and an isosceles right triangle to find the sine and cosine values for the angles $\pi/6$, $\pi/3$, and $\pi/4$. Then use the symmetry of the circle to extend beyond the first quadrant.

From the equation of the circle $x^2 + y^2 = 1$, we get the Pythagorean identities

$$\sin^2\theta + \cos^2\theta = 1, \quad \tan^2\theta + 1 = \sec^2\theta, \quad 1 + \cot^2\theta = \csc^2\theta.$$

By comparing angles taken in the counterclockwise and clockwise directions, we see that cosine and secant are even functions (where $f(-x) = f(x)$) and that the other four are odd functions (where $f(-x) = -f(x)$).

Beyond these, there is a second tier of identities—double angle, half angle, power reduction, etc.—that are not so immediately clear. They can be derived from two big identities, the addition formulas for sine and cosine, but the proofs of those formulas require a more careful look at the geometry of the unit circle. To close this chapter, we will prove them.

Theorem 21.6 *(Addition rule for cosine) For angles measures α and β,*

$$\cos(\alpha + \beta) = \cos\alpha\cos\beta - \sin\alpha\sin\beta.$$

The key to the proof is to compare two distances that we know to be the same, one distance expressed in terms of the angle $\alpha + \beta$, the other in terms of the individual angles α and β. The trick is to make the right choice of distances.

Proof On the unit circle, label:

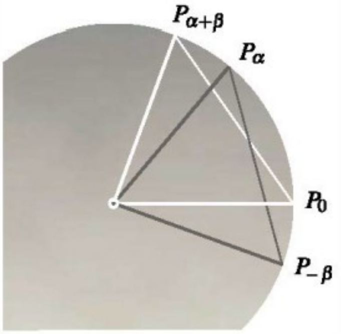

Figure 9. Marking points to derive the cosine addition formula.

$$\begin{aligned} P_0 &= (1, 0) \\ P_\alpha &= (\cos\alpha, \sin\alpha) \\ P_{-\beta} &= (\cos(-\beta), \sin(-\beta)) = (\cos\beta, -\sin\beta) \\ P_{\alpha+\beta} &= (\cos(\alpha+\beta), \sin(\alpha+\beta)). \end{aligned}$$

If O is the origin, then $\triangle OP_0P_{\alpha+\beta}$ and $\triangle OP_{-\beta}P_\alpha$ are congruent (SAS: in each triangle, two of the sides are radii, and the angle between them measures $\alpha + \beta$). So the two segments $P_0P_{\alpha+\beta}$ and $P_{-\beta}P_\alpha$ are congruent, and we can compare their lengths (it is actually easier to work with the squares of those lengths). Throughout these calculations, we make repeated use of the

Pythagorean identity $\sin^2 x + \cos^2 x = 1$.

$$\begin{aligned}
|P_0P_{\alpha+\beta}|^2 &= (\cos(\alpha+\beta)-1)^2 + (\sin(\alpha+\beta)-0)^2\\
&= \cos(\alpha+\beta)^2 - 2\cos(\alpha+\beta) + 1 + \sin^2(\alpha+\beta)\\
&= 2 - 2\cos(\alpha+\beta).\\
|P_{-\beta}P_\alpha|^2 &= (\cos\alpha - \cos\beta)^2 + (\sin\alpha + \sin\beta)^2\\
&= \cos^2\alpha - 2\cos\alpha\cos\beta + \cos^2\beta + \sin^2\alpha + 2\sin\alpha\sin\beta + \sin^2\beta\\
&= 2 - 2\cos\alpha\cos\beta + 2\sin\alpha\sin\beta.
\end{aligned}$$

Set the expressions equal and simplify:

$$\begin{aligned}
2 - 2\cos(\alpha+\beta) &= 2 - 2\cos\alpha\cos\beta + 2\sin\alpha\sin\beta\\
-2\cos(\alpha+\beta) &= -2\cos\alpha\cos\beta + 2\sin\alpha\sin\beta\\
\cos(\alpha+\beta) &= \cos\alpha\cos\beta - \sin\alpha\sin\beta.
\end{aligned}$$ ☐

Now let's look at the addition rule for the sine function. For this proof, one approach would be to use the cofunction identity $\sin(x) = \cos(\pi/2 - x)$ followed by the addition rule for cosine that we just derived (although we have not yet derived this cofunction identity). Instead, let's contrive something in the spirit of the last proof by comparing some distances and then doing a little algebra.

Theorem 21.7 *(Addition rule for sine)*

$$\sin(\alpha+\beta) = \sin\alpha\cos\beta + \cos\alpha\sin\beta.$$

Proof On the unit circle, label:

$$\begin{aligned}
P_0 &= (1,0)\\
P_\alpha &= (\cos\alpha, \sin\alpha)\\
P_\beta &= (\cos\beta, \sin\beta)\\
P_{\alpha+\beta} &= (\cos(\alpha+\beta), \sin(\alpha+\beta)).
\end{aligned}$$

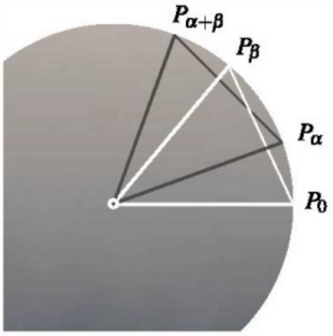

Figure 10. Marking points to derive the sine addition formula.

By SAS, $P_\alpha P_{\alpha+\beta}$ and $P_0 P_\beta$ are congruent. Let's compare the lengths (we use the addition rule for cosine midway through the first distance calculation).

$$\begin{aligned}|P_\alpha P_{\alpha+\beta}|^2 &= (\cos(\alpha+\beta)-\cos(\alpha))^2 + (\sin(\alpha+\beta)-\sin(\alpha))^2\\ &= \cos^2(\alpha+\beta) - 2\cos\alpha\cos(\alpha+\beta) + \cos^2\alpha\\ &\quad + \sin^2(\alpha+\beta) - 2\sin\alpha\sin(\alpha+\beta) + \sin^2\alpha\\ &= 2 - 2\cos\alpha\cos(\alpha+\beta) - 2\sin\alpha\sin(\alpha+\beta)\\ &= 2 - 2\cos\alpha(\cos\alpha\cos\beta - \sin\alpha\sin\beta) - 2\sin\alpha\sin(\alpha+\beta)\\ &= 2 - 2\cos^2\alpha\cos\beta + 2\sin\alpha\cos\alpha\sin\beta - 2\sin\alpha\sin(\alpha+\beta)\end{aligned}$$

and

$$\begin{aligned}|P_0 P_\beta|^2 &= (\cos\beta - 1)^2 + (\sin\beta - 0)^2\\ &= \cos^2\beta - 2\cos\beta + 1 + \sin^2\beta\\ &= 2 - 2\cos\beta.\end{aligned}$$

Set the expressions equal and simplify:

$$\begin{aligned}2 - 2\cos^2\alpha\cos\beta + 2\sin\alpha\cos\alpha\sin\beta - 2\sin\alpha\sin(\alpha+\beta) &= 2 - 2\cos\beta\\ -2\cos^2\alpha\cos\beta + 2\sin\alpha\cos\alpha\sin\beta - 2\sin\alpha\sin(\alpha+\beta) &= -2\cos\beta\\ \cos^2\alpha\cos\beta - \sin\alpha\cos\alpha\sin\beta + \sin\alpha\sin(\alpha+\beta) &= \cos\beta.\end{aligned}$$

Solve for $\sin(\alpha+\beta)$:

$$\begin{aligned}\sin\alpha\sin(\alpha+\beta) &= \cos\beta - \cos^2\alpha\cos\beta + \sin\alpha\cos\alpha\sin\beta\\ &= \cos\beta(1-\cos^2\alpha) + \sin\alpha\cos\alpha\sin\beta\\ &= \cos\beta\sin^2\alpha + \sin\alpha\cos\alpha\sin\beta\\ &= \sin\alpha(\sin\alpha\cos\beta + \cos\alpha\sin\beta).\end{aligned}$$

As long as $\sin\alpha$ is not zero, we can divide both sides by it, and what's left is what we want. That leaves one loose thread: what if $\sin\alpha$ is zero? That is left as an exercise. ☐

Exercise 21.3 Suppose that $\sin(\alpha) = 0$, and hence that α is an integer multiple of π. Prove that the addition formula for sine holds in this case as well.

21.3 Exercises

21.4. (The midpoint formula) Let $P = (a, b)$ and $Q = (c, d)$. Verify that the coordinates of the midpoint of PQ are

$$\left(\frac{a+c}{2}, \frac{b+d}{2}\right).$$

Part IV

Hyperbolic Geometry

The last part of this book is an introduction to hyperbolic geometry, the non-Euclidean neutral geometry. There are three major components.

- In chapters 36 and 37 we will try to get some sense of what to expect of hyperbolic geometry by looking at what would happen if Playfair's axiom were false.
- In chapters 38–41 we will build several models for hyperbolic geometry, starting with a partial model called the Beltrami pseudosphere, then moving to the upper half plane model, before ultimately settling on the Poincaré disk model. The calculations to get to the Beltrami pseudosphere model are difficult. They require multivariable calculus, linear algebra, and even some differential equations. You may want to skip straight ahead to the Poincaré disk model in chapter 41. In that chapter we verify that the Poincaré model satisfies all the axioms of neutral geometry, and so you can see how the Poincaré disk model works. I have included the chapters on the pseudosphere and the upper half plane to provide a better idea of why the Poincaré disk model works.
- The remaining chapters look at some elementary hyperbolic geometry in the Poincaré disk, deriving, for instance, hyperbolic analogs of the Pythagorean theorem and the circumference formula.

36

The Search for a Rectangle

The geometers who sought to prove Euclid's parallel axiom focused a lot of attention on rectangles. They are ubiquitous in Euclidean geometry, but without Euclid's parallel axiom, the situation is different. Let us see what happens when you let a rectangle into your world.

36.1 If there were a rectangle . . .

By definition, a rectangle is a quadrilateral with four right angles. When we talk of a rectangle, we often talk of its *base* and *height*. There is ambiguity about which side to call the base and which to call the height, but the conversation would not make any sense if it weren't for this:

Lemma 36.1 *The opposite sides of a rectangle are congruent.*

Exercise 36.1 Prove the lemma (assuming that rectangles exist). Hint: the result is easy to prove if you use the converse of the alternate interior angle theorem, and the existence of a single rectangle implies the converse of the theorem. However, we have not yet established that. Consider the following approach: let $\square ABCD$ be a rectangle and suppose that $|BC| > |AD|$. Then there is a point E between B and C so that $AD \simeq BE$. Look for a contradiction involving $\triangle DCE$.

Now let's get to work.

Theorem 36.2 *Suppose that a rectangle R exists, with base b and height h. Then for an integer $n \geq 1$, there is a rectangle with base nb and height h.*

Proof By induction. The base case, when $n = 1$, is trivial because R meets the requirements. Now for the inductive step. Suppose that a rectangle with base nb and height h exists. Label it $\square ABCD$ where AB is the base. We need to build a rectangle with base $(n+1)b$ and height h. Two of its vertices are going to be A and D. The other two are E and F where

- $A * B * E$ and $|BE| = b$, and
- $D * C * F$ and $|CF| = b$.

-7 & 6 F !X 6 C / +

By SASAS, $\square BEFC$ is congruent to R, and therefore $\angle E$ and $\angle F$ are both right angles. That is, the interior angles of $\square AEFD$ are right angles so $\square AEFD$ is a rectangle. Its height is $|AD| = h$. Its base is

$$|AE| = |AB| + |BE| = nb + b = (n+1)b.$$

By induction, then, we can build nb-by-h rectangles.

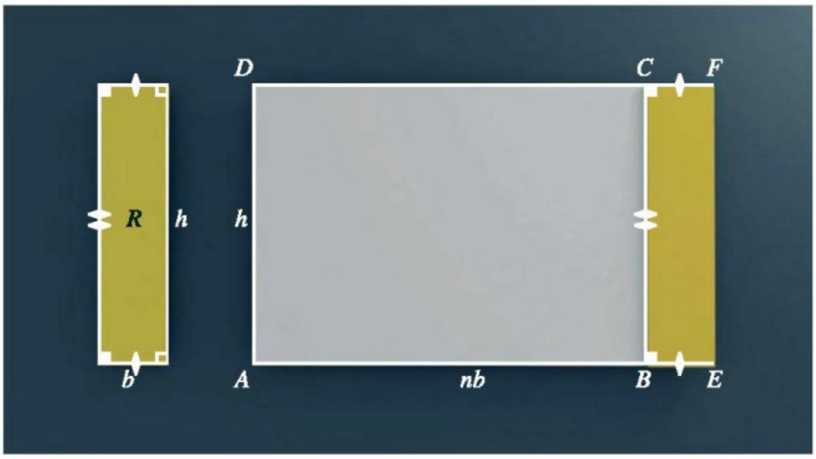

Figure 1. If there is a rectangle with base b and height h, then there is a rectangle with base nb and height h (a proof by induction).

$\square$

Theorem 36.3 *Suppose that a rectangle R exists, with base b and height h. Then for a positive real number x, there is a rectangle with base x and height h.*

Proof There is an integer n so that $nb > x$. By the previous result, there is a rectangle $\square ABCD$ with base $|AB| = nb$ and height $|AD| = h$. Then there are points E and F so that

- $A * E * B$ and $|AE| = x$, and
- $D * F * C$ and $|DF| = x$.

The segment EF cuts $\square ABCD$ into two pieces. We can show that both of those pieces are also rectangles. To see this, start by looking at their angle sums. As a corollary to the Saccheri-Legendre theorem, the angle sum of a quadrilateral is at most 2π. Therefore

$$(\angle A) + (\angle D) + (\angle AEF) + (\angle DFE) \le 2\pi$$
$$(\angle B) + (\angle C) + (\angle BEF) + (\angle CFE) \le 2\pi.$$

Since $(\angle A) = (\angle B) = (\angle C) = (\angle D) = \pi/2$, we get

$$(\angle AEF) + (\angle DFE) \le \pi$$
$$(\angle BEF) + (\angle CFE) \le \pi.$$

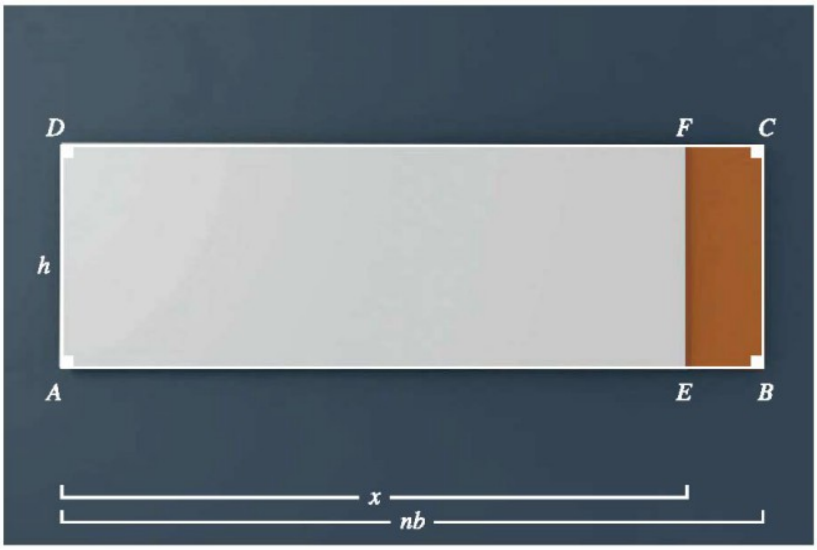

Figure 2. If there is a rectangle with base b and height h, then there is a rectangle with base x and height h. Extend the given rectangle to a new rectangle with base $nb > x$. Then divide that into two pieces, one with a base of x.

But

$$EA \simeq FD, \quad \angle A \simeq \angle D, \quad AD = DA, \quad \angle D \simeq \angle A, \text{ and } DF \simeq AE.$$

By SASAS, $\square AEFD$ is congruent to itself in a non-trivial way, so matching corresponding pieces, $\angle DFE \simeq \angle AEF$. Their supplements, $\angle CFE$ and $\angle BEF$, are also congruent.

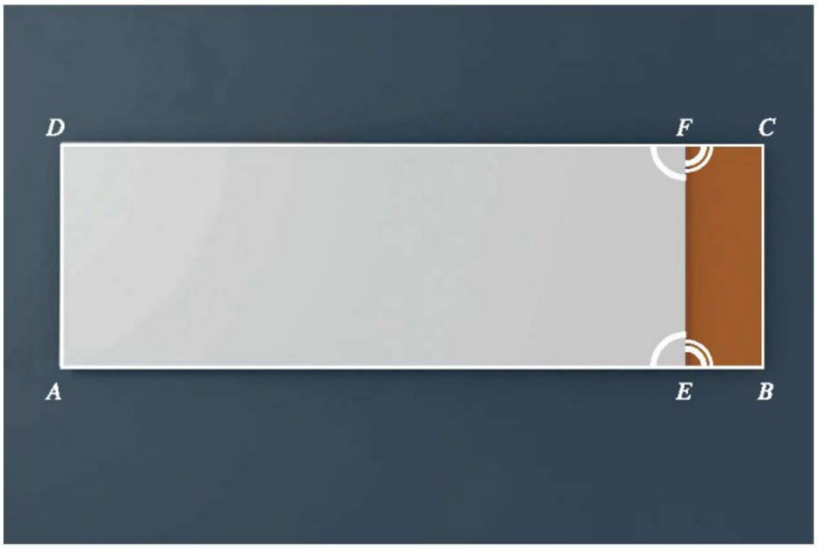

Figure 3. The segment EF cuts the rectangle $\square ABCD$ into two smaller pieces, both of which must also be rectangles.

Substitute this information into the pair of inequalities to get

$$2(\angle AEF) \leq \pi \implies (\angle AEF) \leq \pi/2$$
$$2(\angle BEF) \leq \pi \implies (\angle BEF) \leq \pi/2.$$

But $\angle AEF$ and $\angle BEF$ are supplementary, and so together sum to π. The only way this can happen is if $(\angle AEF) = (\angle BEF) = \pi/2$. That is, they are right angles, as are $\angle DFE$ and $\angle CFE$. Hence $\square AEFD$ and $\square BEFC$ are rectangles. In particular, $\square AEFD$ is a rectangle with base x and height h. □

Theorem 36.4 *Suppose that a rectangle R exists, with base b and height h. Then for positive real numbers x and y, there is a rectangle with base x and height y.*

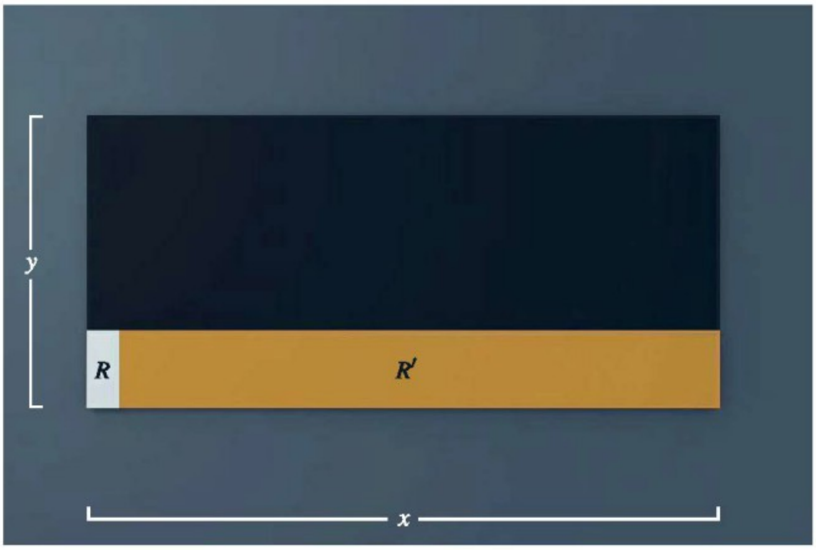

Figure 4. Use the previous result in both directions to build a rectangle with base x and height y.

Proof By the previous result, there is a rectangle R' with base x and height h. The roles of base and height are interchangeable, so that we can think of R' as a rectangle with base h and height x. Using the previous result, there is a rectangle R'' with base y and height x. Switch the roles of base and height in R'' back, so that R'' has a base x and a height y. □

The last three results tell us that if there is a rectangle in our geometry, then they are abundant. What are the implications of all of these rectangles?

Theorem 36.5 *If rectangles of all sizes exist, then the angle sum of a triangle is π.*

Proof There are two cases: first when the triangle is a right triangle, and second when it is not.

Case 1: Suppose that ΔABC is a right triangle with right angle at C. There is a rectangle with base $|AC|$ and height $|BC|$. Label it $\square acbd$ so that ac is the base and cb is the height. The diagonal ab cuts the rectangle into two right triangles. By SAS, both are congruent to ΔABC. Therefore the angle sum of the two copies of ΔABC equals the angle sum of a rectangle:

$$2((\angle A) + (\angle B) + (\angle C)) = 2\pi \implies (\angle A) + (\angle B) + (\angle C) = \pi.$$

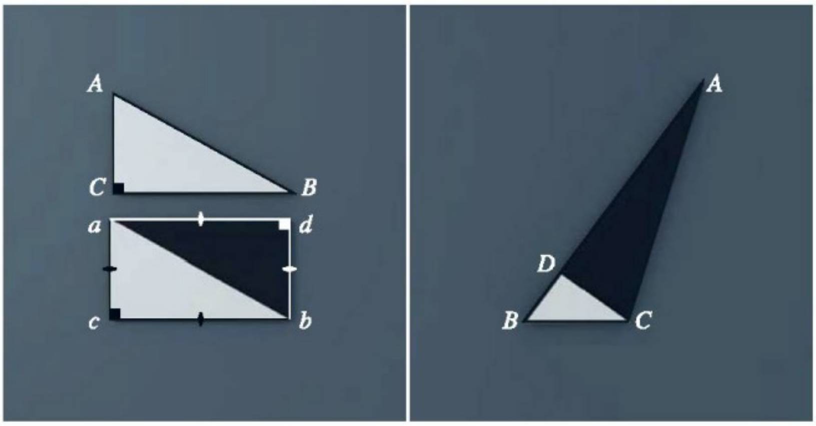

Figure 5. Given rectangles, the sum of the interior angles of the triangles must be π: (l) case 1, for right triangles. (r) case 2, for non-right triangles.

Case 2: Now suppose that ΔABC is not a right triangle, and label it so that $\angle C$ is the largest angle. In that case, the altitude from C intersects AB between A and B. Label the intersection point as D. Then CD divides ΔABC into two smaller right triangles: ΔACD and ΔBCD. From the previous part, both have an angle sum of π. They have right angles at D, so the other two angles sum to $\pi/2$. So

$$(\angle A) + (\angle ACD) = \pi/2 \quad \text{and} \quad (\angle BCD) + (\angle B) = \pi/2.$$

Add the equations to get

$$(\angle A) + (\angle ACD) + (\angle BCD) + (\angle B) = \pi/2 + \pi/2$$
$$(\angle A) + (\angle C) + (\angle B) = \pi.$$

□

Theorem 36.6 *If the angle sum of a triangle is π, then for a line ℓ and a point P not on ℓ, there is a unique line through P parallel to ℓ. That is, Playfair's axiom is true (and does not need to be taken as an axiom).*

Proof Begin by dropping the perpendicular from P to ℓ, and label its foot as Q_0. Let ℓ' be the line through P that is perpendicular to PQ_0. By the alternate interior angle theorem, it is parallel to ℓ. We need to show it is the only parallel. Suppose that ℓ'' is some other line through P. It forms an acute angle with PQ_0 on one of the sides of PQ_0 (and not on the other). On the acute side of PQ_0 we are going to build a sequence of isosceles triangles $\{\Delta PQ_{i-1}Q_i\}$.

(1) Locate Q_1 on ℓ so that $PQ_0 \simeq Q_0Q_1$. Then ΔPQ_0Q_1 is isosceles. The angle at Q_0 is right, so if the angle sum of a triangle is π, then

$$\pi/2 + (\angle P) + (\angle Q_1) = \pi \quad \Longrightarrow \quad (\angle P) + (\angle Q_1) = \pi/2.$$

By the isosceles triangle theorem, $\angle P$ and $\angle Q_1$ are congruent, so they both measure $\pi/4$.

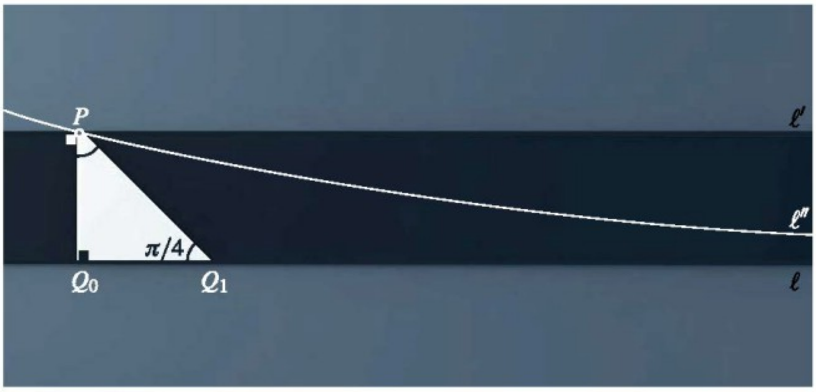

Figure 6. Constructing longer and longer isosceles triangles between ℓ and ℓ'. The first step.

(2) Now move farther out on ℓ, and locate Q_2 so that $Q_1Q_2 \simeq PQ_1$. The angle at Q_1 is $\pi - \pi/4 = 3\pi/4$, so if the angle sum of a triangle is π, then in ΔPQ_1Q_2,

$$3\pi/4 + (\angle P) + (\angle Q_2) = \pi \quad \Longrightarrow \quad (\angle P) + (\angle Q_2) = \pi/4.$$

Because $\angle P$ and $\angle Q_2$ are congruent in this triangle, they each measure $\pi/8$. Therefore

$$(\angle Q_0PQ_2) = (\angle Q_0PQ_1) + (\angle Q_1PQ_2) = \pi/4 + \pi/8 = 3\pi/8.$$

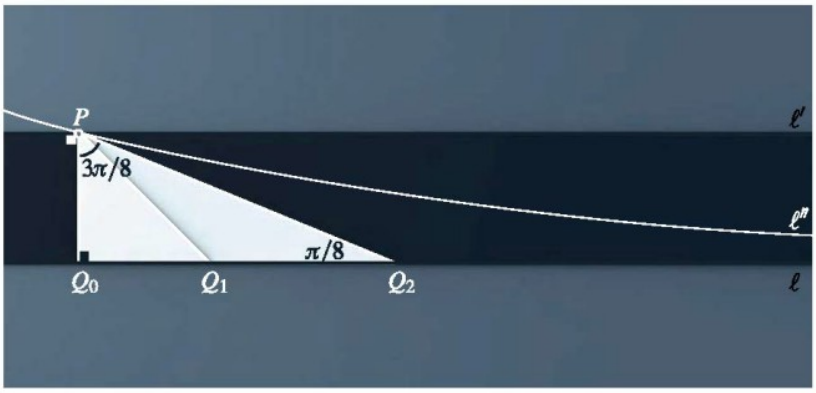

Figure 7. The second step.

(3) We can continue in this way, building isosceles triangles $\triangle PQ_iQ_{i+1}$ with congruent sides PQ_i and Q_iQ_{i+1}. Measuring angles as we go:

i	$(\angle PQ_{i-1}Q_i)$	$(\angle Q_0PQ_i)$
1	$\pi/4$	$\pi/4$
2	$\pi/8$	$3\pi/8$
3	$\pi/16$	$7\pi/16$
4	$\pi/32$	$15\pi/32$
5	$\pi/64$	$31\pi/64$

In general,

$$(\angle Q_0PQ_i) = \frac{2^i - 1}{2^{i+1}}\pi.$$

As i approaches infinity, the angle approaches $\pi/2$. Now ℓ'' forms an acute angle with PQ_0. Therefore, for a large enough i, ℓ'' will lie between $\overrightarrow{PQ_0}$ and $\overrightarrow{PQ_i}$. By the crossbar theorem, ℓ'' will then intersect Q_0Q_i, and so ℓ'' will not be parallel to ℓ. That is, a line through P other than ℓ' will intersect ℓ. This means ℓ' is the unique parallel to ℓ through P. □

36.2 The search for a rectangle

Euclidean geometry is neutral geometry with one more axiom, Playfair's axiom, added. Before the discovery of non-Euclidean geometry, geometers were trying to prove that neutral geometry *is* Euclidean geometry by trying to prove Playfair's axiom from the axioms of neutral geometry. One way to do that would be to prove that there are rectangles in neutral geometry. Hence, much effort was spent in attempts to build a rectangle using only the axioms of neutral geometry. There isn't a construction that is going to just give you all four right angles right away, so the idea was to construct a quadrilateral that has some of the properties of a rectangle, and then to work from there. One such quasi-rectangle is called a Saccheri quadrilateral.

Definition 36.7 A convex quadrilateral $\square ABCD$ is called a *Saccheri quadrilateral* with *base* AB, *summit* CD, and *legs* BC and AD if:

- $\angle A$ and $\angle B$ are right angles, and
- segments BC and AD are congruent.

The angles $\angle C$ and $\angle D$ are called the *summit angles* of the Saccheri quadrilateral.

Saccheri quadrilaterals can be constructed in neutral geometry: start with a segment for the base, draw two rays from the endpoints of the base to form the two right angles, and then mark off congruent segments along them. The segments are the legs. Join their endpoints to form the summit and you have a Saccheri quadrilateral. A Saccheri quadrilateral seems to be about half the way to a rectangle because two of its angles are right, and one pair of opposite sides are congruent. The only Saccheri quadrilaterals in Euclidean geometry are rectangles because by the converse of the alternate interior angle theorem, the two summit angles must be right angles. With only the axioms of neutral geometry, we can't prove that the summit angles are right angles, but we can prove weaker statements. The first statement exploits the internal symmetry of a Saccheri quadrilateral (much like the proof of the isosceles triangle theorem).

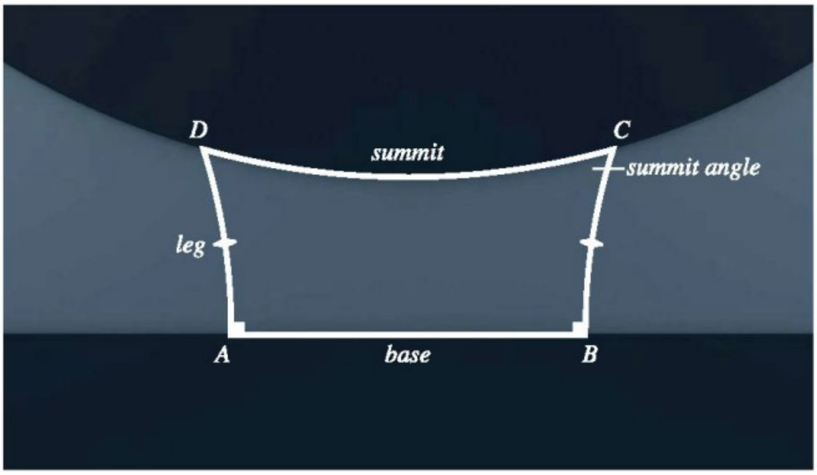

Figure 8. The parts of a Saccheri quadrilateral.

Theorem 36.8 *Let $\square ABCD$ be a Saccheri quadrilateral with base AB. Then the summit angles $\angle C$ and $\angle D$ are congruent.*

Proof Observe that

$$DA \simeq CB, \quad \angle A \simeq \angle B, \quad AB = BA, \quad \angle B \simeq \angle A, \quad \text{and} \quad BC \simeq AD.$$

By SASAS, $\square ABCD$ and $\square BADC$ are congruent. Matching the corresponding parts, $\angle C \simeq \angle D$.

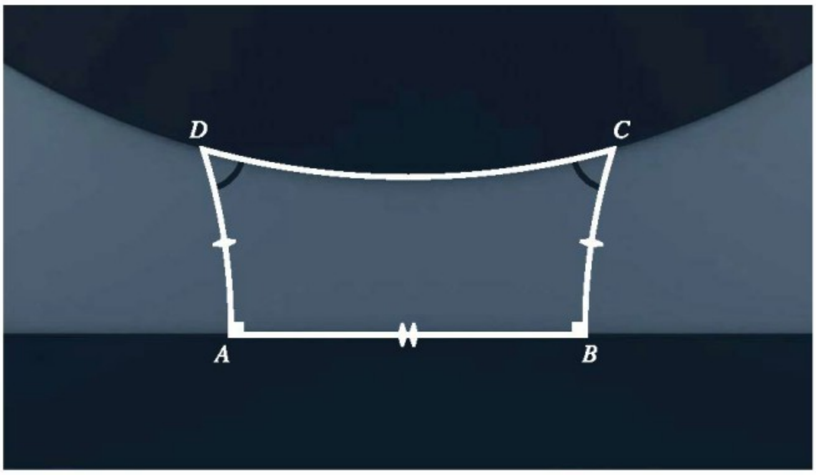

Figure 9. By SASAS, the summit angles of a Saccheri quadrilateral are congruent. □

Theorem 36.9 *Let $\square ABCD$ be a Saccheri quadrilateral with base AB. Then the summit angles $\angle C$ and $\angle D$ cannot be obtuse.*

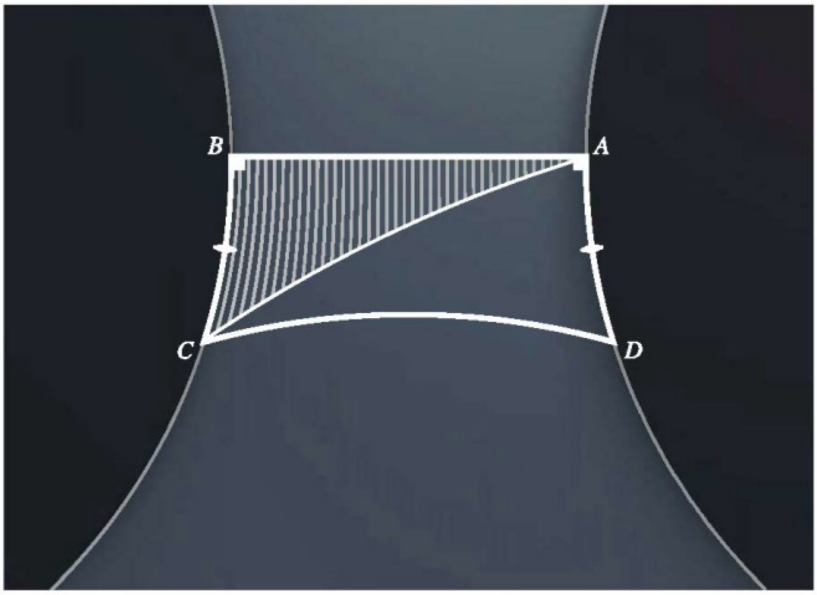

Figure 10. The summit angles cannot be obtuse.

Proof The diagonal AC divides the Saccheri quadrilateral into two triangles, and by the Saccheri-Legendre theorem the angle sum of each is at most π. Therefore the angle sum of $\square ABCD$ is at most 2π. So

$$\begin{aligned}(\angle A) + (\angle B) + (\angle C) + (\angle D) &\le 2\pi\\ (\pi/2) + (\pi/2) + (\angle C) + (\angle D) &\le 2\pi\\ (\angle C) + (\angle D) &\le \pi.\end{aligned}$$

We just proved that $\angle C$ and $\angle D$ are congruent, though, so they must measure at most $\pi/2$. □

If the summit angles are right, then the Saccheri quadrilateral is a rectangle. So in non-Euclidean geometry, the summit angles must be acute.

Definition 36.10 The *altitude* of a Saccheri quadrilateral is the line segment from the midpoint of its base to the midpoint of its summit.

Theorem 36.11 *Let $\square ABCD$ be a Saccheri quadrilateral with base AB and altitude EF (with E on the base and F on the summit). Then EF is perpendicular to the base AB and the summit CD.*

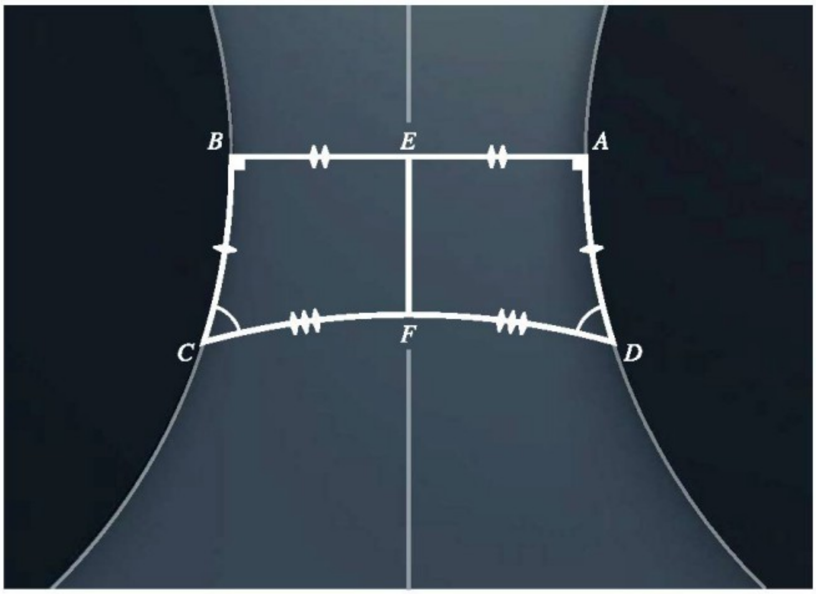

Figure 11. The segment EF is the altitude of $\square ABCD$. It is perpendicular to AB and CD.

Proof Compare the two quadrilaterals $\square AEFD$ and $\square BEFC$. Since $\square ABCD$ is Saccheri, $AD \simeq BC$ and $\angle A \simeq \angle B$, and since the summit angles of a Saccheri quadrilateral are congruent, $\angle D \simeq \angle C$. By the definition of an altitude, $AE \simeq BE$ and $DF \simeq CF$. By SASAS, then, $\square AEFD \simeq \square BEFC$. In particular, $\angle AEF$ is congruent to its own supplement, $\angle BEF$, and $\angle DFE$ is congruent to its own supplement, $\angle CFE$. They are both right angles, then, and so the altitude is perpendicular to both base and summit. □

Theorem 36.12 *Let $\square ABCD$ be a Saccheri quadrilateral with base AB and summit CD. Then $|CD| \geq |AB|$.*

Proof Assume instead that AB is greater than CD. Label E and F the midpoints of AB and CD, so that EF is the altitude. Then $|EB| > |FC|$ so we can locate a point G between E and B so that $EG \simeq FC$. Since $\square EFCG$ has right angles at E and F and a pair of congruent opposite sides, it is a Saccheri quadrilateral with base EF. As we saw above, the summit angle $\angle EGC$ cannot be obtuse, so its supplement cannot be acute. But ΔBGC has a right angle at B and an angle at G that isn't acute, so the angle sum of ΔBGC will exceed π, and this violates the Saccheri-Legendre theorem. □

Theorem 36.13 *Let $\square ABCD$ be a Saccheri quadrilateral with base AB. Let EF be the altitude, with E on AB and F on CD. Then the altitude EF cannot be longer than the legs AD and BC.*

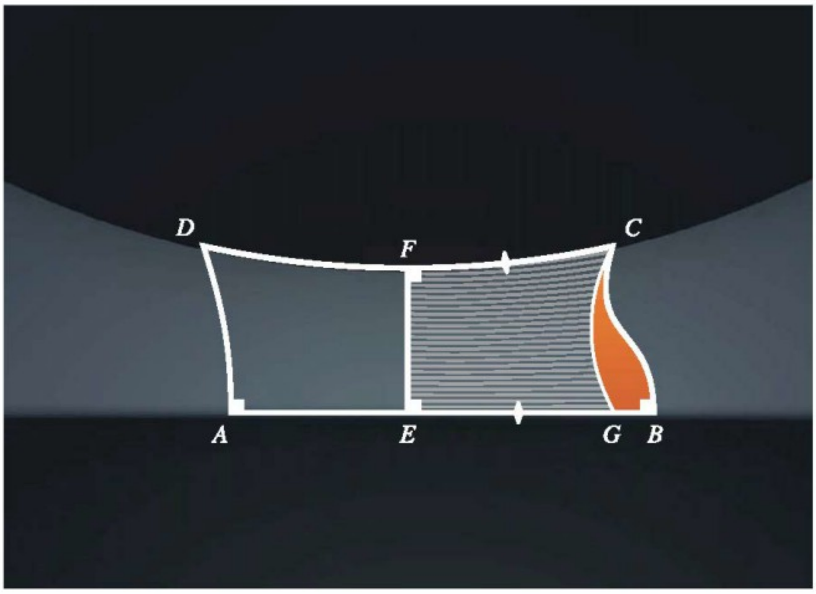

Figure 12. The base cannot be longer than the summit.

Proof Let's build a different Saccheri quadrilateral (see figure 13). Label:

F' : on $\overrightarrow{FE}$ so that $F * E * F'$ and $EF' \simeq EF$, and
C' : on $\overrightarrow{CB}$ so that $C * B * C'$ and $BC' \simeq BC$.

Now we have the congruences:

$$CB \simeq C'B, \quad BE = BE, \quad EF \simeq EF', \quad \angle CBE \simeq \angle C'BE, \text{ and } \angle BEF \simeq \angle BEF'.$$

By SASAS, $\square BEFC$ and $\square BEF'C'$ are congruent. Matching their corresponding pieces, $\angle F'$ is congruent to $\angle F$ and so is a right angle, and $F'C' \simeq FC$. Thus $\square CFF'C'$ is a Saccheri quadrilateral with base FF' and summit CC'. By the previous result, its base cannot be longer than the summit, and so

$$|EF| = \tfrac{1}{2}|FF'| \leq \tfrac{1}{2}|CC'| = |CB|.$$

We see, then, that EF, the altitude of $\square ABCD$ cannot be longer than the leg BC. □

Thinking more generally, what can we say about other perpendiculars that fall between the altitude and a leg?

Theorem 36.14 *Let $\square ABCD$ be a Saccheri quadrilateral with base AB and altitude EF. Let GH be another segment that connects the base to the summit, so that $E * G * B$, $F * H * C$, and GH is perpendicular to the base. Then*

$$|EF| \leq |GH| \leq |BC|.$$

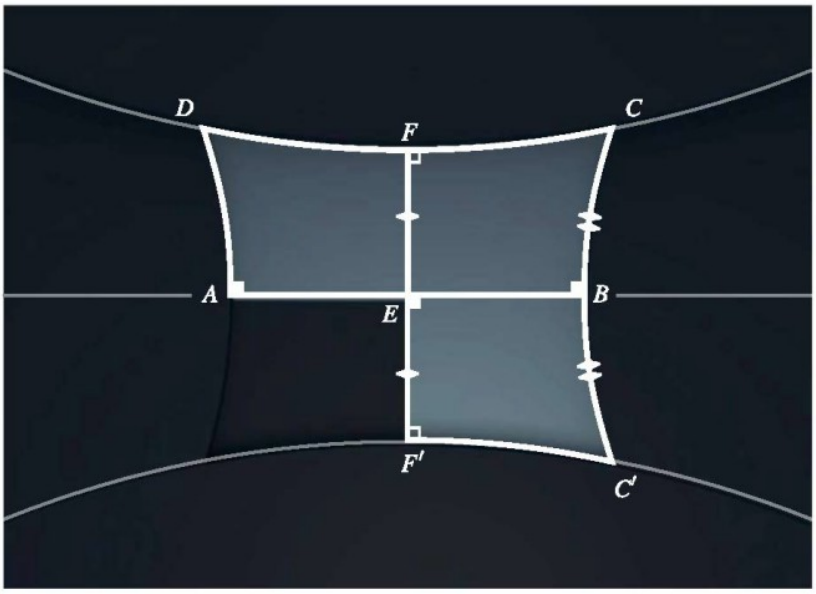

Figure 13. The altitude cannot be longer than a leg.

Proof We will prove the first inequality, and leave the second as an exercise. Suppose that $|EF| > |GH|$. Then there is a point K between E and F so that $EK \simeq GH$. Then $\square EGHK$ is a Saccheri quadrilateral with base EG. Now let's look at $\triangle KFH$. In it, $\angle F$ is right because the altitude is perpendicular to the summit; $\angle K$ is right or obtuse, since it is supplementary to a

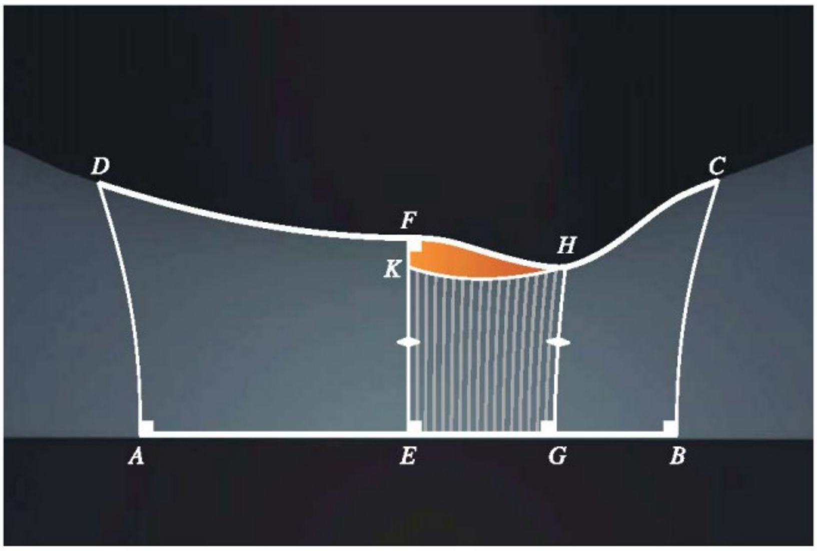

Figure 14. Given a segment GH that is between the leg BC and the altitude EF, $|GH| \geq |EF|$ (a proof by contradiction).

summit angle (remember that the summit angles cannot be obtuse). Then the sum of the angles in $\triangle KFH$ is greater than π, which contradicts the Saccheri-Legendre theorem. Therefore $|GH|$ cannot be less than $|EF|$. □

Exercise 36.2 Complete the proof of the theorem by showing that $|GH| \leq |BC|$.

If the first half of this chapter was a little jarring—it is a little crazy to think about a geometry without rectangles—I hope the second half gave some comfort. On the one hand, yes, things really are different in non-Euclidean geometry; but on the other, there is still order and structure. The next chapter is a more direct approach to understanding the order and structure: we will look at the behavior of parallel lines.

36.3 References

The general theme of this lesson, to start from a rectangle and to use it to establish Playfair's axiom, is taken from Wallace and West's *Roads to Geometry* [WW04].

36.4 Exercises

36.3. Prove that the diagonals of a Saccheri quadrilateral are congruent.

36.4. Prove that the diagonals of a Saccheri quadrilateral intersect one another at a point on its altitude.

36.5. Demonstrate that in neutral geometry it is possible to construct a convex quadrilateral whose four sides are all congruent.

36.6. Prove that if there is a triangle with an angle sum of π, then there must be a rectangle.

36.7. Let $\square ABCD$ be a convex quadrilateral so that $\angle A$ and $\angle B$ are right angles, and so that $\angle C \simeq \angle D$. Prove that $\square ABCD$ is a Saccheri quadrilateral.

36.8. Let $\square ABCD$ be a Saccheri quadrilateral with base AB and altitude EF (so that E is on the base and F is on the altitude). Prove that $|EC| \geq |FB|$.

36.9. Given $\triangle ABC$, let ℓ be the line that passes through the midpoints of AB and AC. Let F_B be the foot of the perpendicular to ℓ that passes through B, and let F_C be the foot of the perpendicular to ℓ that passes through C. Prove that $\square BCF_CF_B$ is a Saccheri quadrilateral with base F_BF_C.

36.10. Show that in non-Euclidean geometry, not every triangle has a circumcenter. The strategy is as follows. The circumcenter is the intersection of the perpendicular bisectors. Let P be a point not on the line ℓ. Let Q be the foot of the perpendicular to ℓ that passes through P. Let ℓ' be a line through Q that is parallel to ℓ but not perpendicular to PQ. Construct a triangle that has ℓ and ℓ' as perpendicular bisectors. Since the perpendicular bisectors don't even intersect, there cannot be a circumcenter.

36.11. Prove that in non-Euclidean geometry, a triangle has an incenter. (We shall see later, though, that some circles cannot be contained in any triangle. This is most easily seen in terms of area.)

37

Non-Euclidean Parallels

From here on out, let's assume that Playfair's axiom is false. That means that our geometry is not Euclidean. It means our triangle angle sums are strictly less than π. It means that Saccheri quadrilaterals are not rectangles, because rectangles do not exist, and so the summit angles are acute (not right). And other absurdities.

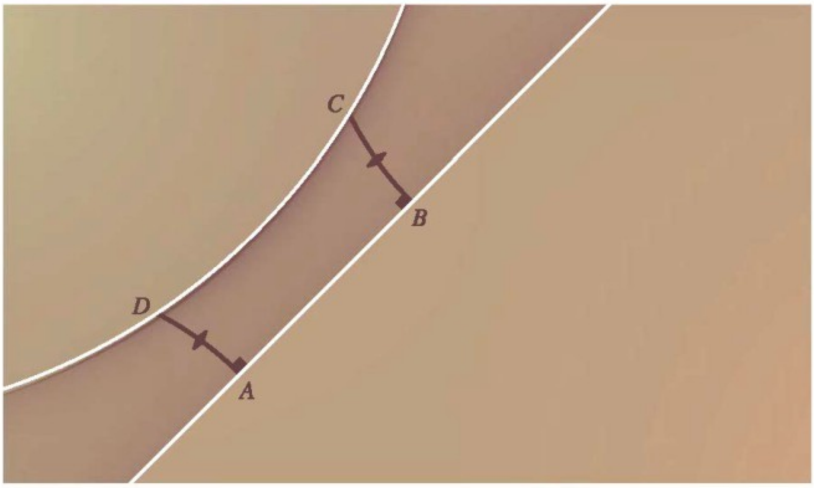

Figure 1. The base and summit of a Saccheri quadrilateral are on parallel lines.

It may have been implied, but in the last chapter we never proved that the base and summit of a Saccheri quadrilateral are parallel.

Exercise 37.1 Let $\square ABCD$ be a Saccheri quadrilateral with base AB and summit CD. Prove that $\overline{AB}$ and $\overline{CD}$ are parallel.

In this section, we will explore parallels more systematically. By the end of it, we should have a better sense of what to look for in a non-Euclidean geometry. To start, let's see that non-Euclidean behavior is pervasive, and not just an anomaly that occurs at a few isolated points.

Theorem 37.1 *Let ℓ be a line and let P be a point that is not on ℓ. Then there are infinitely many lines through P that are parallel to ℓ.*

Proof There are two pieces to this proof. First that there are always at least two parallels. Then that there are infinitely many.

Part 1, that there are (at least) two parallels. Drop the perpendicular from P to ℓ, and mark its intersection with ℓ as Q. Let ℓ' be the line through P that is perpendicular to PQ. According to the alternate interior angle theorem, ℓ' is parallel to ℓ. Now suppose that it is the only parallel. To get a contradiction, we are going to build a Saccheri quadrilateral and see that it would have to be a rectangle. Pick a point on ℓ other than Q and label it R. On the line through R that is perpendicular to ℓ, mark the point S so that $RS \simeq PQ$ (choose S on the same side of ℓ as P). Then $\square PQRS$ is a Saccheri quadrilateral with base QR and summit PS. According to exercise 37.1, $\overline{PS}$ and $\overline{QR} = \ell$ are parallel. But there is only one line through P that is parallel to ℓ, namely ℓ'. Therefore $\overline{PS} = \ell'$. In $\square PQRS$, the summit angle at P is a right angle; and the other summit angle must be congruent to it. Therefore all four angles of $\square PQRS$ are right angles and it is a rectangle. There are no rectangles in non-Euclidean geometry, so there must be more than one parallel to ℓ that passes through P.

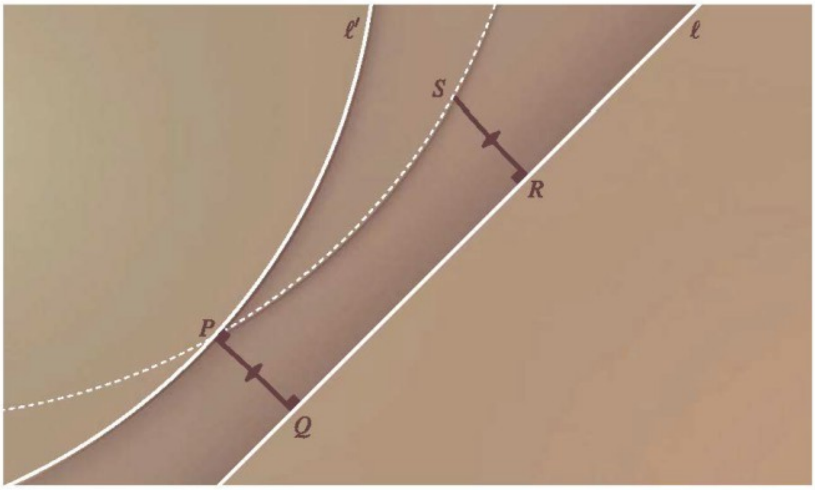

Figure 2. If there are no rectangles, then there must be at least two lines through P that are parallel to $\overline{QR}$.

Part 2, that there are infinitely many parallels. Let ℓ_1 and ℓ_2 be two lines through P that are parallel to ℓ. We can box-in P by surrounding it with more labeled points:

A, A' : on ℓ_1 so that $A * P * A'$,
B : on ℓ_2 and on the same side of PQ as A,
B' : on ℓ_2 and on the same side of PQ as A' (so $B * P * B'$).

Let C be a point on the segment AB. We will argue that $\overline{PC}$ is also parallel to ℓ. Suppose $\overline{PC}$ intersects ℓ at a point D. Then one of $\overrightarrow{PA}$, $\overrightarrow{PA'}$, $\overrightarrow{PB}$, or $\overrightarrow{PB'}$ would have to lie in the interior of

$\angle QPD$. According to the crossbar theorem, the ray would have to intersect QD. This cannot happen since ℓ_1 and ℓ_2 (which contain all four rays) are parallel to ℓ.

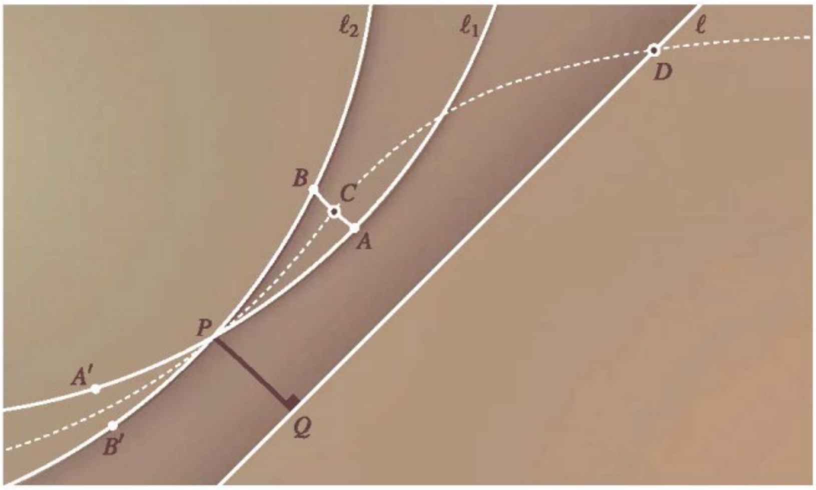

Figure 3. Given two parallels through P, we can find infinitely more between them. □

In Euclidean geometry, parallel lines are everywhere equidistant, so we can measure the distance between them with a single number. Non-Euclidean geometry is not so simple. Given parallel lines ℓ_1 and ℓ_2 in non-Euclidean geometry, the distance from a point P on ℓ_2 to the line ℓ_1 is measured as usual: drop a perpendicular from P to ℓ_1 and mark its foot (the intersection with ℓ_1) as F_P. Then the distance from P to ℓ_1 is $|PF_P|$.

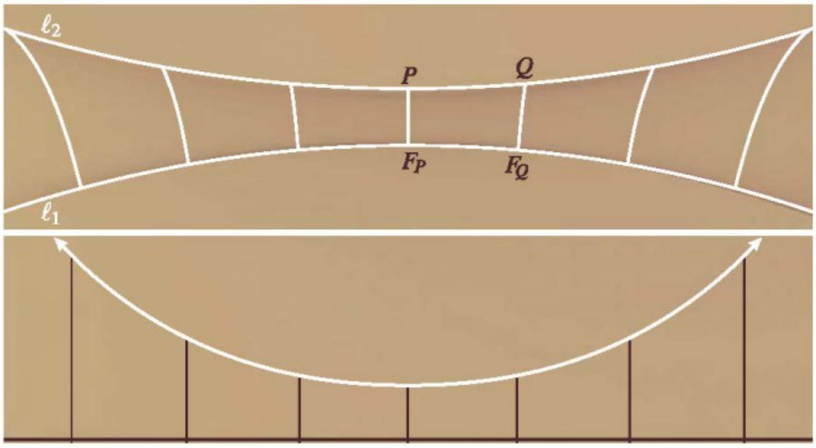

Figure 4. We can view the distance between parallel lines ℓ_1 and ℓ_2 as a function of the points on ℓ_2.

We can define a function $f : \ell_2 \dashrightarrow \mathbb{R}$ by setting $f(P)$ to be the distance from P to ℓ_1. The rest of this chapter investigates it. Before we go any further, we need the following lemma (note its similarity to the theorem in the last chapter that compared the length of the summit to the length of the base).

Lemma 37.2 *Let ℓ_1 and ℓ_2 be parallel lines, let P and Q be points on ℓ_2, and let F_P and F_Q be the respective feet of the perpendiculars on ℓ_1. Then $|F_P F_Q| < |PQ|$.*

Exercise 37.2 Prove the lemma.

Theorem 37.3 *The function f measuring the distance from points of ℓ_2 to the line ℓ_1 is continuous.*

Proof It is always possible to drop a perpendicular from a point P on ℓ_2 to the line ℓ_1, and it is always possible to measure the distance from P to its foot F_P, so the function f is always defined. For f to be continuous at the point P, we need a bit more: as a point Q on ℓ_2 approaches P, the value of $f(Q)$ must approach $f(P)$. To be more precise,

> For every $\epsilon > 0$, there must be a $\delta > 0$ so that if $|PQ| < \delta$ then $|f(P) - f(Q)| < \epsilon$.

The verification of this hinges on a few simple geometric observations that follow from the triangle inequality.

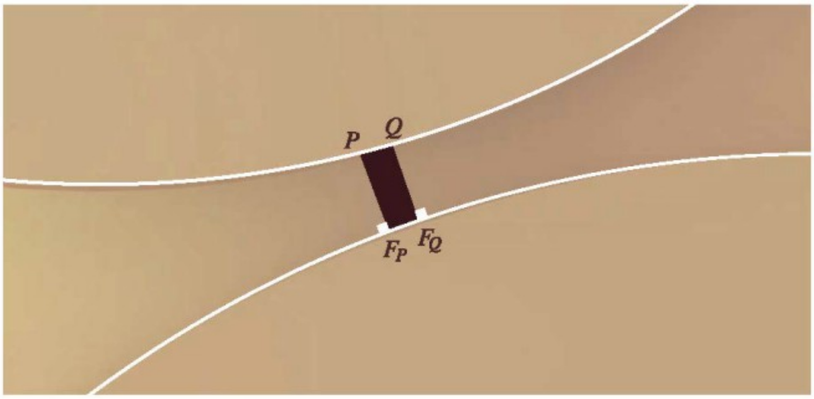

Figure 5. To show that f is continuous, consider two points P and Q that are close to one another.

- $|PF_P| \le |PQ| + |QF_Q| + |F_P F_Q|$.
- $|QF_Q| \le |PQ| + |PF_P| + |F_P F_Q| \implies |PF_P| \ge |QF_Q| - |PQ| - |F_P F_Q|$.
- Therefore

$$|QF_Q| - |PQ| - |F_P F_Q| \le |PF_P| \le |PQ| + |QF_Q| + |F_P F_Q|.$$

- Subtract $|QF_Q|$:

$$-|PQ| - |F_P F_Q| \le |PF_P| - |QF_Q| \le |PQ| + |F_P F_Q|.$$

- We don't know whether $|PF_P| > |QF_Q|$ or if it is the other way around. Either way, we can say that

$$\big||PF_P| - |QF_Q|\big| \le |PQ| + |F_PF_Q|.$$

With that information, verifying continuity is straightforward. Fix $\epsilon > 0$ and put $\delta = \epsilon/2$. If $|PQ| < \delta = \epsilon/2$, then $|F_PF_Q| < \epsilon/2$ as well (according to lemma 37.2), and so

$$|f(P) - f(Q)| = \big||PF_P| - |QF_Q|\big| \le |PQ| + |F_PF_Q| < \epsilon/2 + \epsilon/2 = \epsilon.$$

Therefore f is continuous at P. Since P was an arbitrary point on ℓ_2, f is continuous on all of ℓ_2. □

Theorem 37.4 *For a real number r, $|\{f^{-1}(r)\}| \le 2$. That is, there are at most two points on ℓ_2 that are at a distance r from ℓ_1.*

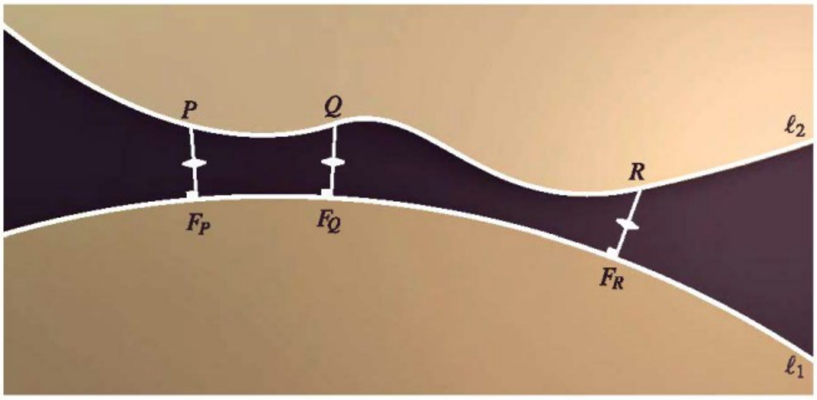

Figure 6. It is not possible for all of P, Q, and R to be the same distance from ℓ_1.

Proof Suppose that there is a real number r so that $|\{f^{-1}(r)\}| > 2$. Then there are (at least) three distinct points P, Q, and R on ℓ_2 with $P * Q * R$ so that $f(P) = f(Q) = f(R) = r$. If we label the feet of their respective perpendiculars as F_P, F_Q, and F_R, then

$$|PF_P| = |QF_Q| = |RF_R| = r.$$

Thus $\square F_PF_QQP$ and $\square F_QF_RRQ$ are Saccheri quadrilaterals. They cannot be rectangles, though, so their summit angles $\angle PQF_Q$ and $\angle RQF_Q$ must be acute. But the angles are supplementary so they cannot both be acute. □

Theorem 37.5 *The function f has no local maxima and at most one local minimum.*

Proof Suppose that f has a local maximum at a point B. Then, since f is continuous, for a sufficiently small value positive value ϵ, there are points A and C on either side of B so that

$$f(A) = f(C) = f(B) - \epsilon.$$

Let F_A, F_B, and F_C be the feet of the perpendiculars to ℓ_1 from A, B, and C respectively. Then

$$|AF_A| = f(A) = f(C) = |CF_C|$$

so $\square F_AF_CCA$ is a Saccheri quadrilateral with base F_AF_C. The segment BF_B connects the summit to the base and is perpendicular to the base. We saw at the end of the last chapter that such segments cannot be longer than the legs. But the legs of this Saccheri quadrilateral are AF_A and CF_C, and they are shorter (by ϵ) than BF_B. This is a contradiction, and so f cannot have a local maximum.

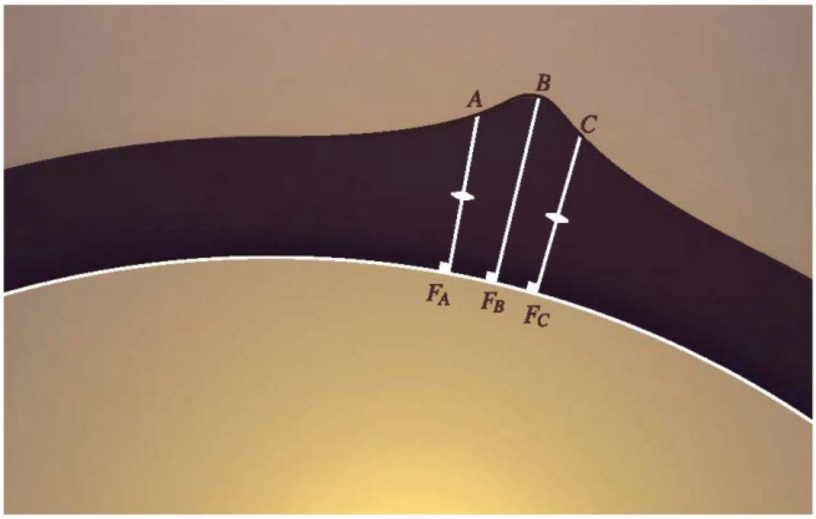

Figure 7. It is not possible for f to have a local maximum (as is suggested here at the point B).

The second part of the theorem follows immediately: if f had more than one minimum, then, because it is continuous, it would have a local maximum in between them. □

Theorem 37.6 *Let P and Q be points on ℓ_2 and suppose that $f(Q) > f(P)$. Then f approaches infinity along $\overrightarrow{PQ}$.*

It should be clear that the value of f continues to increase past Q. If at some point it began to decrease, then we would have found a local maximum, and we have just seen that f has none. But could it be that f continues to grow, but is bounded above? Is there an upper bound that f approaches in the limit but never surpasses? This is a more delicate question. The strategy of the proof is to build a wall of congruent Saccheri quadrilaterals that appears to contain $\overrightarrow{PQ}$, and then see why that cannot happen.

Proof Suppose that f does have an upper bound so that it approaches but never exceeds a number k. Starting from the point F_Q, the foot of the perpendicular from Q, mark off congruent segments along ℓ_1 on the same side of PF_P as $\overrightarrow{PQ}$. That is, label points F_i so that

$$F_Q = F_0 * F_1 * F_2 * F_3 * \cdots$$

and so that the segments F_iF_{i+1} are congruent. Above each point F_i (on the same side of ℓ_1 as ℓ_2), erect a perpendicular segment F_iP_i of length k. Then each $\square F_iF_{i+1}P_{i+1}P_i$ is a Saccheri quadrilateral, and by SASAS they are all congruent.

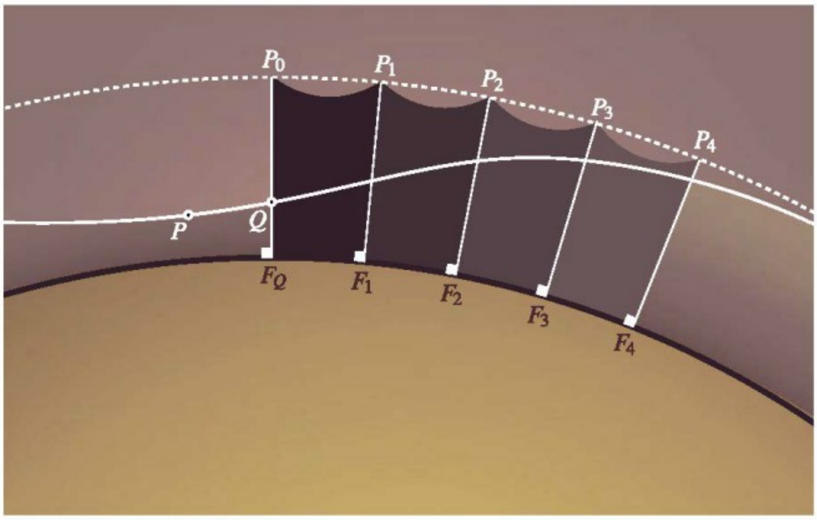

Figure 8. It is not possible for f to level off at some asymptotic value, as suggested here.

Their altitudes are shorter than their legs, by an amount that we can call ϵ (since the quadrilaterals are congruent, the discrepancy will be the same for all of them). Now let's get back to $\overrightarrow{PQ}$. For a while, it may run below the summits of the quadrilaterals we have assembled. But f has a limiting value of k along it, so eventually there is a point beyond which f is greater than $k - \epsilon$. Look beyond that point, at the interaction of $\overrightarrow{PQ}$ with one of the summits P_nP_{n+1}. Points P_n and P_{n+1} are on the opposite side of ℓ_2 from ℓ_1. But the altitude between them is on the same side of ℓ_2 as ℓ_1. This would imply that ℓ_2 intersects P_nP_{n+1} twice. Two distinct lines can intersect only once, so this is a contradiction. □

Looking in the other direction, if $f(Q) > f(P)$, then $f(P) < f(Q)$, and it is natural to wonder what happens as we progress along $\overrightarrow{QP}$. Does the distance to ℓ_2 continue to decrease, or does it at some point begin to increase again?

Definition 37.7 If f achieves a minimum, then ℓ_1 and ℓ_2 are called *divergent* parallels. If instead f approaches zero, then ℓ_1 and ℓ_2 are called *asymptotic* parallels.

If ℓ_1 and ℓ_2 are divergent parallels, then once $\overrightarrow{QP}$ has crossed over the minimum value, the value of f will begin to go up. Once that happens, by the previous result, f will go to infinity. Both types of parallels exist in non-Euclidean geometry. The base and summit of a Saccheri quadrilateral are divergent parallels. Asymptotic parallels are more elusive, but one of the exercises outlines a proof of their existence. Beyond that, there is one more obvious question: are there any parallels that are neither divergent nor asymptotic? Suppose ℓ_1 and ℓ_2 are not divergent. Then f does not achieve its minimum. It is easy then to pick points P and Q

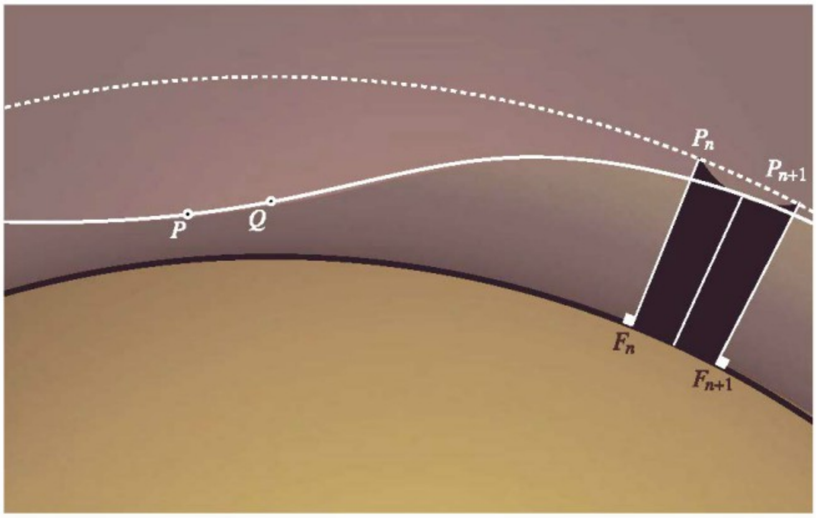

Figure 9. If $\overrightarrow{PQ}$ approached an asymptote, it would eventually intersect the summit of a constructed Saccheri quadrilateral more than once.

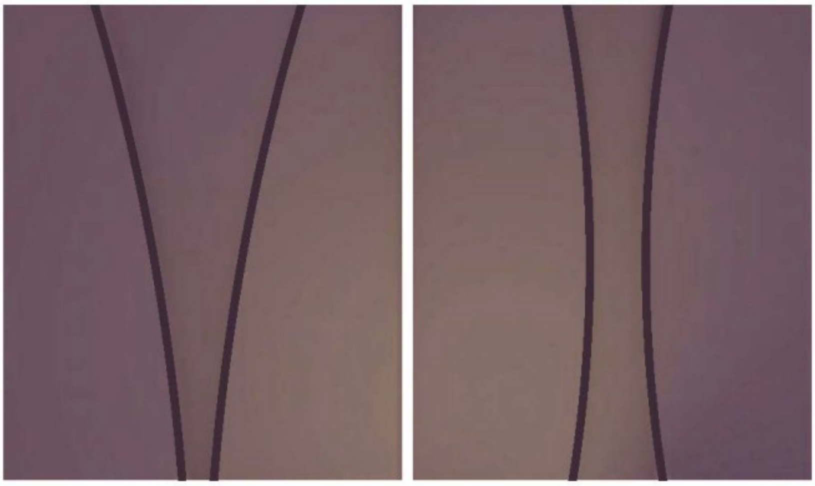

Figure 10. (l) asymptotic parallels; (r) divergent parallels.

so that $f(P) < f(Q)$, so f must continue to decrease past P as we move out along $\overrightarrow{QP}$. By definition, the lines are asymptotic if the value of f decreases to zero. Is it possible that the value of f is always decreasing, but never drops below some positive number k? No. The argument against a nonzero lower bound is essentially the same as the argument against an upper bound in the proof above.

Theorem 37.8 *If ℓ_1 and ℓ_2 are parallel, then they are either divergent or asymptotic.*

Exercise 37.3 Prove theorem 37.8.

The results of this chapter should give you some sense of the look of non-Euclidean geometry. But can such a geometry exist? If we want to answer YES, we need to find a model that meets all the requirements of neutral geometry, and has the non-Euclidean characteristics. In the next chapters, we will look at such models.

37.1 Exercises

37.4. Let r_1 and r_2 be two non-opposite rays with endpoint A. Label point B and C on r_1 and B' and C' on r_2 so that $A * B * C$ and $A * B' * C'$. Prove that the angle sum of $\triangle ACC'$ is less than the angle sum of $\triangle ABB'$.

37.5. Suppose that ℓ_1 and ℓ_2 are divergent parallels. Let P be the point on ℓ_2 that is the minimum distance from ℓ_1, and let Q be the foot of the perpendicular from P. Prove that QP intersects ℓ_2 at a right angle.

37.6. Let ℓ be a line and let P be a point that is not on ℓ. Prove that there is a line through P which is asymptotic to ℓ. Hint: let r_1 and r_2 be rays from P, one that intersects ℓ and one that is along a divergent parallel to ℓ. Let A be a point on r_1 and B be a point on r_2. A point Q on AB falls into one of two sets: either PQ is parallel to ℓ or it isn't. By Dedekind's axiom, there is a point Q_0 that separates those two sets. Show that PQ_0 is an asymptotic parallel.

37.7. Suppose that lines ℓ_1 and ℓ_2 intersect at a point O. Suppose that P and Q are on ℓ_2 so that $O * P * Q$, and that F_P and F_Q are the feet of the perpendiculars, from P and Q respectively, to ℓ_1. Prove that $|PF_P| < |QF_Q|$.

37.8. Let r_1 and r_2 be two rays with a common endpoint O. Prove that for a positive real number x, there is a point P on r_1 so that $d(P, r_2) > x$.

Curves and Vector-Valued Functions of One Variable

2.1 Conic Sections

We begin this chapter by looking at the *conic sections*, which were regarded by the Greeks as the simplest curves after the straight line and circle.

A major source of information about classical Greek mathematics is Pappus of Alexandria (*ca.* 300 AD), a formidable geometer of the late third century AD.[1] In his *Mathematical Collection*[2] he surveyed the work of his predecessors; many of these works have been lost. He classified mathematical problems according to the kinds of loci (curves) required for their solution:

- *planar* problems can be solved using circles and straight lines, or **planar loci**. These are often called **compass and straightedge constructions**;
- *solid* problems involve the intersection of a plane with a cone (**solid loci**, or **conic sections**);

---

[1] The work of Pappus is sometimes taken to mark the end of the classical Greek tradition in mathematics.

[2] Parts of this survive in a twelfth-century copy.

A

Conic Sections: Apollonius' approach

Here we give some more details of the argument for certain assertions in § 2.1. Our exposition loosely follows [27, pp. 355-9].
Recall the setup (Figure A.1):

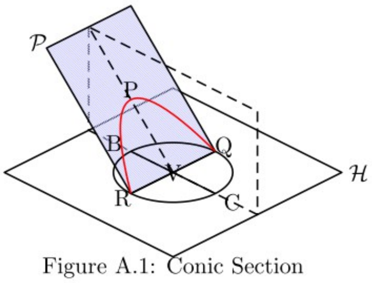

Figure A.1: Conic Section

We wish to investigate the conic section $\gamma = \mathcal{P} \cap \mathcal{K}$, where the plane $\mathcal{P}$ does not contain the origin, and intersects any horizontal plane in a line parallel to the x-axis. The yz-plane (which is perpendicular to any such line) intersects γ in a point P, and possibly in a second point P'—the vertices of γ. Given a point Q on γ distinct from the vertices (*i.e.*, not in the yz-plane), the horizontal plane $\mathcal{H}$ through Q intersects $\mathcal{K}$ in a circle containing Q. The intersection of $\mathcal{H}$ with the yz-plane is a line through the center of this circle, and so contains a diameter BC of the circle. We draw the chord of the circle through Q perpendicular to this diameter, denoting by R the other end of the chord, and by V its intersection with BC. The

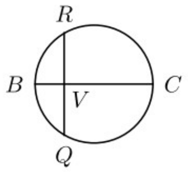

Figure A.2: Lines in $\mathcal{H}$

line segments QV and PV are, respectively, the **ordinate** and **abcissa**. We know that V bisects QR, and also, by Prop. 13, Book VI of the *Elements*, that

$$|QV|^2 = |QV| \cdot |VR| = |BV| \cdot |VC| . \tag{A.1}$$

Parabolas: Suppose first that PV is parallel to AC, so that P is the only vertex of γ. Consider the triangle $\triangle ABC$ in the yz-plane, noting that P lies on AB and V lies on BC (Figure A.3). Since AC is parallel to PV,

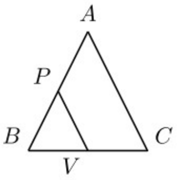

Figure A.3: Equation (A.2)

the triangles $\triangle ABC$ and $\triangle PBV$ are similar and (since $AD = AC$) isosceles. In particular,

$$\frac{|BV|}{|BP|} = \frac{|BC|}{|BA|}$$

and (again since AC and PV are parallel)

$$\frac{|VC|}{|BC|} = \frac{|PA|}{|BA|}$$

or equivalently

$$\frac{|VC|}{|PA|} = \frac{|BC|}{|BA|}.$$

Multiplication of these two equations yields

$$\frac{|BV|\,|VC|}{|BP|\,|PA|} = \left(\frac{|BC|}{|BA|}\right)^2.$$

Since $|BP| = |PV|$, we conclude that

$$|BV|\,|VC| = \left[\left(\frac{|BC|}{|BA|}\right)^2 |PA|\right] |PV|\,. \tag{A.2}$$

Note that replacing Q with another point Q' on γ replaces $\mathcal{H}$ with a parallel plane $\mathcal{H}'$, and gives a picture similar to Figure A.3 (Figure A.4). In particular, the quantity in brackets in Equation (A.2) depends only on γ: it is called the **parameter of ordinates** for γ—we will denote it by p. Apollonius represents it by a line segment PL perpendicular to the abcissa PV (indicated in Figure A.4), called the **orthia**,[1] or in Latin, the **latus rectum** .[2]

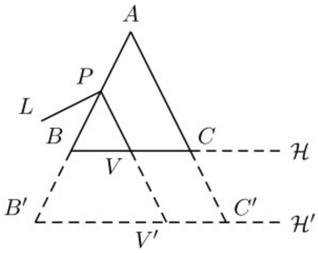

Figure A.4: Independence of Q

---

[1] Fried and Unguru argue that for Apollonius, the orthia is a specific line segment, not the representation of an independent quantity.

[2] The term "latus rectum" is also used to refer to the **parameter of ordinates** (the number p in Equation (A.3)).

If we introduce rectangular coordinates in $\mathcal{P}$ with the origin at P and axes parallel to QV and PV, setting

$$y = |QV|$$
$$x = |PV|$$

then Equation (A.1) says that

$$y^2 = |BV|\,|VC|\,,$$

and substituting this information into Equation (A.2) leads to the equation

$$y^2 = px \tag{A.3}$$

where p is the parameter of ordinates defined above.

For the other two cases, when PV is not parallel to AC, then the line PV (extended) meets the line AB (extended) at the second vertex P'. If ϕ denotes the (acute) angle between $\mathcal{P}$ and a horizontal plane $\mathcal{H}$, then V lies between P and P' if $0 \leq \phi < \frac{\pi}{2} - \alpha$ and P lies between V and P' if $\frac{\pi}{2} - \alpha < \phi \leq \frac{\pi}{2}$.

Ellipses: In the first case (see Figure A.5), let J be the point at which the line through A parallel to PV (and hence to PP') meets BC (extended). As in the case of the parabola (but with C replaced by J), the triangles $\triangle ABJ$ and $\triangle PBV$ are similar (but no longer isosceles), so

$$\frac{|BV|}{|PV|} = \frac{|BJ|}{|AJ|}.$$

Also, since the lines AP' and VJ are transversals to the two parallels AJ and PP' meeting at C, the triangles $\triangle AJC$ and $\triangle P'VC$ are similar, so

$$\frac{|VC|}{|VP'|} = \frac{|JC|}{|AJ|}.$$

Multiplying these equalities and invoking Equation (2.2), we have

$$\frac{|QV|^2}{|PV|\,|VP'|} = \frac{|BV|\,|VC|}{|PV|\,|VP'|} = \frac{|BJ|\,|JC|}{|AJ|^2}$$

or, as the analogue of Equation (A.2),

$$|QV|^2 = \left[\left(\frac{|BJ|\,|JC|}{|AJ|^2}\right)|VP'|\right]|PV|\,. \tag{A.4}$$

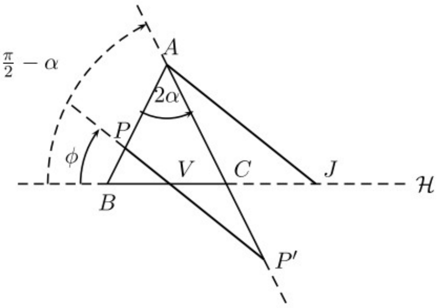

Figure A.5: $0 \leq \phi \leq \frac{\pi}{2} - \alpha$

Again as in the case of the parabola, the fraction in parentheses in Equation (A.4) depends only on the curve γ. We again form the "orthia" of γ, a line segment PL perpendicular to PV with length[3]

$$p = |PL| = \left(\frac{|BJ|\,|JC|}{|AJ|^2}\right)|PP'|\,. \tag{A.5}$$

Now let S be the intersection of LP' with the line through V parallel to PL (Figure A.6). Note that the triangles $\triangle LP'P$ and $\triangle SP'V$ are similar, so

$$\frac{|PL|}{|PP'|} = \frac{|VS|}{|VP'|}$$

---

[3] This defintion of the orthia is on the face of it quite different from the definition in the case of the parabola. I have not been able to find a reasonable explanation of why the two definitions yield analogous line segments. It can be shown (M. N. Fried, private correspondence) that if one considers the orthia of hyperbolic or elliptic sections whose diameter has inclination approaching that of a generator (*i.e.*, approaching a parabolic section), then these orthia tend toward the parabolic orthia of the limit. This, however, is clearly an anachronistic point of view, and Fried has pointed out that Apollonius never discusses varying the section. In fact, in his view, Apollonius did not intend the properties of the conic sections with respect to application of areas—known as the **symptomata**—to unify the different types; he viewed them as separate objects, and only noted these somewhat analogous properties as incidental observations. Fried's point of view (but not a specific commentary on this issue) is given at length in [16, pp. 74-90].

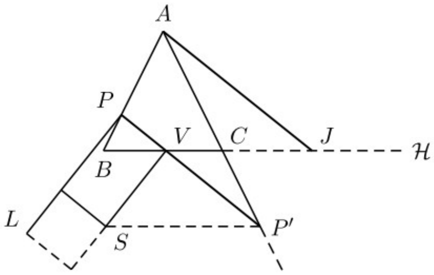

Figure A.6: Definition of S

and substituting this (via Equation (A.5)) into Equation (A.4), we have

$$\begin{aligned}|QV|^2 &= \left[\left(\frac{|PL|}{|PP'|}\right)|VP'|\right]|PV| \\ &= \left[\left(\frac{|VS|}{|VP'|}\right)|VP'|\right]|PV|\end{aligned}$$

or

$$|QV|^2 = |VS| \cdot |PV|\,. \tag{A.6}$$

This is like Equation (A.3), but $|PL|$ is replaced by the shorter length $|VS|$. To obtain the rectangular equation of the ellipse, we set

$$d = |PP'|$$

(the **diameter**): by similarity of $\triangle LP'P$ and $\triangle SP'V$,

$$\frac{|VS|}{|PL|} = \frac{|VP'|}{|PP'|} = 1 - \frac{|PV|}{|PP'|}$$

so (again setting $x = |PV|$ and $y = |QV|$) we have as the equation of the ellipse

$$y^2 = |VS|\,x = p\left(1 - \frac{x}{d}\right)x = px - \frac{p}{d}x^2. \tag{A.7}$$

Hyperbolas: In the final case, when $\frac{\pi}{2} - \alpha < \phi \leq \frac{\pi}{2}$, P lies between V and P' (Figure A.7). Formally, our constructions in this case are the same as in the case of the ellipse: as before, the two similarities $\triangle ABJ \sim \triangle PBV$ and $\triangle AJC \sim \triangle P'VC$ lead to Equation (A.4); we form

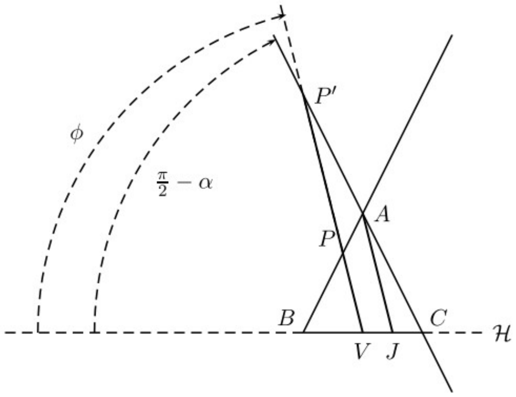

Figure A.7: $\frac{\pi}{2} - \alpha < \phi \leq \frac{\pi}{2}$

the orthia PL perpendicular to PV satisfying Equation (A.5) and let S be the intersection of $P'L$ (extended) with the line through V parallel to PL (Figure A.8). The same arguments as in the ellipse case yield Equation (A.6), but this time the segment VS *exceeds* PL.

A verbatim repetition of the calculation leading to Equation (A.7) leads to its hyperbolic analogue,

$$y^2 = px + \frac{p}{d}x^2. \tag{A.8}$$

Surface Area: the Counterexample of Schwarz and Peano

We present here an example, due to H. A. Schwarz [48] and G. Peano [44][1] which shows that the analogue for surfaces of the usual definition of the length of a curve cannot work.

Recall that if a curve $\mathcal{C}$ was given as the path of a moving point $\overrightarrow{p}(t)$, $a \leq t \leq b$, we partitioned $[a, b]$ via $\mathcal{P} = \{a = t_0 < t_1 < \cdots < t_n\}$ and approximated $\mathcal{C}$ by a piecewise-linear path consisting of the line segments $[\overrightarrow{p}(t_{i-1}), \overrightarrow{p}(t_i)]$, $i = 1, \ldots, n$. Since a straight line is the shortest distance between two points, the distance travelled by $\overrightarrow{p}(t)$ between $t = t_{i-1}$ and $t = t_i$ is at least the length of this segment, which is $\|\overrightarrow{p}(t_i - \overrightarrow{p}(t_{i-1}))\|$. Thus, the total length of the piecewise-linear approximation is a lower bound for the length of the actual path: we say $\mathcal{C}$ is *rectifiable* if the supremum of the lengths of all the piecewise-linear paths arising from different partitions of $[a, b]$ is finite, and in that case define the (arc)length of the curve to be this supremum. We saw in § 2.5 that every regular arc (that is, a curve given by a one-to-one differentiable parametrization with non-vanishing velocity) the length can be calculated from any regular parametrization as

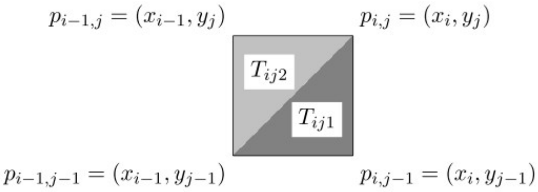
---

[1] Schwarz tells the story of this example in a note [49, pp. 369-370]. Schwarz initially wrote down his example in a letter to one Angelo Gnocchi in December 1880, with a further clarification in January 1881. In May, 1882 Gnocchi wrote to Schwarz that in a conversation with Peano, the latter had explained that Serret's definition of surface area (to which Schwarz's example is a counterexample) could not be correct, giving detailed reasons why it was wrong; Gnocchi had then told Peano of Schwarz's letters. Gnocchi reported the example in the Notices of the Turin Academy, at which point it came to the attention of Charles Hermite (1822-1901), who publihsed the correspondence in his *Cours d'analyse*. Meanwhile, Peano published his example. After seeing Peano's article, Schwarz contacted him and learned that Peano had independently come up with the same example in 1882.

$$\mathfrak{s}\left(\mathcal{C}\right) = \int_a^b \left\| \dot{\overrightarrow{p}}(t) \right\| \, dt.$$

The analogue of this procedure could be formulated for surface area as follows. [2] Let us suppose for simplicity that a surface $\mathfrak{S}$ in $\mathbb{R}^3$ is given by the parametrization $\overrightarrow{p}(s, t)$, with domain a rectangle $[a, b] \times [c, d]$. If we partition $[a, b] \times [c, d]$ as we did in § 5.1, we would like to approximate $\mathfrak{S}$ by rectangles in space whose vertices are the images of "vertices" $p_{i,j} = \overrightarrow{p}(x_i, y_j)$ of the subrectangles R_{ij}. This presents a difficulty, since *four* points in $\mathbb{R}^3$ need not be coplanar. However, we can easily finesse this problem if we note that *three* points in $\mathbb{R}^3$ are *always* contained in some plane. Using diagonals (see Figure H.1)[3] we can divide each subrectangle R_{ij} into two triangles, say

$$\begin{aligned} T_{ij1} &= \triangle p_{i-1,j-1} p_{i,j-1} p_{i,j} \\ T_{ij2} &= \triangle p_{i-1,j-1} p_{i-1,j} p_{i,j}. \end{aligned}$$



$p_{i-1,j} = (x_{i-1}, y_j)$
$p_{i,j} = (x_i, y_j)$
T_{ij2}
T_{ij1}
$p_{i-1,j-1} = (x_{i-1}, y_{j-1})$
$p_{i,j-1} = (x_i, y_{j-1})$

Figure H.1: Dividing R_{ij} into triangles

This tiling $\{T_{ijk} \,|\, i = 1, \ldots, m, \quad j = 1, \ldots, n, \quad k = 1, 2\}$ of the rectangle $[a, b] \times [c, d]$ is called a **triangulation**. Now, it would be natural to try to look at the total of the areas of the triangles whose vertices are the points $\overrightarrow{{p^*}_{i,j}} = \overrightarrow{p}(p_{i,j})$ on the surface

---

[2] This approach was in fact followed by J. M. Serret

[3] There are two ways to do divide each rectangle, but as we shall see, this will not prove to be an issue.

$$\begin{aligned} T^*_{ij1} &= \triangle \overrightarrow{{p^*}_{i-1,j-1}}\,\overrightarrow{{p^*}_{i,j-1}}\,\overrightarrow{{p^*}_{i,j}} \\ T^*_{ij2} &= \triangle \overrightarrow{{p^*}_{i-1,j-1}}\,\overrightarrow{{p^*}_{i-1,j}}\,\overrightarrow{{p^*}_{i,j}}. \end{aligned}$$

and define the area of $\mathfrak{S}$ to be the supremum of these over all triangulations of $[a, b] \times [c, d]$.

Unfortunately, this approach doesn't work; an example found (simultaneously) in 1892 by H. A. Schwartz and G. Peano shows

Proposition H.0.1. *There exist triangulations for the standard parametrization of the cylinder such that the total area of the triangles is arbitrarily high.*

Proof. Consider the finite cylinder surface

$$\begin{aligned} x^2 + y^2 &= 1 \\ 0 \leq z &\leq 1. \end{aligned}$$

We partition the interval $[0, 1]$ of z-values into m equal parts using the $m + 1$ horizontal circles $z = \frac{k}{m}$, $k = 0, \ldots, m$. Then we divide each circle into n equal arcs, but in such a way that the endpoints of arcs on any particular circle are directly above or below the midpoints of the arcs on the neighboring circles. One way to do this is to define the angles

$$\theta_{jk} = \begin{cases} \frac{2\pi j}{n} & \text{for } k \quad \textit{even}, \\ \frac{2\pi j}{n} - \frac{\pi}{n} & \text{for } k \ \textit{odd} \end{cases}$$

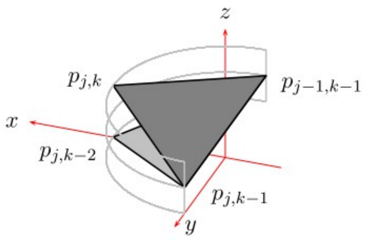
and then the points

$$p_{jk} = (\cos \theta_{jk}, \sin \theta_{jk}, \frac{k}{m}).$$

That is, the points $\{p_{jk}\}$ for k fixed and $j = 1, \ldots, n$ divide the k^{th} circle into n equal arcs. Now consider the triangles whose vertices are the endpoints of an arc and the point on a neighboring circle directly above or below the midpoint of that arc (Figure H.2).

The resulting triangulation of the cylinder is illustrated in Figure H.3.

To calculate the area of a typical triangle, we note first (Figure H.4) that



z
$p_{j,k}$
$p_{j-1,k-1}$
x
$p_{j,k-2}$
$p_{j,k-1}$
y

Figure H.2: Typical Triangles

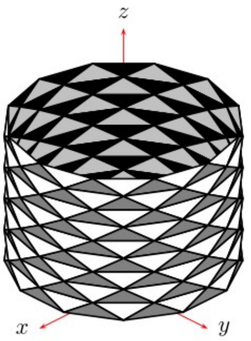


Figure H.3: Triangulation of the Cylinder

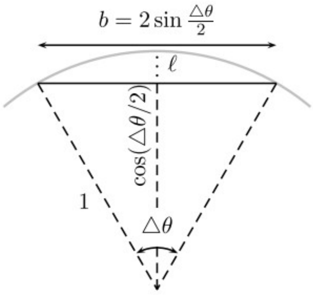

$b = 2\sin\frac{\triangle\theta}{2}$
ℓ
$\cos(\triangle\theta/2)$
1
$\triangle\theta$

Figure H.4: The Base of a Typical Triangle

its base is a chord of the unit circle subtending an arc of $\triangle\theta = \frac{2\pi}{n}$ radians; it follows from general principles that the length of the chord is

$$b_n = 2\sin\frac{\triangle\theta}{2} = 2\sin\frac{\pi}{n}.$$

We also note for future reference that the part of the perpendicular bisector of the chord from the chord to the circle has length

$$\ell = 1 - \cos\frac{\triangle\theta}{2} = 1 - \cos\frac{\pi}{n}.$$

To calculate the height of a typical triangle, we note that the vertical distance between the plane containing the base of the triangle and the other vertex is $\frac{1}{m}$, while the distance (in the plane containing the base) from the base to the point below the vertex (the dotted line in Figure H.5) is $\ell = 1 - \cos\frac{\pi}{n}$; it follows that the height of the triangle (the dashed line in Figure H.5) is itself the hypotenuse of a right triangle with sides ℓ and $\frac{1}{m}$, so

$$h_{m,n} = \sqrt{\left(\frac{1}{m}\right)^2 + \ell^2} = \sqrt{\left(\frac{1}{m}\right)^2 + \left(1 - \cos\frac{\pi}{n}\right)^2}.$$

Thus the area of a single triangle of our triangulation (for a given choice of

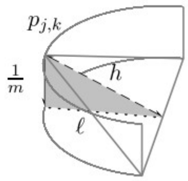

Figure H.5: Calculating the Height of a Typical Triangle

m and n) is

$$\begin{aligned}\triangle A_{m,n} &= \frac{1}{2} b_n h_{m,n} \\ &= \frac{1}{2}\left[2\sin\frac{\pi}{n}\right]\sqrt{\left(\frac{1}{m}\right)^2 + \left(1-\cos\frac{\pi}{n}\right)^2} \\ &= \left[\sin\frac{\pi}{n}\right]\sqrt{\left(\frac{1}{m}\right)^2 + \left(1-\cos\frac{\pi}{n}\right)^2}.\end{aligned}$$

Now let us count the number of triangles. There are $m+1$ horizontal circles, each cut into n arcs, and the chord subtending each arc is the base of exactly two triangles of our triangulation, except for the two "end" circles, for which each chord is the base of *one* triangle. This means there are $2mn$ triangles, giving a total area of

$$\begin{aligned}A_{m,n} &= 2mn\triangle Am,n \\ &= 2mn\left[\sin\frac{\pi}{n}\right]\sqrt{\left(\frac{1}{m}\right)^2 + \left(1-\cos\frac{\pi}{n}\right)^2} \\ &= 2\left[n\sin\frac{\pi}{n}\right]\sqrt{1+m^2\left(1-\cos\frac{\pi}{n}\right)^2}.\end{aligned}$$

Now, the quantity in brackets converges to π as $n \to \infty$ and, for n fixed, the square root goes to ∞ as $m \to \infty$; it follows that we can fix a sequence of pairs of values $\{(m_k, n_k)\}$ (for example, as Schwarz suggests, $m = n^3$) such that the quantity A_{m_k,n_k} diverges to infinity, establishing that the supremum of the total area of piecewise-linear approximations of a cylinder is infinite, and hence gives a bad definition for the area of the cylinder itself. □

To see what is going on here, we might note that at the vertex opposite the chord of each triangle, the plane tangent to the cylinder is vertical, while the plane of the triangle makes an angle with it of size $\theta(m,n)$, where

$$\tan\theta(m,n) = \frac{\ell}{1/m} = \frac{1-\cos\frac{\pi}{n}}{1/m} = m\left(1-\cos\frac{\pi}{n}\right).$$

If for example $m = n^3$, one can check (using, *e.g.*, L'Hôpital's rule) that the tangent goes to infinity with n, so in the limit the triangles approach being *perpendicular* to the cylinder.

It turns out that the approach of Serret (using these triangulations) can be made to work, provided we replace the *supremum* of all such total areas with the *limit*, as $\varepsilon \to 0$, of the *infimum* of all such total areas for triangulations with mesh size less than ε. In effect, this means we are looking at triangulations in which the triangles are as close as possible to being tangent to the cylinder.

An Inequality on $\pi(x)$

It is not known whether or not

$$\pi(x+y) \leq \pi(x) + \pi(y)$$

for all sufficiently large x, y.

data 06.05.2020

Extending work of Rosser and Schoenfeld, various authors have proved related results.

Krawczyk proved the following, $\pi(kx) < k\pi(x)$ for $k \geqslant e, x \geqslant 67$.

For $\epsilon > 0, x \geqslant 17, y \geqslant 17, x+y \geqslant 1 + e^{4(1+1/\epsilon)}$, it has been shown that

$$\pi(x+y) < (1+\epsilon)(\pi(x)+\pi(y)).$$

There is an interesting connection between Conjecture A ($\pi(x+y) \leq \pi(x)+\pi(y)$, $x, y \geqslant 2$) and the generalization of the twin prime conjecture that follows it.

CHAPTER 2

Inside and Outside

2.1 REFLECTING IN A CIRCLE[1]

If, on a square grid, a gridline h is chosen as axis of a straight-line reflection, the reflection of lattice points can be done by "counting squares" (Figure 18). In this way one half-plane is mapped onto the other half-plane.

Now we try, with a comparable procedure, to map the interior of a circle on the exterior, and the other way round. This seems at first sight self-contradictory, since the outside of a circle is much "bigger" than its interior. However, Figure 19 shows a "square structure", in which the "squares" become smaller as one moves inwards. Thus, indeed, can a mapping of A onto A' be achieved, square by square.

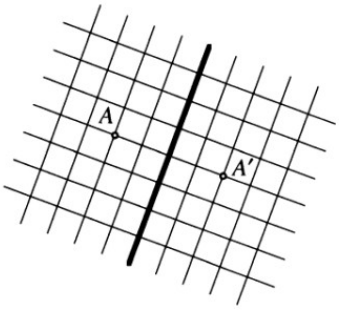

FIGURE 18
Reflection in a gridline on a square grid

---

[1] Here, and subsequently, the author has "reflection" where many standard English-language texts would speak of "inversion."

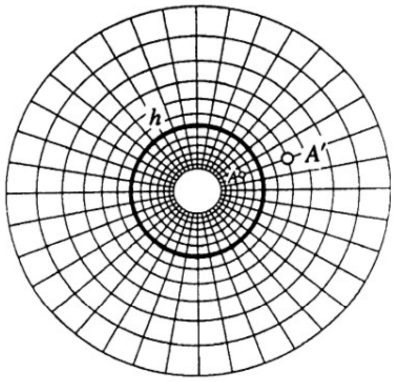

FIGURE 19
Reflection in a circle

This mapping we call a ***circle-reflection*** (or ***inversion***). The highlighted circle h is called the ***reference circle;*** it corresponds to the axis of a straightline-reflection. In constructing such a "circular square" pattern we have choices, so we must clarify how the radii of the concentric circles for the scaling $t = \cdots, -2, -1, 0, 1, 2, \cdots$ are related to each other (Figure 20). For that purpose, we imagine the "square pattern" further subdivided, so that the quadrilaterals are almost squares.

We now study such a "near-square", lying in a circular sector of angle α radians at a distance r from the center of the circle (Figure 21). This near-square has a side of length Δr in the radial direction and a side of length

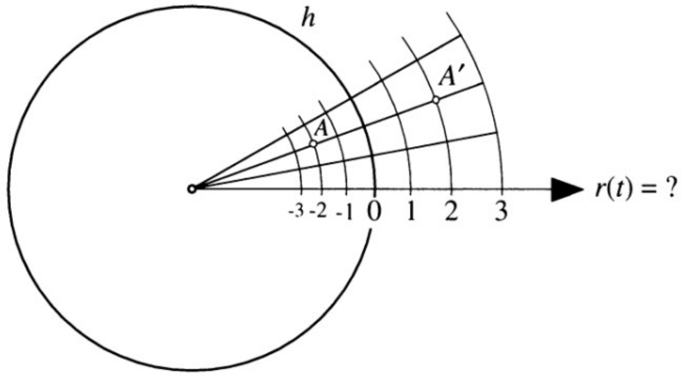

FIGURE 20
$r(t) = ?$

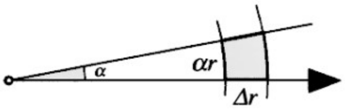

FIGURE 21
Near-squares

αr in the tangential direction. We may reason heuristically as follows. These two lengths should be equal, so that $\Delta r = \alpha r$. In terms of differentials we obtain $dr = \alpha r$, so, through separation of variables,

$$\frac{dr}{r} = \alpha,$$

and thus, through integration, $\ln r = \alpha t + C_1$, so that, finally, $r(t) = Ce^{\alpha t}$. If we denote the radius of the reference-circle h by r_0, we get, from the boundary condition $r(0) = r_0$, the function

$$r(t) = r_0 e^{\alpha t}.$$

The radii depend exponentially on t. As $t \to -\infty$, $r \to 0$; thus the interior of the circle has room for infinitely many "squares". For the further investigation of the mapping of A onto A' polar coordinates are appropriate (Figure 22).

The point A and its image A' have the same polar angle ϕ, and their polar distances belong to equal and opposite t-values: thus

$$r = r_0 e^{\alpha t}, \quad r' = r_0 e^{-\alpha t}.$$

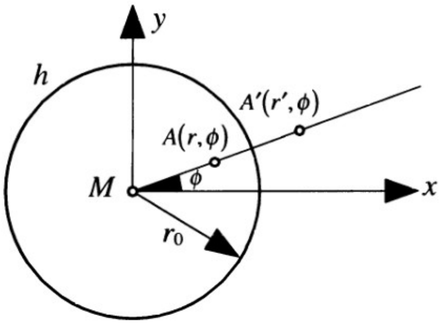

FIGURE 22
Polar coordinates

Thus we obtain

$$rr' = r_0^2.$$

Remark If we choose a unit circle for the reference circle h, so that $r_0 = 1$, then the polar distances r and r' of a point and its image are reciprocals of each other. In this case the mapping can be described in the complex plane by $w = f(z) = \frac{1}{z}$.

2.2 COMPOSITION OF TWO CIRCLE-REFLECTIONS

We now study the case of two circle-reflections (or inversions) whose reference-circles h and H are concentric, with radii r_0 and R_0. Under reflection in h the point A is mapped to the point A'; by reflection in H the point A' is mapped to the point A'' (Figure 23). In the passage from A to A' we have $rr' = r_0^2$; in going from A' to A'' we have $r'r'' = R_0^2$. For the passage from A to A'' we thus have $\frac{r''}{r} = \frac{R_0^2}{r_0^2}$; so the composition of two circle-reflections with concentric reference-circles is a central dilatation with magnification ratio $\frac{R_0^2}{r_0^2}$; the center of dilatation is the common center of the two reference-circles.

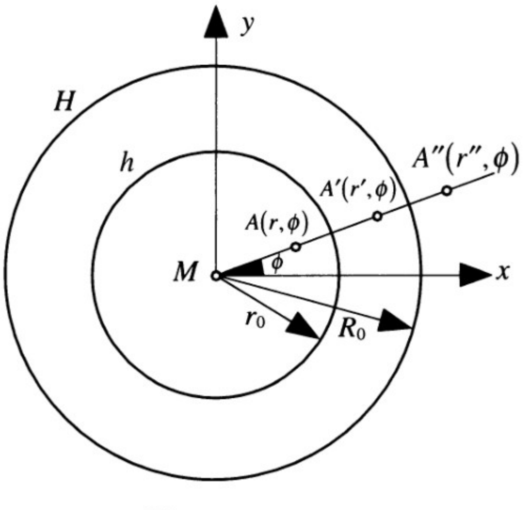

FIGURE 23
The composition of two circle-reflections

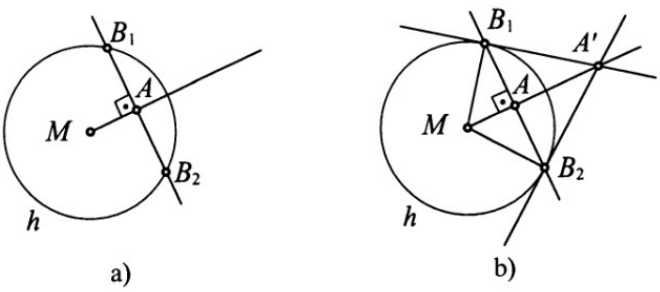

FIGURE 24
Direct construction of the image point

2.3 DIRECT CONSTRUCTION OF THE IMAGE POINT

Figure 24 shows in two steps how, for a given point A in the interior of the reference-circle h, the image point A' may be constructed.

To prove the correctness of this construction we consider the right-angled triangle $MA'B_1$ (Figure 24b) with its right angle at B_1. In this triangle r_0 is the length of MB_1, r is the length of the part MA of the hypotenuse, and r' is the length of the hypotenuse. By the similarity of the triangles MAB_1 and MB_1A' we have $rr' = r_0^2$.

Question 2.1 How may the point A' be constructed, when its pre-image A lies outside the reference-circle h?

Question 2.2 Which are the fixed points of a circle-reflection?

2.4 CIRCLE-REFLECTION INVARIANTS

The usual straight-line reflection is a congruence mapping: thus the images of straight lines, circles, squares, etc. are again straight lines, circles, squares, etc. The circle-reflection is not a congruence mapping, since the bounded interior of the reference-circle is mapped onto the unbounded exterior. Nevertheless some configurations are such that their images are of the same kind.

A bishop on a chessboard follows along the diagonals of neighboring ("by corners") chessboard squares. A sequence of such diagonals lies naturally on a straight line. The situation is very different in the case of the square grid of Figure 19. Here a sequence of square-diagonals gives rise to a curved

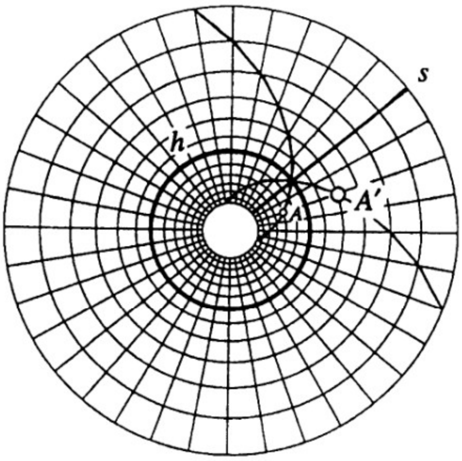

FIGURE 25
"Diagonal curves"

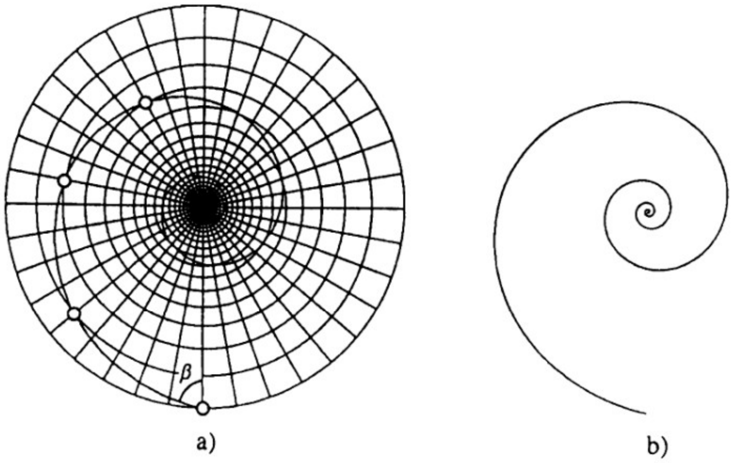
line of spiral shape (Figure 25). Precisely, a sequence of square-diagonals gives rise to a broken line with vertices at the grid points of the square grid. But if we subdivide the square grid ever finer and think of it provided with square-diagonals, there arises a beautifully curved spiral. Reflection of this spiral in the reference-circle h, which maps A to A', gives rise to a spiral of exactly the same kind. The two spirals are thus mirror images with respect to circle-reflection in h. Moreover, they are obviously also mirror images with respect to straight line reflection in the radial grid line s. For such a diagonal spiral the polar angle ϕ increases, for each grid step in the radial direction, by the same value α; α is the angle of intersection of two neighboring radial grid lines. If we denote by t the number of grid steps from h towards the exterior, then the relation $\phi = \alpha t$ holds, so that $t = \frac{\phi}{\alpha}$. Since $r(t) = r_0 e^{\alpha t}$, the diagonal spiral is represented in polar coordinates by the equation

$$r\left(\frac{\phi}{\alpha}\right) = r_0 e^{\phi}.$$

The diagonal spiral is thus the graph of an exponential function drawn in polar coordinates. In general a spiral with the polar representation

$$r(\phi) = r_0 e^{m\phi}$$

is called a ***logarithmic spiral,*** since the polar angle ϕ depends logarithmically on the polar distance r. Figure 26 shows a logarithmic spiral with $m = \frac{1}{5}$.



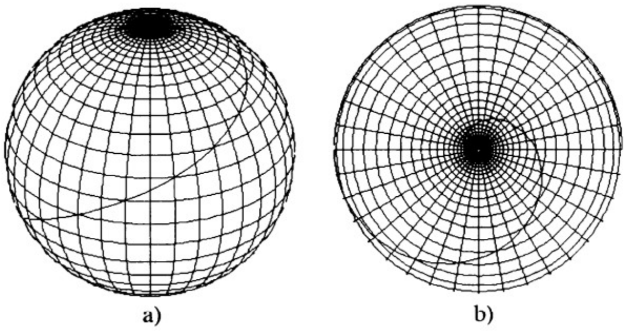
a) b)

FIGURE 26
A logarithmic spiral with $m = \frac{1}{5}$

With this spiral a unit-square in the radial direction arises from 5 unit-squares in the tangential direction; the "gradient" is thus $m = \frac{1}{5}$. In general, a logarithmic spiral with gradient m is transformed, under a circle-reflection in a reference-circle concentric with the spiral center, into a logarithmic spiral with a gradient $(-m)$. In a logarithmic spiral the angle to the radial gridlines is always the same, namely $\beta = \operatorname{arc\,cot} m$.

A logarithmic spiral thus follows a constant course β with respect to the grid-center. Such curves appear in the real world. For a few insects, for example, for bees, the lateral placing of the immovable eyes has the consequence that the insects fly towards an object in view, for example a flower, with a systematic angular error β; the flight curve is thus a logarithmic spiral. Also, in aviation and navigation, constant courses are adopted; the curves thus arising, the so-called ***loxodromes,*** are, in view of the sphericity of the earth, not logarithmic spirals, but they can be approximated by such curves near the poles.

Figure 27a shows a loxodrome, in which, for two unit-squares in the easterly direction, there occurs a unit-square in the northerly direction. It cuts each meridian at an angle $\arctan 2 \approx 63.43°$, and so follows a constant course of 63.43°. Figure 27b shows the same loxodrome as viewed from the north. In Figure 28 (from [32, p. 318]) we recognize the same loxodrome as the basis of the design.



a) b)

FIGURE 27
Loxodrome with constant course

Question 2.3 How long is a logarithmic spiral from reference-circle to its innermost point?

Question 2.4 Which curves are given by the polar equations $r(\phi) = a\phi + b,\ r(\phi) = \frac{a}{\phi}$?

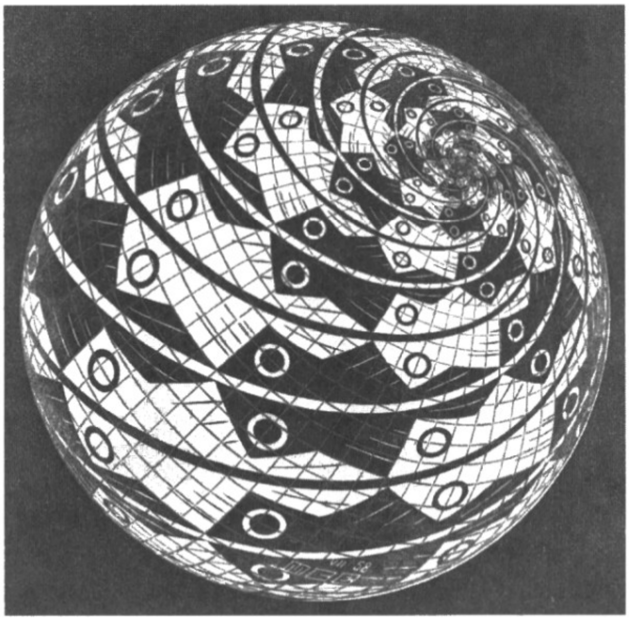


FIGURE 28
M. C. Escher: *Spherical surface with fish,* July 1958. ⓒ 1997 Cordon Art–Baarn–Holland. All rights reserved.

Question 2.5 How long is the loxodrome of Figure 27 from South Pole to North Pole?

2.5 IMAGE OF A STRAIGHT LINE

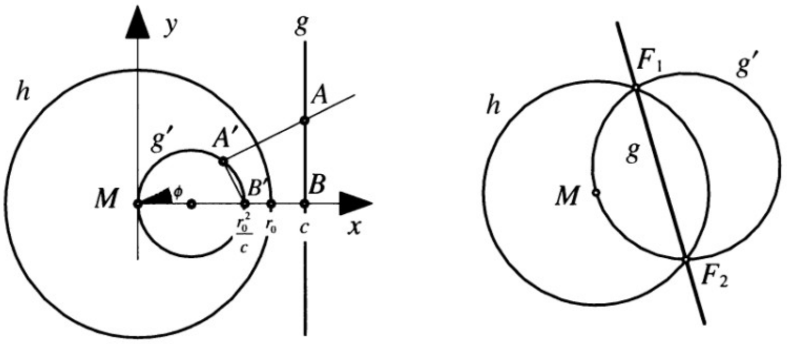
We study the image of a straight line g under a circle-reflection in a reference-circle h. To this end we choose a Cartesian coordinate system such that h is given by the equation $x^2 + y^2 = r_0^2$ and g is given by the equation $x = c$ (Figure 29a).

The line g is then given in polar coordinates by the equation $c = r\cos\phi$. Since $rr' = r_0^2$, the equation for the image figure, in polar coordinates, is

$$r' = \frac{r_0^2}{c}\cos\phi\,.$$

The points which satisfy this equation lie on the circle having the line-segment joining $M(0,0)$ and $B'(\frac{r_0^2}{c}, 0)$ as diameter (see Figure 29a). The image g' of g is thus a circle through M itself. The center M of h can, however, be interpreted as the image of the ***point at infinity*** on g. The tangent to g' at M is parallel to g.

Remark The image of a straight line g is, of course, also a circle if G intersects the reference-circle (Figure 29b). In this case g' may simply be described as the circle through M and the two fixed points F_1 and F_2.



a) b)

FIGURE 29
Image of a straight line

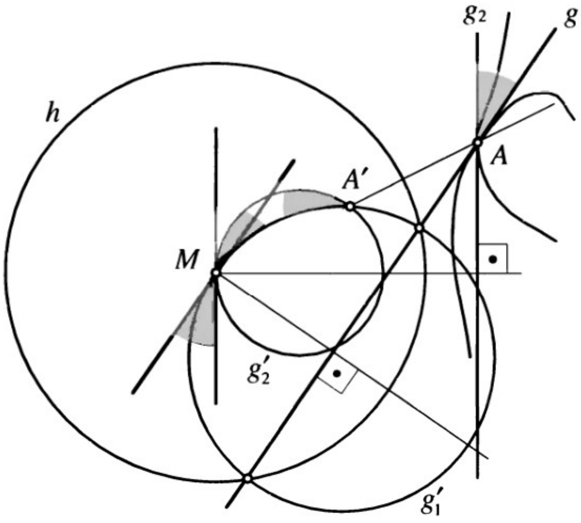


FIGURE 30
The angle remains fixed

Question 2.6 Are there exceptional straight lines whose image under a circle-reflection is not a circle?

We can now show that the angle is preserved under a circle-reflection in h. The angle of intersection of two curves is defined as the angle of intersection of their tangents at the point of intersection A (Figure 30). But this angle is equal to the angle between the image circles of the two tangents to the curves at M and is thus equal to the angle at the image point A'.

A mapping under which angles are preserved is called ***angle-preserving*** or ***conformal.*** Conformal mappings play an important role in cartography in the construction of angle-preserving maps.

Circle-reflections are conformal mappings.

In particular, right angles are preserved under conformal mappings. The image of a Cartesian square lattice is thus itself an orthogonal network, consisting of orthogonal circles through M (Figure 31).

Question 2.7 How did the gothic quatrefoil window in the center of Figure 31 arise?

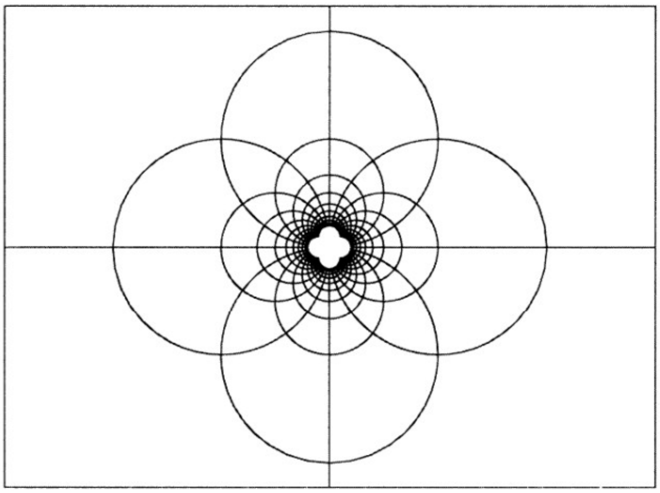

FIGURE 31
Image of a square lattice

2.6 REPRESENTATION IN CARTESIAN COORDINATES

We consider a Cartesian coordinate system with the center M of the reference-circle as origin (Figure 32). With the notations $A(x, y)$ and $A'(x', y')$, we can write $r = \sqrt{x^2 + y^2}$, $r' = \sqrt{x'^2 + y'^2}$ and $\frac{x'}{x} = \frac{r'}{r}$.

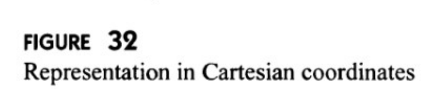

FIGURE 32
Representation in Cartesian coordinates

Since $rr' = r_0^2$, it further follows that

$$\frac{x'}{x} = \frac{r'}{r} = \frac{r_0^2}{r^2} = \frac{r_0^2}{x^2+y^2}.$$

This yields the mapping equations

$$x' = r_0^2\,\frac{x}{x^2+y^2}, \quad y' = r_0^2\,\frac{y}{x^2+y^2}.$$

Remark For the inverse mapping we have the symmetric mapping equations

$$x = r_0^2\,\frac{x'}{x'^2+y'^2}, \quad y = r_0^2\,\frac{y'}{x'^2+y'^2}.$$

2.7 IMAGE OF A CIRCLE

The image of a circle k concentric with the reference-circle h is again a circle k' concentric with h; for the radii ρ, ρ' of the circles k, k' we have $\rho\rho' = r_0^2$. A circle k through the center M of h has as image a straight line. We study now the image of a circle k which is neither concentric with h nor passes through M (Figure 33). In an appropriate Cartesian coordinate system such a circle k with center at $(u, 0)$ and radius ρ is given by the equation $(x-u)^2 + y^2 = \rho^2$. By substituting from the mapping equations for the

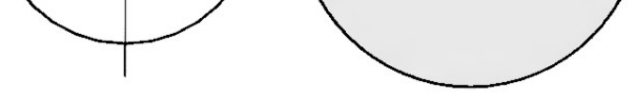

FIGURE 33
Image of a circle

inverse mapping, we obtain from this for the image figure k' the equation

$$\left(r_0^2\,\frac{x'}{x'^2+y'^2}-u\right)^2+\left(r_0^2\,\frac{y'}{x'^2+y'^2}\right)^2=\rho^2.$$

We manipulate this into the form

$$r_0^4-2ur_0^2x'+u^2(x'^2+y'^2)=\rho^2(x'^2+y'^2).$$

This is again the equation of a circle; it can be brought into the form

$$\left(x'-\frac{ur_0^2}{u^2-\rho^2}\right)^2+y'^2=\left(\frac{r_0^2\rho}{u^2-\rho^2}\right)^2$$

The image k' of the circle k is thus a circle with center $(u',0)$ and radius ρ', where

$$u'=\frac{ur_0^2}{u^2-\rho^2},\quad \rho'=\frac{r_0^2\rho}{u^2-\rho^2}.$$

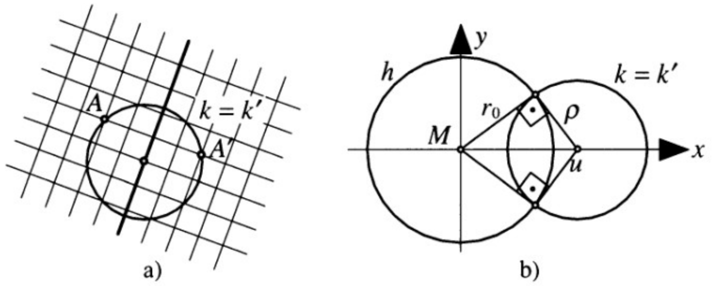
Remark We have $uu'=\frac{u^2r_0^2}{u^2-\rho^2}\neq r_0^2$; this means that the center of one circle is *not* mapped onto the center of the other.

Under a straightline reflection, a circle which cuts the axis of reflection orthogonally is fixed (Figure 34a).

The same is true with a circle-reflection; a circle k which cuts the reference-circle h orthogonally is a fixed circle (Figure 34b). In this situation we have, from Pythagoras' Theorem, $u^2-\rho^2=r_0^2$. Hence

$$u'=\frac{ur_0^2}{u^2-\rho^2}=u;\quad \rho'=\frac{r_0^2\rho}{u^2-\rho^2}=\rho.$$

Remark Thus, with circle-reflections, circles and straight lines are transformed, according to the situation, into circles and/or straight lines. It is



a) b)

FIGURE 34
Fixed circles

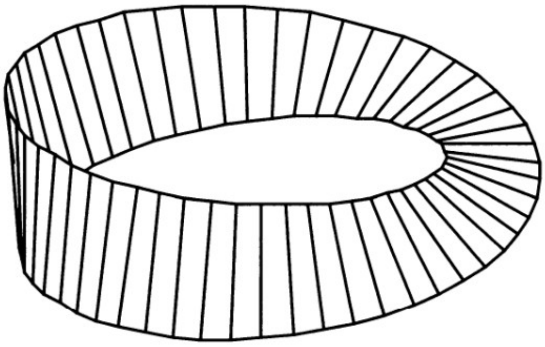


FIGURE 35
The Möbius band

therefore meaningful to subsume both ideas under one all-embracing idea. The concept of ***Möbius circle*** brings together circles and straight lines; a Möbius circle is one or the other. Under a circle-reflection the image of a Möbius circle is always a Möbius circle. The name Möbius circle reminds us of A. F. Möbius.

August Ferdinand Möbius (born 17/11/1790 in Schulpforta, died 26/9/1868 in Leipzig) was, after studies at Leipzig University and study leave in Göttingen and Halle, called in 1816 on the recommendation of Gauss to Leipzig. In 1820 he became Director of the Observatory, and in 1844 full professor for astronomy and mechanics. He contributed decisively to the education of Gymnasium (academic high school) teachers in the kingdom of Saxony and was heavily involved in the new orientation of geometry in the first half of the 19th century. He is also the discoverer of the Möbius band (Figure 35). A Möbius band is easily constructed from a strip of paper, into which one introduces a single twist before sticking the ends together. The Möbius band has some interesting topological properties. It is a "one-sided surface", that is, it has no "inside" and "outside". If we start anywhere on the apparent outside to color the band we find ourselves, as we continue the work, suddenly on the apparent inside. The ants of Figure 36 (from [32, p. 324]) pass without problem from the apparent outside to the apparent inside, without having to climb over the edge of the strip.

Question 2.8 What happens if we try to cut a Möbius band in two along the center line?

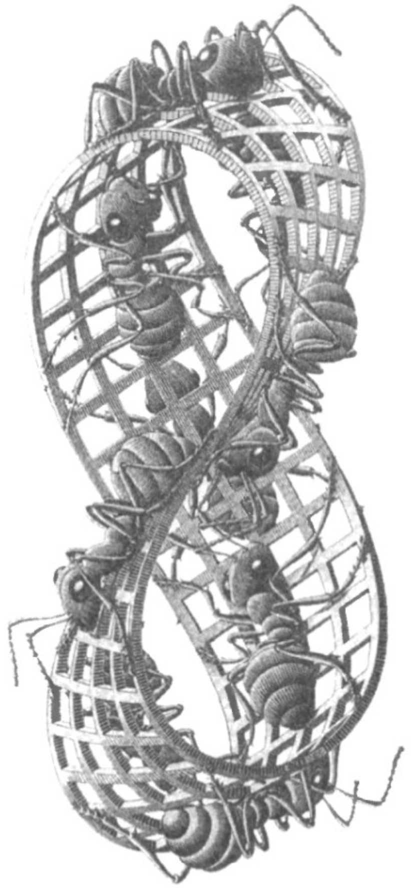

FIGURE 36
M. C. Escher: Möbius strips II (Red Forest Ants), 1963. © 1997 Cordon Art–Baarn–Holland. All rights reserved.

The concept of circle-reflection can be extended to sphere-reflection in 3-dimensional space. Then the inside of the sphere is mapped onto the outside and conversely.

Question 2.9 How does a mathematician catch a lion?

2.8 SQUARE-REFLECTION

The idea of reflecting from the inside to the outside and vice versa can be carried over to other closed figures. For the inspiration of this idea I must thank Georg Schierscher. In Figure 37 a reflection in a square of side length 2 is represented. The "reflection in a square" is defined as follows: the point A' lies on the same ray emanating from the center M of the square as the

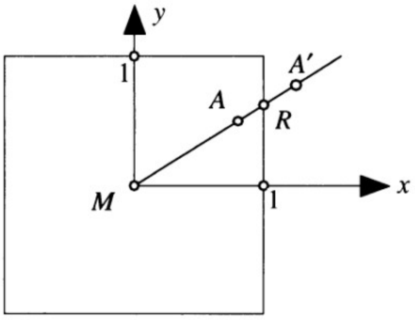

FIGURE 37
Reflection in a square

original point A. The point R, with now a variable polar distance, which we still denote by r_0, is the intersection of the ray with the square. For the polar distances r and r' of A and A', respectively, we have the relationship $rr' = r_0^2$.

Question 2.10 Express the mapping equations of this reflection in a square in Cartesian coordinates. How does the image of the square grid parallel to the axes look? What is the image of the square grid turned through 45°?

2.9 OTHER REFLECTIONS

Question 2.11 What problem presents itself if one reflects in a parabola p of the parabolic network of Figure 38 by "counting the unit squares"?
Further "near-reflections" are considered in [4].

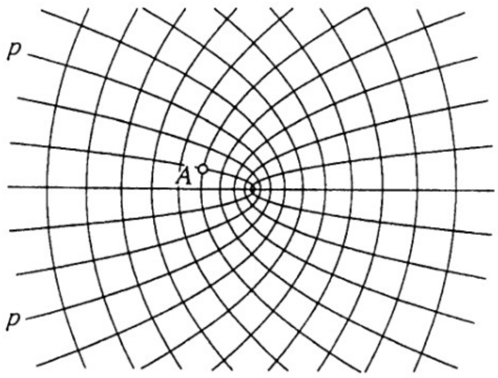

FIGURE 38
Reflection in a parabola?

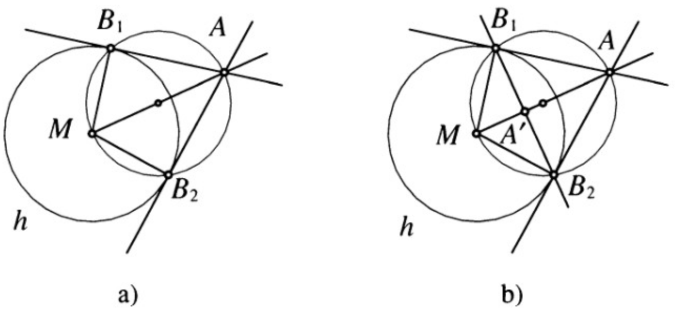

FIGURE 39
The point A lies outside h

Answers to Questions

Answer 2.1 The construction proceeds in the reverse sequence according to Figure 39.

Answer 2.2 Precisely the points of the reference-circle h are the fixed points.

Answer 2.3 A path-length ds on a logarithmic spiral has, in view of the constant course, a radial variation given by $dr = ds \cos \beta$. Thus the length of the logarithmic spiral from the reference-circle h with radius r_0 to its innermost point is given by $s_0 = \frac{r_0}{\cos \beta}$.

Answer 2.4 A linear function $r(\phi) = a\phi + b$ in polar coordinates yields an ***archimedean spiral*** (Figure 40a). For an archimedean spiral the radial difference between two revolutions is always the same, namely, $r(\phi+2\pi)-r(\phi) = 2a\pi$. Such spirals arise from the rolling up of material of constant thickness (rolls of carpet, rolls of film, rolls of toilet paper). The mirror-image of an archimedean spiral in a circle-reflection is no longer an archimedean spiral.

The function $r(\phi) = \frac{a}{\phi}$ yields a ***hyperbolic spiral,*** which, in view of its appearance, is also known as a ***bishop's staff*** or ***crosier*** (Figure 40b). We see such a hyperbolic spiral when we look at a screw in the direction of its axis, for example, by looking at the central shaft of a winding staircase.

Answer 2.5 According to the Theorem of Pythagoras, the arc length for a unit length in the northerly direction is $\sqrt{5}$ times this unit length (Figure 41). The entire loxodrome length is thus $\sqrt{5}$ times the meridian length. For the loxodrome with constant course β the length, from Pole to Pole, is $\frac{1}{\cos \beta}$ times the meridian length. Thus it is also clear that, in general, the loxodrome does not constitute the shortest path on the spherical

FIGURE 42
Image of a straight line through the center

surface. The shortest path is given by arcs of great circles. Nevertheless on sea journeys the loxodrome is preferred on practical grounds (constant course) when the difference in length is not too great.

Answer 2.6 A straight line g through the center M is a fixed line, though not a line of fixed points. It has only the two diametrical fixed points F_1 and F_2. As to the other points, the inner and outer points are exchanged; the point M is mapped to the point at infinity, and conversely (Figure 42). The image straight line g' can be viewed as a circle of infinite radius.

Answer 2.7 Figure 31 is the image of a bounded Cartesian square network; the region runs in both dimensions from -12 to $+12$. The gothic quatrefoil window is the image of the boundary square with $x = \pm 12$ and $y = \pm 12$ under reflection in a circle.

Answer 2.8 The Möbius band cannot literally be cut in two along its center line. If attempted, there results a *single* band, twice as long and with a double twist. Try it!

Answer 2.9 He (or she) sits in the center of an empty lion cage and comes out through a reflection in a sphere. Then he (or she) is outside and the lion is inside. Indeed, all lions are then in the cage. Moreover, the mathematician, and the rest of humanity, no longer have their hearts in the right place. (Translator's note: the lion cage is assumed spherical.)

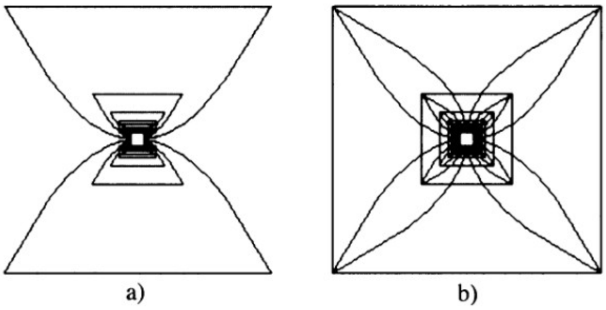
Answer 2.10 For the mapping equations we need a separation of cases. If $|y| \leq |x|$ we have

$$x' = \frac{x}{x^2}; \ y' = \frac{y}{x^2},$$

and if $|y| > |x|$ we have

$$x' = \frac{x}{y^2}; \ y' = \frac{y}{y^2}.$$

Figure 43a shows the image of the gridline $y = \text{const}$. Instead of the circles of



a) b)

FIGURE 43
Image of the square network parallel to the axes

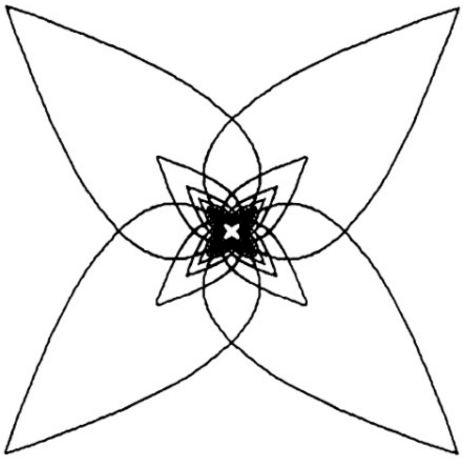


FIGURE 44
Image of the square network turned through 45°

Figure 31 we obtain curves which are put together from quadratic parabolae and line segments. Figure 43b shows the image of the entire square grid parallel to the axes. Figure 44 shows the image of the square grid turned through 45°.

Answer 2.11 The mirror image is not uniquely defined; there is an "upper" and a "lower" solution (Figure 45).

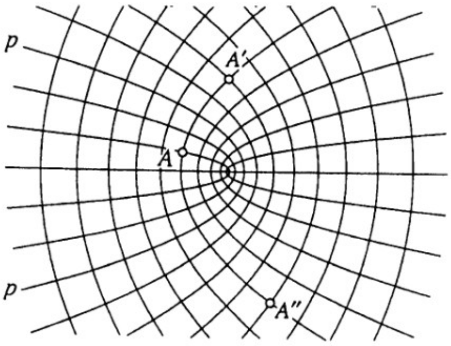

FIGURE 45
The mirror image is not uniquely defined.

data 06.05.2020

Extending work of Rosser and Schoenfeld, various authors have proved related results.

Krawczyk proved the following, $\pi(kx) < k\pi(x)$ for $k \geq e, x \geq 67$.

For $\epsilon > 0, x \geq 17, y \geq 17, x+y \geq 1 + e^{4(1+1/\epsilon)}$, it has been show that

$$\pi(x+y) < (1+\epsilon)(\pi(x)+\pi(y)).$$

There is an interesting connection between Conjecture A ($\pi(x+y) \leq \pi(x)+\pi(y)$, $x, y \geq 2$) and the generalization of the twin prime conjecture that follows it.

In the spring of 1816 Gauss had proposed as a prize problem for a new astronomical journal founded by von Lindenau and Bohnenberg (Bohnenberger), the projecting of two curved surfaces on each other, yet preserving similarity in the smallest parts.

At the time he had the solution and had thought out a projection by means of parallel normals on the sphere of radius unity.

In his concept the development or bending of curved surfaces was a special case of projection.

(resolveu)
At this time he had worked out the concept of the total curvature of a portion of a surface and the concept of the measure of curvature at one point of a surface, as well as preservation of the measure of curvature in spite of bendings.

In the time from 1812 to 1816 he was busy with the theory of the shortest lines on the elliptic spheroid, and conceived of the cartesian coordinates of a point of a curved surface as functions of two auxiliar magnitudes. (eixos curvos)

CHAPTER I

The properties of circles discussed in this chapter are those which have the habit of appearing in other branches of mathematics.

1. The nine-point circle

This circle is the first really exciting one to appear in any course on elementary geometry. It is a circle which is found to pass through nine points intimately connected with a given triangle *ABC*. Three proofs are given. Each has its own peculiar merits.

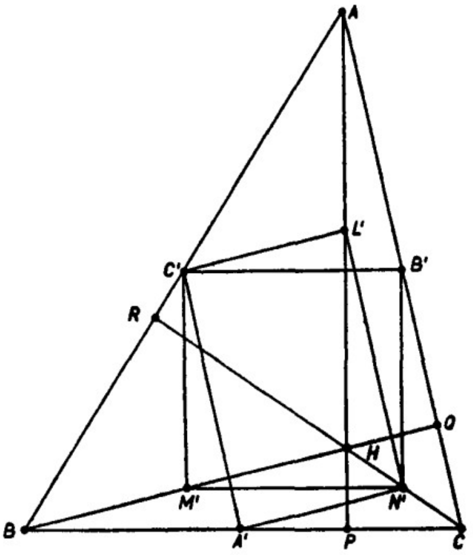

FIG. 1

(i) *H* is the orthocentre of triangle *ABC*, the intersection of the altitudes *AP*, *BQ*, *CR*. The midpoints of *BC*, *CA* and *AB* are *A'*, *B'* and *C'* respectively. *L'*, *M'*, *N'* are the midpoints of *HA*, *HB*, *HC*. We show that a circle passes through the nine points *A'*, *B'*, *C'*, *L'*, *M'*, *N'*, *P*, *Q*, *R*. We use the theorem that the line joining the midpoints of two sides of a triangle is parallel to the third side.

Both *B'C'* and *N'M'* are ‖ to *BC*, and both *B'N'* and *C'M'* are ‖ to *AH*. Hence *B'C'M'N'* is a rectangle. Similarly *C'A'N'L'* is a rectangle.

Hence $A'L'$, $B'M'$ and $C'N'$ are three diameters of one circle. Since $A'P$ and $L'P$ are $\perp$, this circle passes through P. Similarly it passes through Q and R.

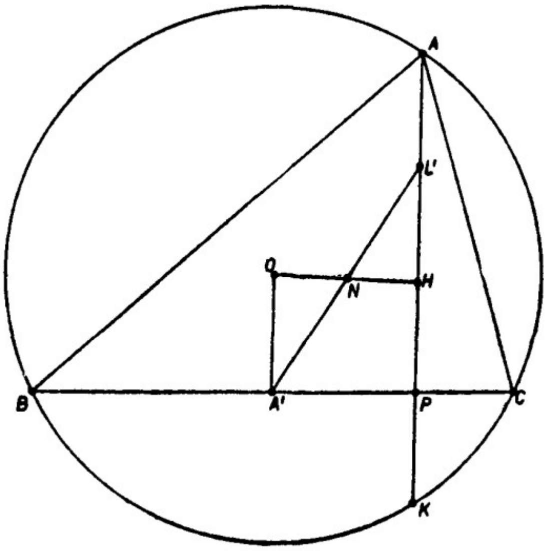

FIG. 2

(ii) Let O be the circumcentre of ABC and R the circumradius. We know that $AH = 2OA'$. Since L' bisects AH, $L'H = OA'$, and therefore OH and $L'A'$ bisect each other, in N, say.

Now $NL' = NA' = NP$ (since $\angle APB = 90°$). We also know that $HP = PK$, and since $ON = NH$, we have

$$NP = \tfrac{1}{2}OK = \tfrac{1}{2}R.$$

Therefore the circle centre N and radius $\frac{1}{2}R$ passes through P, A', L'. Similarly it passes through Q, B', M' and R, C', N'.

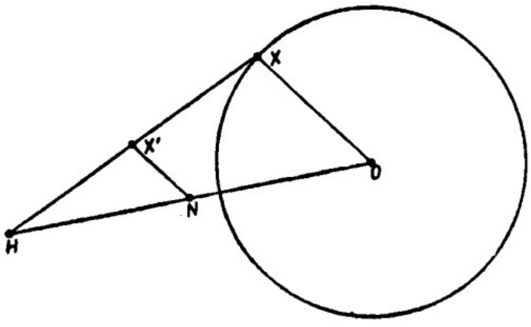

FIG. 3

(iii) The third proof uses a lemma from the theory of similar figures. If X is a point on a given circle of centre O and radius R, and H is any given fixed point, the locus of X', the midpoint of HX, is a circle centre N, where N bisects HO, and radius $\frac{1}{2}R$. The proof is clear.

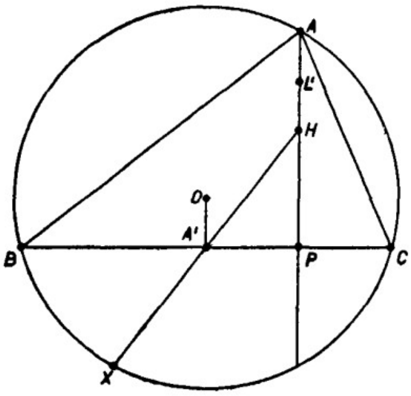

Fig. 4

Applying this lemma to the case of the circumcircle of ABC, H being the orthocentre, we see that a circle centre N and radius $\frac{1}{2}R$ passes through P, Q, R, L', M', N'. We must now show that this circle also passes through A', B', C'. It is sufficient to show that if HX contains A', then HX is bisected at A'.

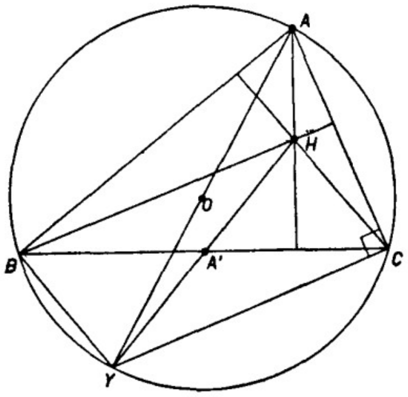

Fig. 5

Let AO meet the circumcircle in Y. Then $\angle ACY = 90°$, so that $YC \parallel BH$. Since also $\angle ABY = 90°$, $YB \parallel CH$. Therefore $YBHC$ is a parallelogram, and the diagonals YH and BC

bisect each other. Hence Y is the same point as X in the previous diagram, and the theorem is proved.

The methods used above are elementary, and at least one of the three proofs will be familiar to most readers of this book. In chapter II we shall need to assume some theorems in inversion and coaxal systems of circles. As fashions in mathematical teaching change, it cannot be assumed that all readers will be familiar with these theories, and a brief (but adequate) outline of each will now be given.

2. Inversion

This is a one-to-one transformation of the points of the plane by means of a given circle, which we shall call Σ, of radius k and centre O. To obtain the transform X' of any given point X, or the *inverse* of X in the circle Σ, we join X to O, and find X' on OX such that $OX.OX' = k^2$. The point O itself is excluded from the points of the plane which may be transformed. It is clear that

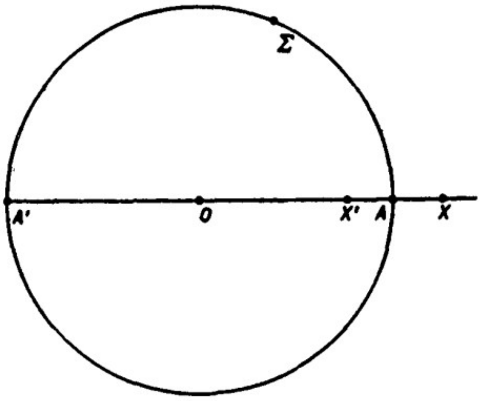

FIG. 6

(i) X is the inverse of X';
(ii) points on Σ transform into themselves;
(iii) if A, A' are the ends of the diameter of Σ through X, then X, X' are harmonic conjugates with respect to A, A'.

All circles through X and X' cut Σ orthogonally, since the square of the tangent from O to such a circle $= OX.OX' = k^2$.

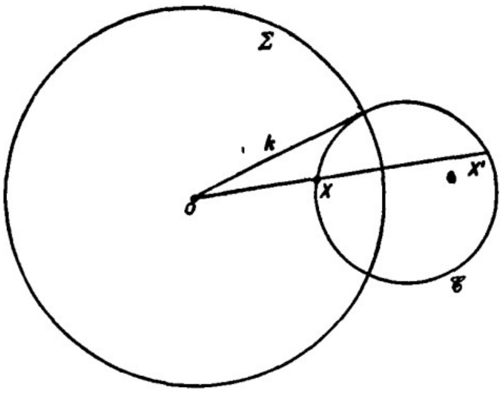

FIG. 7

As a corollary to this remark, we see that if $\mathscr{C}$ is any circle orthogonal to Σ, all points on $\mathscr{C}$ invert into points on $\mathscr{C}$, for $OX.OX' = k^2$. It is sometimes necessary to consider the process of inversion when Σ, the circle of inversion, is a line. If we keep A fixed, and let A' move off to infinity, we see that X' moves towards the geometrical image of X in the resulting line.

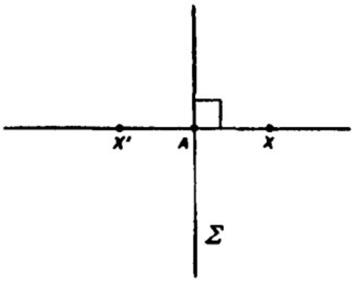

FIG. 8

For future application we now give a construction, using only a

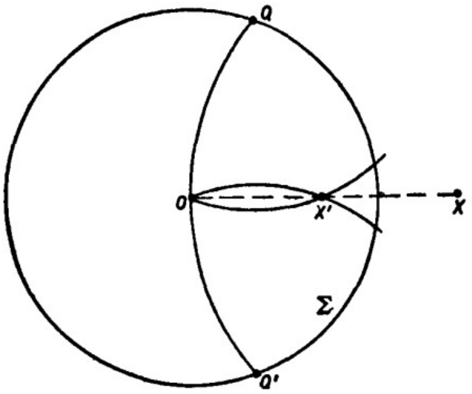

FIG. 9

pair of compasses, by which we can find the inverse of a point X in a circle Σ of given centre O. Let the circle centre X and radius XO cut Σ in Q and Q', and let O and X' be the intersections of the two circles with centres Q and Q' and radii QO and $Q'O$ respectively. Then X' is the inverse of X in Σ.

For QOX and $X'OQ$ are isosceles triangles with a common base angle. They are therefore similar, and $OX : OQ = OQ : OX'$. Hence $OX . OX' = OQ^2$.

This construction lies at the basis of the discussion on *compass geometry* in §11.

We are interested in the locus of inverse points X' as X describes a given curve $\mathscr{C}$. This locus is called the *inverse of the curve* $\mathscr{C}$ with respect to Σ. When $\mathscr{C}$ is a circle orthogonal to Σ, we have seen that the inverse is $\mathscr{C}$ itself. The general theorem is:

The inverse of a circle is a straight line or a circle.

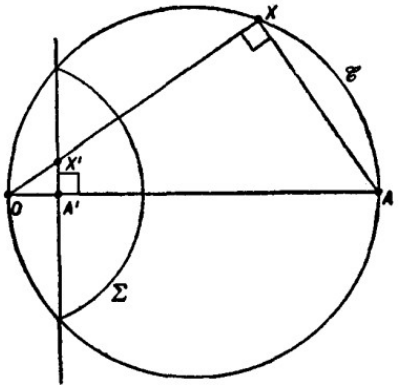

FIG. 10

(i) The centre of inversion O is on $\mathscr{C}$:

Let OA be the diameter of $\mathscr{C}$ through O, and let A' be the inverse of A. Then $OA . OA' = k^2$. If X is any point on $\mathscr{C}$, and X' its inverse,

$$OX . OX' = k^2 = OA . OA'.$$

Hence A, X, X', A' are concyclic points, and since $\angle AXO = 90°$, $\angle X'A'A = 90°$. Therefore X' describes the line through $A' \perp$ to OA.

We note that this line is $\parallel$ to the tangent to $\mathscr{C}$ at O. It naturally passes through the intersections of $\mathscr{C}$ and Σ, since points on Σ invert into themselves.

Corollary. The inverse of a straight line is a circle through the centre of inversion.

(ii) The centre of inversion O is not on $\mathscr{C}$. Let C be the centre of $\mathscr{C}$. Since

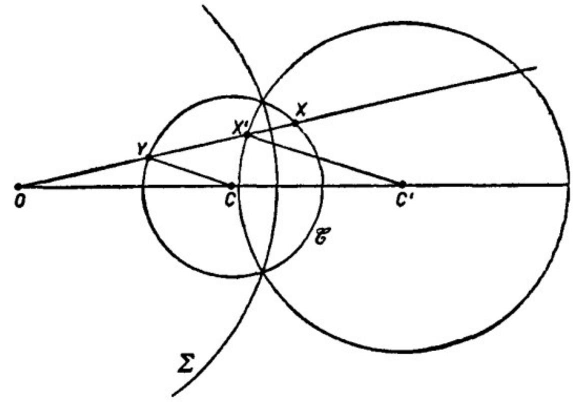

FIG. 11

$$OX.OX' = k^2,$$

and $$OX.OY = t^2,$$

where t is the tangent[†] from O to $\mathscr{C}$, by division we have

$$\frac{OX'}{OY} = \frac{k^2}{t^2}.$$

Since this ratio is constant, it follows that if C' is a point on OC such that $C'X' \parallel CY$, then C' is a fixed point, and $C'X'$ is constant. Hence X' moves on a circle centre C'.

Note that C' is not necessarily the inverse of C. We shall soon find what point the centre of $\mathscr{C}$ does invert into.

We need only one further theorem from the theory of inversion:

The angle of intersection of two circles is unaltered by inversion.

In fact a more general theorem is true, but this one will suffice for our subsequent needs.

[†] We shall see later that t^2 may be negative. Then O is inside $\mathscr{C}$.

(i) If both circles $\mathscr{C}$ and $\mathscr{D}$ pass through the centre O of inversion, they transform into straight lines parallel to the tangents to $\mathscr{C}$ and $\mathscr{D}$ at O, so that the theorem is evident.

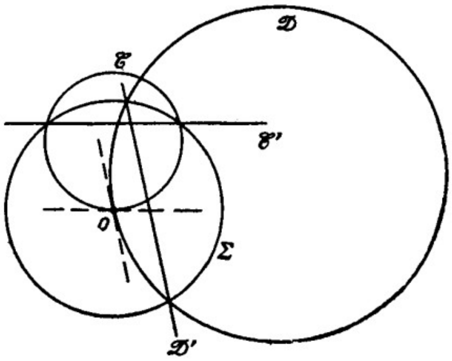

FIG. 12

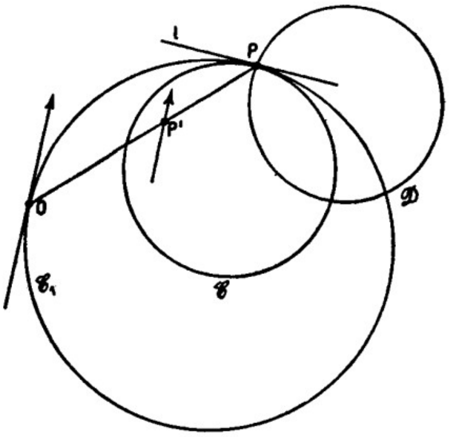

FIG. 13

(ii) If at least one of the circles $\mathscr{C}$, $\mathscr{D}$ does not pass through O, let P be a point of intersection of the two circles, and let l, m be the tangents at P to $\mathscr{C}$, $\mathscr{D}$ respectively. We may draw a circle $\mathscr{C}_1$ through O which touches l at P, and a circle $\mathscr{D}_1$ through O which touches m at P. Then the angle between $\mathscr{C}_1$ and $\mathscr{D}_1$ is the same as that between $\mathscr{C}$ and $\mathscr{D}$.

Now if P' is the inverse of P, the tangent at P' to the inverse of $\mathscr{C}$ is the inverse of $\mathscr{C}_1$. Hence the angle between the circles inverse to $\mathscr{C}$ and to $\mathscr{D}$ is equal to the angle between $\mathscr{C}_1$ and $\mathscr{D}_1$ (by (i) above), and this is equal to the angle between $\mathscr{C}$ and $\mathscr{D}$.

With the help of this theorem we can now find the inverse of the centre of a circle $\mathscr{C}$. All lines through the centre C cut $\mathscr{C}$ orthogonally. These lines invert into circles through the centre of inversion O and the inverse of C. Since all circles through O and the inverse of C cut the inverse of $\mathscr{C}$ orthogonally, the inverse of C must be *the inverse of* O *in the inverse of* $\mathscr{C}$.

If O lies on $\mathscr{C}$, so that the inverse of $\mathscr{C}$ is a straight line, the centre of $\mathscr{C}$ inverts into the geometrical image of O in this line.

We now give some applications of the theory of inversion.

3. Feuerbach's theorem

The nine-point circle of a triangle touches the incircle and excircles of the triangle.

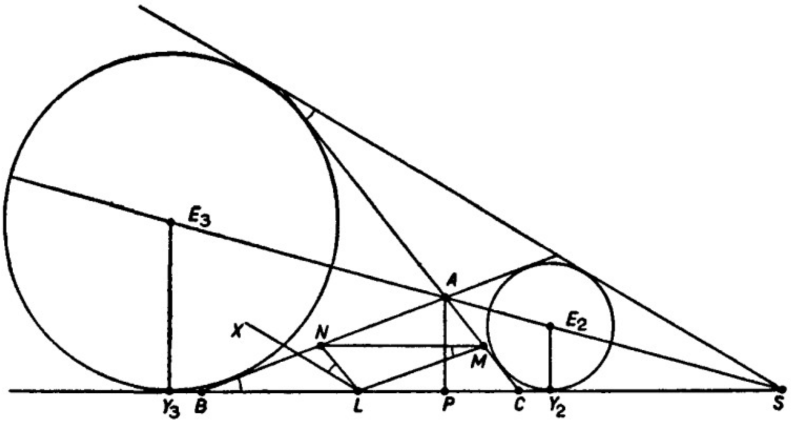

FIG. 14

We consider the excircles opposite B and C. Let their centres be E_2 and E_3, and their points of contact with BC Y_2 and Y_3. The points A, S divide E_2E_3 internally and externally in the same ratio, that of the radii of the two excircles. Dropping perpendiculars on BC, it follows that P and S also divide Y_2Y_3 internally and externally in the same ratio. That is, P and S are harmonic conjugates with respect to Y_2 and Y_3.

Let L, M, N be midpoints of BC, CA, AB. We note that $BY_2 = \frac{1}{2}(BC + CA + AB) = CY_3$, so that L is also the midpoint of Y_2Y_3. From the harmonic relation just proved we see that

$$LP.LS = LY_2{}^2 = LY_3{}^2.$$

Now let LX be the tangent at L to the circle LMN, where X is on the same side of BC as N. Then

$$\angle XLN = \angle NML = \angle ABC.$$

Hence the angle between LX and $CA = \angle ABC$. It follows that LX is $\parallel$ to the fourth common tangent of the two excircles, the common tangent through S other than BC.

Now since $LP.LS = LY_2^2 = LY_3^2$, the nine-point circle LMN is the inverse of this fourth common tangent with respect to the circle centre L and radius LY_2. For this nine-point circle contains P, and inverts into the line through S parallel to the tangent to the circle at L.

Also since the circle of inversion cuts both excircles orthogonally, each excircle inverts into itself. We have seen that the inverse of the nine-point circle touches these excircles. It follows that the nine-point circle touches the excircles centres E_2, E_3. In precisely the same way we can show that the nine-point circle touches the incircle and the excircle opposite A.

4. Extension of Ptolemy's theorem

If A, B, C, D are any four points in a plane, then

$$AB.CD + AD.BC > AC.BD,$$

unless A, B, C, D lie, in the order $ABCD$, on a circle or a straight line. In the latter case, the inequality becomes an equality.

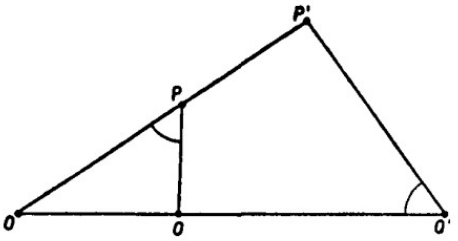

FIG. 15

This is proved by noting the influence of inversion on the length of a segment. If the points P, Q invert into the points P', Q', with O as centre of inversion, then OPQ and $OQ'P'$ are similar triangles. Hence

$$\frac{P'Q'}{PQ} = \frac{OP'}{OQ} = \frac{OP.OP'}{OP.OQ} = \frac{k^2}{OP.OQ},$$

so that

$$P'Q' = \frac{k^2\,PQ}{OP.OQ}.$$

Now, given the four points A, B, C, D, we invert with respect to A. Let B', C', D' be the respective inverses of B, C, D. Then $B'C' + C'D' > B'D'$ unless C' lies on the line $B'D'$ between B' and D′. In the latter case we have

$$B'C' + C'D' = B'D'.$$

The first inequality becomes

$$\frac{BC}{AB.AC} + \frac{CD}{AC.AD} > \frac{BD}{AB.AD},$$

or

$$AB.CD + AD.BC > AC.BD,$$

unless C' lies on the line $B'D'$ between B' and D', in which case A, B, C, D lie on a circle in the order $ABCD$, or on a straight line.

5. Fermat's problem

A, B, C are any three points in a plane. To find a point P such that $PA + PB + PC$ shall be least.

Let B and C be the acute angles of the triangle ABC. On BC, and away from A, describe an equilateral triangle BCD. Then by the extension of Ptolemy's theorem, unless P lies on the circle BCD so that the order of the points is $BPCD$, we have

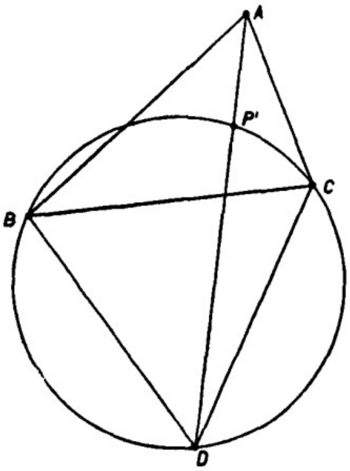

FIG. 16

$$BP.CD + PC.DB > PD.BC,$$

or

$$PB + PC > PD,$$

since $CD = DB = BC$. Therefore

$$PA + PB + PC > PA + PD.$$

Now, unless P lies on AD, we have $PA + PD > AD$. Hence, unless P is at P' (the other intersection of AD with the circle BCD), we have $PA + PB + PC > AD$.

But if P is at P', both the above inequalities become equalities; so that $P'A + P'B + P'C = AD$.

Hence $P'A + P'B + P'C < PA + PB + PC$.

Therefore P' is the required point.

If $\angle BAC = 120°$, $A = P'$, and A is the required point.

If $\angle BAC > 120°$, A is still the required point.

6. The centres of similitude of two circles

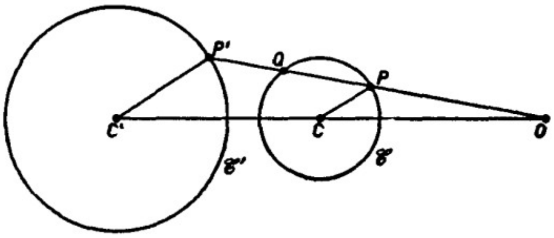

FIG. 17

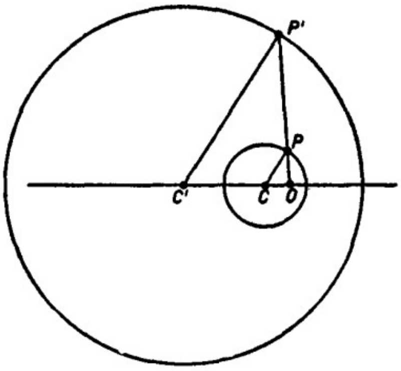

FIG. 18

These points have already appeared in some of our proofs. We now define them.

External centre of similitude. Let $\mathscr{C}$ and $\mathscr{C}'$ be two circles of unequal radii, with centres C and C'. Let CP and $C'P'$ be parallel radii drawn in the *same* sense. Then it is clear that $P'P$ cuts $C'C$ in a fixed point O, which divides $C'C$ externally in the ratio of the radii of the two circles. This is the external centre of similitude. If the ratio of the radii $= k$, then $OP' : OP = k$. We also have $OP \, . \, OQ =$ constant. Therefore

$$OP' \, . \, OQ = \text{constant}.$$

It follows that with centre of inversion O, and a suitable radius of inversion, $\mathscr{C}$ can be inverted into $\mathscr{C}'$.

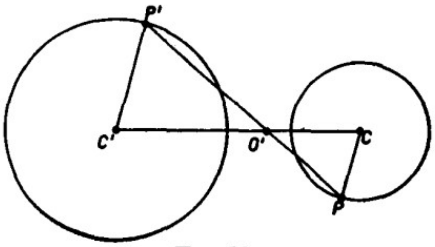

FIG. 19

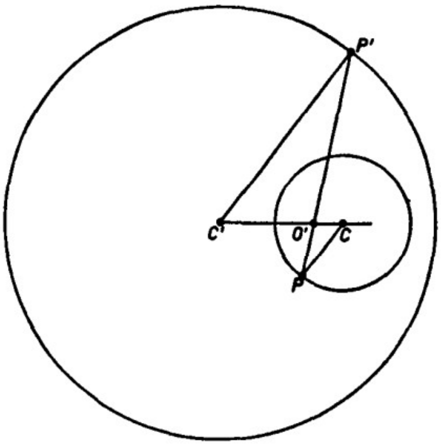

FIG. 20

Internal centre of similitude. Here the radii of the circles $\mathscr{C}$ and $\mathscr{C}'$ may be equal. CP and $C'P'$ are parallel radii in opposite senses. $P'P$ cuts $C'C$ in a fixed point O', the internal centre of similitude, which divides $C'C$ internally in the ratio of the radii.

Direct common tangents of $\mathscr{C}$ and $\mathscr{C}'$, if they exist, cut the line of centres in O, and transverse common tangents, if they exist, cut the line of centres in O'.

If $\mathscr{C}$ and $\mathscr{C}'$ are concentric, the common centre is both the internal and external centre of similitude.

If $\mathscr{C}$ and $\mathscr{C}'$ touch externally, that is, if they lie on opposite sides of the tangent at the point of contact, this point is the *internal* centre of similitude. If the circles touch internally, the point of contact is the *external* centre.

If we have three circles, no two of which have equal radii, and the centres of which form a triangle, the six centres of similitude lie in threes on four straight lines. This is easily proved, using the theorem of Menelaus.

7. Coaxal systems of circles

These are best introduced by using the methods of coordinate geometry.

The equation of any line passing through the origin of coordinates in the (x,y)-plane may be written as

$$\lambda x + \mu y = 0.$$

These lines are said to form a *pencil* of lines, and the equation of the system depends *linearly* on two distinct lines of the pencil, given by $x = 0$ and $y = 0$.

Similarly, if $u \equiv ax + by + c = 0$ and $v \equiv a'x + b'y + c' = 0$ are any two distinct lines, the line

$$\lambda u + \mu v = 0$$

represents, for suitable λ, μ, any line through the intersection of $u = 0$ and $v = 0$.

When we consider two distinct circles $\mathscr{C}$ and $\mathscr{C}'$, given by the equations

$$C \equiv x^2 + y^2 + 2gx + 2fy + c = 0,$$
$$C' \equiv x^2 + y^2 + 2g'x + 2f'y + c' = 0,$$

the system $\lambda C + \mu C' = 0$, derived linearly from them, is a system of circles, since it may also be written as

$$x^2 + y^2 + \frac{2x(\lambda g + \mu g')}{\lambda + \mu} + \frac{2y(\lambda f + \mu f')}{\lambda + \mu} + \frac{\lambda c + \mu c'}{\lambda + \mu} = 0.$$

If (x',y') is a point of intersection of $\mathscr{C}$ and $\mathscr{C}'$,

$$C(x',y') = C'(x',y') = 0,$$

that is, the point satisfies the equations of both circles. Since also, for all values of λ, μ,

$$\lambda C(x',y') + \mu C'(x',y') = 0,$$

this same point lies on all circles of the system $\lambda C + \mu C' = 0$. Such a system of circles therefore passes through the points of intersection (if any) of $\mathscr{C}$ and $\mathscr{C}'$. The system may be described as a *pencil* of circles, but for reasons which will soon become clear, we give it the more normal title of a *coaxal system* of circles.

A geometrical meaning may be given to the ratio of the parameters $\lambda : \mu$. Let $P\ (x',y')$ be any point in the plane, and let any line through P cut $\mathscr{C}$ in Q and R. Then it is elementary that the product

$$PQ.PR = x'^2 + y'^2 + 2gx' + 2fy' + c.$$

This constant, which is > 0 if P is outside the circle and equal to the square of the tangent from P to $\mathscr{C}$, is called, in all cases, the *power* of P with respect to $\mathscr{C}$. If P is inside $\mathscr{C}$, the power is negative, and it is zero, of course, if P is on $\mathscr{C}$. Since

$$\lambda C + \mu C' = 0$$

may be written as

$$\frac{\lambda}{\mu} = \frac{-C'}{C},$$

we see that *the locus of a point which moves so that the ratio of its powers with respect to two given circles $\mathscr{C}$ and $\mathscr{C}'$ is a constant is a circle of the coaxal system determined by $\mathscr{C}$ and $\mathscr{C}'$.*

A particular and important member of the system is obtained by taking the ratio of the powers to be unity. We then obtain

$$C - C' \equiv 2(g - g')x + 2(f - f')y + c - c' = 0,$$

a straight line, called the *radical axis* of the system. If $\mathscr{C}$ and $\mathscr{C}'$ intersect, this line is the common chord of the two circles, and it is evident that points on the common chord of two circles do have equal powers with respect to each circle. But the radical axis exists even if the circles do not intersect. It is easily verified that the radical axis of two circles is perpendicular to the line of centres.

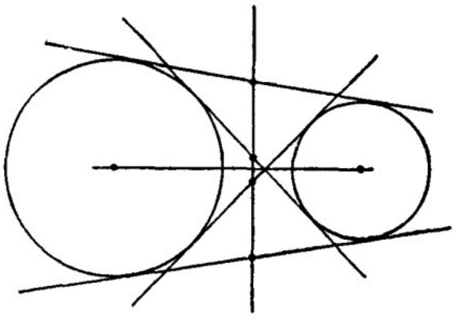

FIG. 21

We deduce that the midpoints of the common tangents of two circles lie on a line which is perpendicular to the line of centres.

We obtain the same coaxal system of circles if we take any two distinct members of the system $\lambda C + \mu C' = 0$, say

$$C_1 \equiv \lambda_1 C + \mu_1 C' = 0,$$

and

$$C_2 \equiv \lambda_2 C + \mu_2 C' = 0,$$

where $\lambda_1/\mu_1 \neq \lambda_2/\mu_2$, and write down the system of circles which depend linearly on C_1 and C_2. This should be verified. Another theorem of importance is that any two circles of a coaxal system have the same radical axis. This explains the term ***coaxal system.*** We can verify this directly. The radical axis of C_1 and C_2 is

$$2x\left[\frac{\lambda_1 g + \mu_1 g'}{\lambda_1 + \mu_1} - \frac{\lambda_2 g + \mu_2 g'}{\lambda_2 + \mu_2}\right] + 2y\left[\frac{\lambda_1 f + \mu_1 f'}{\lambda_1 + \mu_1} - \frac{\lambda_2 f + \mu_2 f'}{\lambda_2 + \mu_2}\right] + \left[\frac{\lambda_1 c + \mu_1 c'}{\lambda_1 + \mu_1} - \frac{\lambda_2 c + \mu_2 c'}{\lambda_2 + \mu_2}\right] = 0.$$

This easily reduces to

$$(\lambda_1\mu_2 - \lambda_2\mu_1)[2x(g - g') + 2y(f - f') + c - c'] = 0.$$

It follows that the centres of all circles of a coaxal system lie on a line perpendicular to the radical axis. This is also clear from the fact that the centre of $\lambda C + \mu C' = 0$ is the point

$$\left[\frac{\lambda(-g) + \mu(-g')}{\lambda + \mu},\ \frac{\lambda(-f) + \mu(-f')}{\lambda + \mu}\right].$$

In the next chapter we shall need to be familiar with a few more properties of coaxal systems, and we derive them here.

8. Canonical form for coaxal system

The line of centres and the radical axis of a coaxal system offer, in a sense, a natural system of coordinate axes for the system. We take the line of centres as the x-axis, and the radical axis as the y-axis, and see what form the equation of the system takes.

Since their centres are on the x-axis, any two circles $\mathscr{C}$ and $\mathscr{C}'$ have equations of the form,

$$C \equiv x^2 + y^2 + 2gx + c = 0,$$

and

$$C' \equiv x^2 + y^2 + 2g'x + c' = 0.$$

The radical axis of these two circles is

$$C - C' \equiv 2(g - g')x + c - c' = 0,$$

and since this is to be $x = 0$, we must have $c = c'$. The circles of the system may therefore be written in the form

$$x^2 + y^2 + 2\lambda x + c = 0,$$

where c is constant, and λ a parameter. This is a canonical, or standard form for a coaxal system.

We note that the system now depends linearly on the circle $x^2 + y^2 + c = 0$, and the radical axis $x = 0$.

We can now easily distinguish between the intersecting and non-intersecting type of coaxal system. Intersections, if any, must lie on the radical axis $x = 0$. This meets circles of the system where $y^2 + c = 0$. If c is positive, there are no intersections, and we have the non-intersecting type of coaxal system. If c is negative, all circles of the system cut the radical axis in the same two points.

(i) $c = k^2 > 0$. Any circle of the system may be written in the form

$$(x + \lambda)^2 + y^2 = \lambda^2 - k^2.$$

For real circles, we must have $\lambda^2 \geqslant k^2$. There are two circles of zero radius in the system, with centres at $(-k, 0)$ and $(k, 0)$. These points, which we denote by L and L', are called the *limiting points* of the system. No circles of the system have their centres between L and L'. If a circle of the system cuts the line of centres in A, A', then $OA . OA' = k^2 = OL^2$, and it follows that L and L' are harmonic conjugates with respect to A and A'. Hence any circle through L and L' cuts all circles of the coaxal system orthogonally.

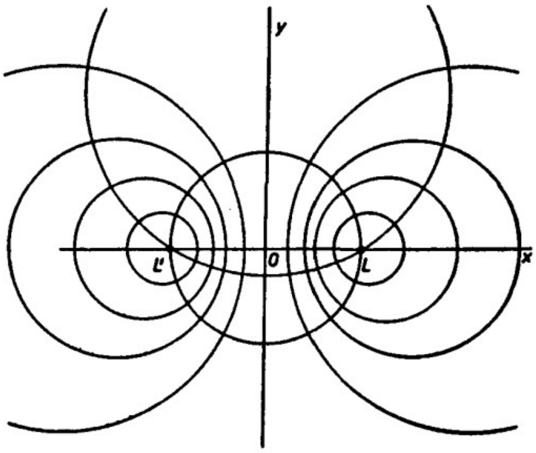

FIG. 22

(ii) $c = -k^2 < 0$. This case presents no features which are not evident geometrically.

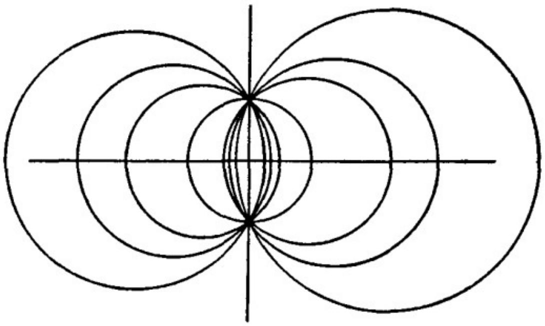

FIG. 23

(iii) $c = 0$. This can be regarded as an intermediate case.

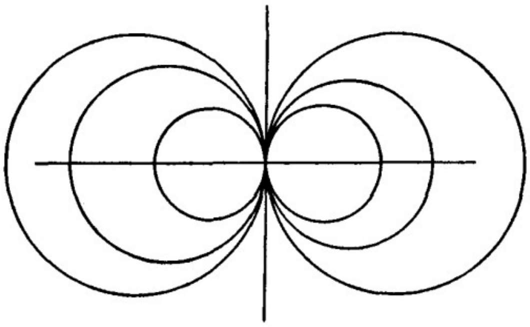

FIG. 24

All circles of the system touch the radical axis, and the point of contact may be regarded as consisting of two coincident limiting points.

We have remarked that in (i) any circle through L and L' is orthogonal to every circle of the given system. The equation of a circle through L and L' is

$$x^2 + y^2 + 2\mu y - k^2 = 0,$$

and this, of course, is a coaxal system of the intersecting type. The orthogonality relation is evident algebraically, since the condition to be satisfied, $2gg' + 2ff' - c - c' = 0$, becomes here $2\lambda . 0 + 2 . 0 . \mu - k^2 + k^2 = 0$, which is the case.

Hence, associated with every coaxal system of a given type there is a coaxal system of the opposite type, and the circles of one cut the circles of the other orthogonally. Such systems are called *conjugate systems*, for reasons which will become clear in chapter II.

9. Further properties

If we try to find the circles of the coaxal system

$$x^2 + y^2 + 2\lambda x + c = 0$$

which pass through $P(x',y')$, we see that

$$\lambda = -\frac{(x'^2 + y'^2 + c)}{2x'};$$

that is, there is a unique value of the parameter which determines the circle. Hence one circle of a coaxal system passes through a given point P. The construction of this circle is evident for intersecting systems, since a circle is determined by three points, but not so evident for a non-intersecting system. In this case we invoke the *conjugate system*, which is of the intersecting type, and draw the unique circle of this system which passes through P. We can then construct the required circle by drawing the unique circle through P which is orthogonal to the constructed circle and has its centre on the line of centres of the given coaxal system.

If we invert a coaxal system of circles, it is fairly clear that we obtain an intersecting coaxal system in the intersecting case, but this is not so clear in the non-intersecting case. However we can bring in the *conjugate system*, which is of the intersecting type, and remembering that circles which are orthogonal invert into orthogonal circles, we see that the circles of the non-intersecting system invert into circles which are orthogonal to all the circles of a coaxal system. Such a system of circles must form the conjugate coaxal system.

However, inversion is a transformation which sometimes does more than we demand of it, and the reader may feel reluctant to accept the proof indicated when we show, as we do now, that *any non-intersecting system of coaxal circles may be inverted into a system of concentric circles.* The question he will ask is: if a system of concentric circles is a coaxal system, why have we not come across it in the above treatment?

We leave the reader to ponder on this apparent paradox, and prove the theorem. Let L and L' be the limiting points of the non-intersecting coaxal system, and invert with respect to a circle centre L. Then the circles of the system invert into circles which are orthogonal to the inverses of all circles through L and L'. But these inverses are straight lines through a fixed point, the inverse of L'. Hence the coaxal system inverts into a system of concentric circles, with centre at the inverse of L'.

This theorem provides a solution of the attractive problem: given two circles $\mathscr{C}$ and $\mathscr{C}'$, one lying inside the other, can we find a chain of circles, $\mathscr{C}_1, \mathscr{C}_2, \mathscr{C}_3, \ldots, \mathscr{C}_n$, all of which touch $\mathscr{C}$ and $\mathscr{C}'$, such that $\mathscr{C}_1$ touches $\mathscr{C}_2$ and $\mathscr{C}_n$, $\mathscr{C}_2$ touches $\mathscr{C}_3$ and $\mathscr{C}_1, \ldots,$ $\mathscr{C}_n$ touches $\mathscr{C}_{n-1}$ and $\mathscr{C}_1$?

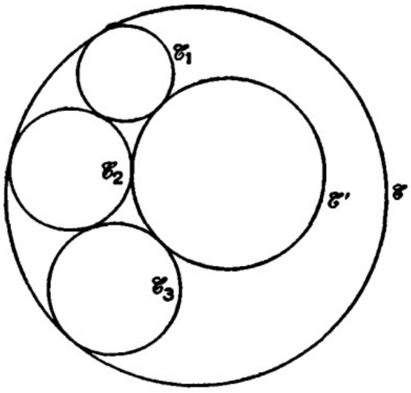

FIG. 25

Inverting $\mathscr{C}$ and $\mathscr{C}'$ into concentric circles, we see that the problem does not always have a solution, but that when there is a solution, we can begin the chain by drawing any circle which touches $\mathscr{C}$ and $\mathscr{C}'$, and can then fit in the other members of the chain in an obvious manner.

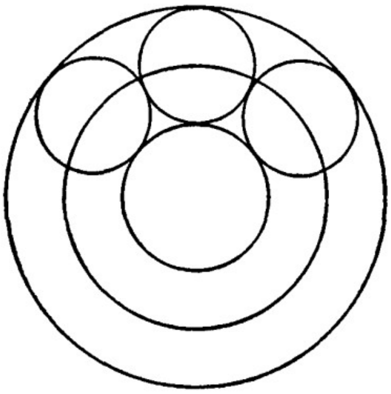

FIG. 26

We conclude this discussion of coaxal circles by considering the radical axes, in pairs, of three circles $\mathscr{C}$, $\mathscr{C}'$, $\mathscr{C}''$. The intersection of two of these radical axes is a point which has equal powers with respect to all three circles. This point is therefore on the third radical axis. Hence, if they are not parallel, the radical axes of the three pairs of circles which can be formed from three given circles are concurrent. The point of concurrence is called the *radical centre* of the three circles. The circle which has its centre at the radical centre, and radius equal to the length of the tangent from the centre to any one of the three circles, if it lies outside one, and therefore all three circles, cuts each of the three circles orthogonally and is the only circle which does this. With respect to this circle as circle of inversion, each of the three circles inverts into itself.

10. Problem of Apollonius

Given three circles $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$, to draw a circle touching all three.

We need two preliminary results:

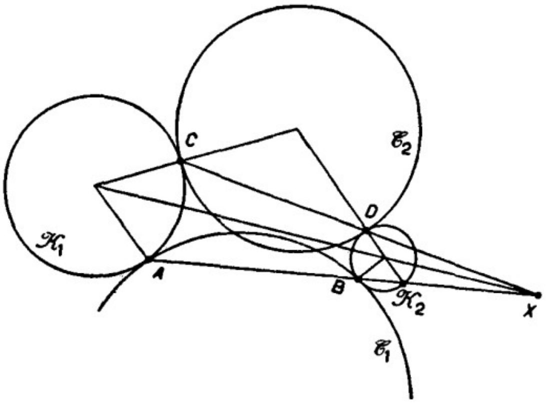

FIG. 27

(i) If two non-concentric circles $\mathscr{K}_1$, $\mathscr{K}_2$ touch two other non-concentric circles $\mathscr{C}_1$, $\mathscr{C}_2$ at A, B and C, D respectively, and if the contacts at C and D are of like[†] or unlike type according as those at A and B are, then AB and CD meet in a centre of similitude of the circles $\mathscr{K}_1$, $\mathscr{K}_2$, or they are parallel to the line of centres of these circles.

To prove this result we join the centres of $\mathscr{K}_1$, $\mathscr{K}_2$ and $\mathscr{C}_1$ and find, using the theorem of Menelaus, where AB cuts the line joining the centres of $\mathscr{K}_1$, $\mathscr{K}_2$. If the given conditions are satisfied, and we consider the triangle formed by the centres of $\mathscr{K}_1$,

---

[†] Contacts are of " like type " when both are external or both are internal.

$\mathscr{K}_2$ and $\mathscr{C}_2$, we see that CD passes through the same point X, and that this is a centre of similitude of $\mathscr{K}_1$ and $\mathscr{K}_2$.

(ii) We remarked earlier (see page 12) that $XA.XB = XC.XD$, so that X is on the radical axis of $\mathscr{C}_1$ and $\mathscr{C}_2$.

We also note that if the contacts at A and B are of like or unlike type according as those at C and D are, then the contacts at A and C are of like or unlike type according as those at B and D are. Therefore AC and BD meet at a centre of similitude of $\mathscr{C}_1$ and $\mathscr{C}_2$, and this centre is on the radical axis of $\mathscr{K}_1, \mathscr{K}_2$.

We have therefore shown that the radical axis of $\mathscr{C}_1$ and $\mathscr{C}_2$ contains a centre of similitude of $\mathscr{K}_1$ and $\mathscr{K}_2$, and the radical axis of $\mathscr{K}_1$ and $\mathscr{K}_2$ contains a centre of similitude of $\mathscr{C}_1$ and $\mathscr{C}_2$.

We now return to our problem, and assume, for simplicity, that the radii of $\mathscr{C}_1$, $\mathscr{C}_2$, $\mathscr{C}_3$ are three distinct numbers, so that all the centres of similitude exist.

Let $\mathscr{K}_0$ be a circle touching the three circles externally. Inversion from the radical centre of $\mathscr{C}_1$, $\mathscr{C}_2$, $\mathscr{C}_3$ changes these circles into themselves, and $\mathscr{K}_0$ is transformed into a circle $\mathscr{K}_1$ which is touched internally by the three circles. The joins of the points of contact of each circle $\mathscr{C}_i$ $(i = 1, 2, 3)$ with $\mathscr{K}_0$ and with $\mathscr{K}_1$ pass through the radical centre.

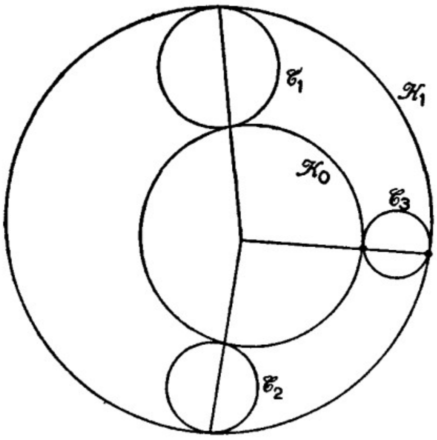

FIG. 28

The pole, for $\mathscr{C}_1$, of the line joining the points of contact of $\mathscr{K}_0$ and $\mathscr{C}_1$ and of $\mathscr{K}_1$ and $\mathscr{C}_1$ is the intersection of the tangents at these points of contact. These tangents are the radical axes of $\mathscr{K}_0$ and $\mathscr{C}_1$ and of $\mathscr{K}_1$ and $\mathscr{C}_1$, and since the radical axes of three circles, taken in pairs, are concurrent, this pole lies on the radical axis of $\mathscr{K}_0$ and $\mathscr{K}_1$.

By the reciprocal property of pole and polar, the polar of this point contains the pole, for $\mathscr{C}_1$, of the radical axis. Now the polar is the line joining the points of contact of $\mathscr{K}_0$ and $\mathscr{C}_1$ and of $\mathscr{K}_1$ and $\mathscr{C}_1$ and passes through the radical centre of $\mathscr{C}_1$, $\mathscr{C}_2$, $\mathscr{C}_3$. Since also the radical axis of $\mathscr{K}_0$ and $\mathscr{K}_1$ contains the external centres of similitude of the circles $\mathscr{C}_1$, $\mathscr{C}_2$, $\mathscr{C}_3$ taken in pairs (this was proved in (ii) above), we have the following construction, due to Gergonne:

Draw the line through the external centres of similitude of $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$, taken in pairs, and join its poles for each of these circles to the radical centre of the three circles. These joins cut the given circles in points of contact of two of the required circles.

The centres of similitude of $\mathscr{C}_1$, $\mathscr{C}_2$, $\mathscr{C}_3$ lie by threes on four lines, and each line of centres of similitude gives two tangent circles. In the most favourable case we therefore expect to find *eight* solutions of the problem of Apollonius.

We shall verify this from another point of view in chapter II.

11. Compass geometry

We conclude this chapter by showing how the straight edge may be dispensed with in the elementary constructions of Euclidean geometry.

A straight edge is used to connect two given points by a straight line. No pair of compasses will do this. At the same time the straight edge and compasses are primarily used to determine certain points. The fundamental problems in Euclidean geometry are:

(i) to find the intersections of two circles, the centre and radius of each being given;

(ii) to find the intersection of a line given by two points with a circle given by its centre and radius;

(iii) to find the intersections of two lines, each given by two points.

The solution of (i) is naturally possible using only the compasses. Problems (ii) and (iii) reduce to (i) after inversion.

Therefore, to show that all Euclidean constructions are possible using only a pair of compasses, we must show:

(a) how to find the inverse of a given point in a circle of given centre and radius;

(b) how to find the centre of a circle which is to pass through three given points.

We gave the solution of (a) in §2, page 5.

Before dealing with (b), we show how to find, using compasses only, the midpoint of the segment determined by two given points. In the first place we show how to extend a given segment AO to twice its length. Draw the circle centre O and radius OA, and mark off the chords $AP = PQ = QA' = OA$. Then AOA' is a straight line, and $AA' = 2OA$.

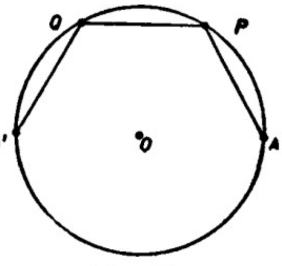

FIG. 29

We can now find the midpoint of the segment OA. Extend AO to A', where $AO = OA'$, and find the inverse of A' in the circle centre A and radius AO. If A'' is the inverse,

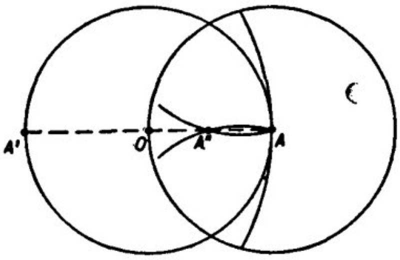

FIG. 30

$$AA''.AA' = AO^2,$$

and since $AA' = 2AO$, the point A'' is the midpoint of OA.

We can extend OA to A', where $OA' = nOA$, n being any positive integer, and the inverse of A' in the circle centre A and radius AO gives OA/n.

(b) Let A, B, C be the three given points. Invert with respect to the circle centre A and radius AB. The circle ABC inverts

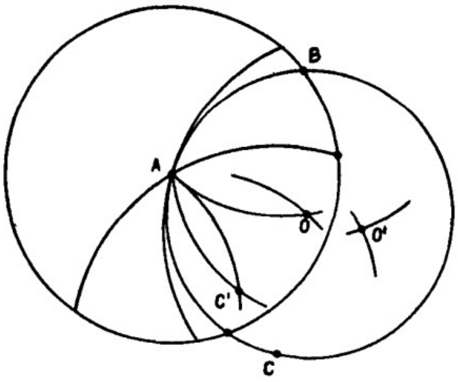

FIG. 31

into the line BC', where C' is the inverse of C in the circle of inversion. This point can be constructed. The centre of circle ABC inverts into the inverse of the centre of inversion, which is A, in the inverse of circle ABC, namely, the line BC' (see §2, page 9). The inverse of A in BC' is the geometrical image of A in BC'. This is easily constructed, as indicated in Fig. 31. If this geometrical image be O', we finally find the inverse of O' in the circle of inversion. This final point O is the centre of circle ABC.

The reader should carry out this construction for himself.

To find where two lines determined by points A,B and C,D respectively meet, we invert with respect to any suitable circle, centre O, say. If the respective inverse points are A',B' and C',D', the intersection of the circles $OA'B'$ and $OC'D'$, other than O, is the inverse of the point required. We can draw these circles, by the above construction, and find this point.

Bright students often rediscover this compass geometry for themselves, and are dashed to find that it was fully investigated, without the benefit of inversion, by Mascheroni in *La Geometria del Compasso*, Pavia, 1797.

7. Circles cutting at a given angle

We now return to the general relation (1) of the previous section, and see that the points representing circles which cut a fixed circle $\mathscr{C}'$ at an angle α or $\pi - \alpha$ satisfy the equation

$$4(x^2 + y^2 - z)(\xi'^2 + \eta'^2 - \zeta')\cos^2\alpha = (2x\xi' + 2y\eta' - z - \zeta')^2. \tag{1}$$

This represents a quadric surface, and the form of its equation shows that it has *ring-contact* with Ω along the intersection of Ω with the plane

$$2x\xi' + 2y\eta' - z - \zeta' = 0. \tag{2}$$

If the reader is unfamiliar with the idea of ring-contact he need not be disturbed, since it is only the algebraic form of (1) which will concern us. We know already that the curve in which the plane given by (2) meets Ω projects into the circle $\mathscr{C}'$ itself.

We wish to investigate the circles which cut three given circles $\mathscr{C}_1$, $\mathscr{C}_2$ and $\mathscr{C}_3$ at angles α or $\pi - \alpha$. To do this, we must examine the common intersections of the three quadric surfaces:

$$4(x^2 + y^2 - z)(\xi_r^2 + \eta_r^2 - \zeta_r)\cos^2\alpha = (2x\xi_r + 2y\eta_r - z - \zeta_r)^2 \qquad (r = 1, 2, 3).$$

For the sake of brevity we write these equations as

$$4(x^2 + y^2 - z)k_r\cos^2\alpha = X_r^2 \qquad (r = 1, 2, 3), \tag{3}$$

where k_r is a constant, and $X_r = 0$ is the polar plane of (ξ_r, η_r, ζ_r). If we equate the common value of $x^2 + y^2 - z$ in the three equations, we obtain the equations

$$\frac{X_1^2}{k_1} = \frac{X_2^2}{k_2} = \frac{X_3^2}{k_3}.$$

We note that these equations do not depend on $\cos\alpha$. If we take them in pairs, the system is equivalent to

$$\begin{cases} \sqrt{k_2}\,X_1 \pm \sqrt{k_1}\,X_2 = 0, \\ \sqrt{k_3}\,X_2 \pm \sqrt{k_2}\,X_3 = 0. \end{cases} \tag{4}$$

Taking all the possible combinations of signs, we have four sets of two linear equations in x, y, z. Since two planes determine a line, the solutions of (4) lie on four straight lines. Since $X_1 = X_2 = X_3 = 0$ automatically satisfies (4), these four lines all pass through the point determined by the intersection of the polar planes of (ξ_r, η_r, ζ_r) $(r = 1, 2, 3)$. This point represents the circle orthogonal to the three given circles.

Each one of the lines determined by (4) meets each one of the three quadrics given by (3) in the same two points. Hence there are *eight* solutions of the equations, for a given value of $\cos\alpha$, and we have proved the following theorem:

There are eight circles which intersect three given circles at a given angle α *or* $\pi - \alpha$. *As the angle* α *varies the circles vary in four coaxal systems with a common circle, the circle orthogonal to the three given circles.*

The case $\alpha = 0$ gives the solution of the problem of Apollonius (see chapter I, §10). Since each one of the lines determined by (4) gives two solutions of (3), each one of the four coaxal systems contains two of the circles which satisfy the given conditions.

8. Representation of inversion

Let A, A' be inverse points in a circle $\mathscr{C}$. Then $\mathscr{C}$ is orthogonal to any circle through A and A', and $\mathscr{C}$ is a member of the coaxal system which is determined by the limiting points A, A'. Let P represent the circle $\mathscr{C}$. The zero circles centres A, A' are represented by points on Ω. By the remark above, P is collinear with these two points on Ω.

Since P is regarded as fixed, and A, A' as variable, we have the following method for finding the inverse, in a given circle $\mathscr{C}$, of a given curve, $\mathscr{D}$, say:

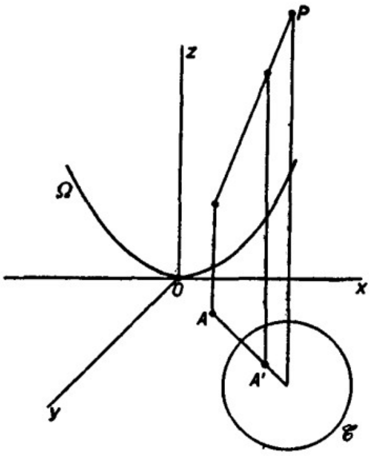

FIG. 40

Erect perpendiculars to the plane Oxy at the points of $\mathscr{D}$, and let $\mathscr{E}$ be the curve in which these perpendiculars meet Ω. The cone of lines joining P to the points of $\mathscr{E}$ meets Ω in a further curve $\mathscr{E}'$. Project $\mathscr{E}'$ down on to the plane Oxy. The resulting curve $\mathscr{D}'$ is the inverse of $\mathscr{D}$ in $\mathscr{C}$.

We remark that this construction shows at once that the eight circles which were discussed in the preceding section are inverse in pairs in the common orthogonal circle of the three circles. Since each of the three given circles inverts into itself with respect to the common orthogonal circle, this result is to be expected.

If the curve $\mathscr{D}$ to be inverted is a circle, we know that the curve $\mathscr{E}$ obtained by projecting it on to Ω is a plane section. The cone of lines joining P to the points of $\mathscr{E}$ is a quadric cone, and since the inverse of a circle is another circle, this cone meets Ω again in a further plane section $\mathscr{E}'$. Again, a circle, the circle of inversion and the inverse circle are coaxal, so that we obtain the theorem:

A quadric cone which meets Ω in one plane section will meet it again in another plane section, and the poles of the two plane sections are collinear with the vertex of the cone.

The more advanced reader will realize that this is a *projective* theorem, and is therefore true for any quadric Ω.

9. The envelope of a system

We may measure the complexity of a system of circles by the complexity of the curve in E_3 which represents the system. From this point of view a coaxal system of circles is the simplest kind of system, since a line is the simplest curve in E_3. A coaxal system of circles has no *envelope*: that is, there is no curve touched by all circles of the system. For intersecting systems we may, if we wish, say that the envelope consists of the two points common to all circles of the system. But interesting envelopes only appear when we consider *conic systems of circles*.

A conic system of circles is one represented by a conic in E_3. A conic is a plane curve, and this plane will have a pole with respect to Ω. This pole represents a circle which is orthogonal to all the circles of the conic system. Again, the projection of the conic on to the plane Oxy is, except in one special case, a conic, and gives the locus of centres of circles of the conic system.

Hence the centres of circles of a conic system lie on a conic, and all circles of the system are orthogonal to a fixed circle.

Euler and Differentials[1]

Anthony P. Ferzola

Two recent articles by Dunham [5] and Flusser [10] have presented examples of Leonhard Euler's work in algebra. Both papers are a joy to read; watching Euler manipulate and calculate with incredible facility is a pleasure. A modern mathematician can see the logical flaws in some of the arguments, yet at the same time be aware that the mind behind it all is that of a unique master.

These two articles reminded me how much fun it is to read Euler. In researching the evolution of the differential a few years ago, I found the work of Euler refreshingly different from that of other seventeenth- and eighteenth-century mathematicians. One can read about Euler's use and misuse of infinite series in most histories of mathematics (e.g., [2, pp. 486–490]). This paper offers a glimpse at how Euler used infinitesimals and infinite series to compute differentials for the elementary functions encountered in a typical undergraduate calculus sequence. I hope the reader of this brief survey of Euler's work with differentials will seek out original sources such as [8] and [9]. As Harold Edwards [7] has cogently argued, we have much to learn from reading the masters.

Euler and the 18th Century

Euler (1707–1783) was the most prolific and one of the most influential mathematicians who ever lived. He made major contributions to both pure and applied mathematics and his collected works amount to over 70 volumes. So strong was his influence that historians like Boyer [2] and Edwards [6] refer to the eighteenth century as the Age of Euler.

Euler made the function concept fundamental in analysis. He saw a function as both any quantity depending on variables and also as any algebraic combination of constants and variables (including infinite sums or products). This is obviously not a modern definition of a function. Still, Euler used his function concept to maximal advantage. As we examine some of Euler's computations, keep in mind the immense insight and unity he achieved with the function approach—a point of view we now take for granted.

---

[1] Reprinted from the *College Mathematics Journal*, Vol. 25, March, 1994, pp. 102–111. This article received the George Pólya Award in 1995.

In his *Introducio in analysin infinitorum* (1748), one sees the first systematic interpretation of logarithms as exponents. Prior to Euler, logarithms were typically viewed as terms of an arithmetic series in one-to-one correspondence with terms of a geometric series [3]. Euler viewed trigonometric functions as numerical ratios rather than as ratios of line segments. He also studied properties of the elementary transcendental functions by the frequent use of their infinite series expansions [6, p. 270]. Euler often used infinite series indiscriminately, without regard to questions of convergence.

Euler's understanding and use of differentials within the framework of functions is the focus of this paper. Before presenting his work, a word about the differential before Euler.

For Leibniz (1646–1716) the differentials dx and dy were, as the name suggests, (infinitesimal) differences in the abscissa x and the ordinate y, respectively [4, pp. 70–76]. The infinitesimal was considered to be a number smaller than any positive number. The omission of the "even smaller" higher-order infinitesimals such as $(dx)^2$ or $dx\,dy$, which were deemed negligible relative to dx and dy, was basic to his methods. So powerful were the notation and methods that the differential calculus was truly a *differential* calculus for nearly one and a half centuries: The differential (and not the derivative) was the main object of study.

Leibniz gave other interpretations of the differential, but the mathematicians working in the early eighteenth century tended to favor Leibniz's formulation of a differential as an infinitesimal. It appears in the work of Johann Bernoulli (1667–1748) and in the first calculus textbook, *Analyse des infiniment petits pour l'intelligence des lignes courbes* (1696), which was written by L'Hôpital and which made free use of Bernoulli's ideas (see [18, p. 315]). Euler was one of Bernoulli's pupils.

Many of Euler's results and infinite series discussed below were known to Newton, Leibniz, Bernoulli, and others. Euler's work with differentials is unique, however, in his definition of infinitesimals as absolute zeros and in his heavy reliance on infinite series to *develop* his differential calculus.

Differentials as Absolute Zeros

In his *Institutiones calculi differentialis* (1755), Euler stated: "To those who ask what the infinitely small quantity in mathematics is, we answer it is actually equal to zero" [18, p. 384]. Euler felt that the view of the infinitesimal as zero adequately removed the mystery and ambiguity of statements such as "The infinitesimal is smaller than any given quantity" or the postulate of Johann Bernoulli that "Adding an infinitesimal to a quantity leaves the quantity unchanged."

Euler then said that the quotient $0/0$ can actually take on any value because

$$n \cdot 0 = 0$$

for all real n and therefore, he concluded,

$$\frac{n}{1} = \frac{0}{0}. \tag{1}$$

He noted that if two zeros can have an arbitrary ratio, then different symbols should be used for the zero in the numerator and the zero in the denominator of the fraction on the right-hand side of equation (1). It is here that Euler introduced the Leibnizian notation of differentials.

Euler denoted an infinitely small quantity by dx. Here $dx = 0$ and $a\,dx = 0$ for any finite quantity a. But for Euler these two zeros are different zeros that cannot be confused when the ratio $a\,dx/dx = a$ is investigated [18, p. 385]. In a similar way dy/dx can denote a finite ratio even though dx and dy are zero. "Thus for Euler the calculus was simply the determination of the ratios of evanescent increments—a heuristic procedure for finding the value of the expression 0/0" [1].

The neglect of higher-order infinitesimals was also explained employing quotients. Noting that $dx = 0$ and $(dx)^2 = 0$, where $(dx)^2$ is a zero (or infinitesimal) of second order, Euler reasoned that

$$dx + (dx)^2 = dx$$

because

$$\frac{dx + (dx)^2}{dx} = 1 + dx = 1.$$

By the same reasoning, Euler established that

$$dx + (dx)^{n+1} = dx$$

for all $n > 0$. The omission of higher-order differentials was frequently utilized by Euler in finding the differential dy, where y is a function of x.

Computations with Elementary Functions

The computations discussed in this section are all found in Euler's *Institutiones calculi differentialis*. Their most noteworthy feature is the use of power series expressions for functions from the outset, with no mention of questions of convergence. Thus, whereas in modern textbooks the justification of such infinite series expansions is an advanced topic in differential calculus, for Euler they were the foundation for the calculation of derivatives.

To find dy if $y = x^n$ (n any real number), Euler used the binomial expansion [9, p. 99]. If x is increased by an infinitesimal amount dx, then y experiences a change of dy where

$$\begin{aligned} dy &= (x + dx)^n - x^n \\ &= nx^{n-1}\,dx + \frac{n(n-1)}{1}\,x^{n-2}\,(dx)^2 + \cdots \\ &= nx^{n-1}\,dx \end{aligned}$$

upon the omission of the higher-order infinitesimals $(dx)^2$, etc. Newton and Leibniz did similar computations for finding the derivative of $y = x^n$, Leibniz using a comparable differential argument while Newton worked with fluxions [6, p. 192]. Within the rigorous context of

$$\lim_{\Delta x \to 0} \frac{(x + \Delta x)^n - x^n}{\Delta x}$$

we all use the essence of this computation (for positive integer powers of x) in our first semester calculus courses.

Euler derived the product rule as follows:

$$\begin{aligned} d(pq) &= (p+dp)(q+dq)-pq \\ &= p\,dq + q\,dp + dp\,dq \\ &= p\,dq + q\,dp \end{aligned}$$

where the last step is due to the omission of the higher-order infinitesimal $dp\,dq$. Similar computations were done by Leibniz [4, p. 143]. This argument is analogous to the proof of the product rule still found in a few present-day textbooks (e.g., [12]).

Euler's derivation of the quotient rule is unique in its use of a geometric series [9, p. 103]:

$$\begin{aligned} \frac{1}{q+dq} &= \frac{1}{q}\left(\frac{1}{1+dq/q}\right) \\ &= \frac{1}{q}\left(1-\frac{dq}{q}+\frac{dq^2}{q^2}-\cdots\right) \\ &= \frac{1}{q}-\frac{dq}{q^2}. \end{aligned}$$

Then

$$\begin{aligned} d\left(\frac{p}{q}\right) &= \frac{p+dp}{q+dq}-\frac{p}{q} \\ &= (p+dp)\frac{1}{q+dq}-\frac{p}{q} \\ &= (p+dp)\left(\frac{1}{q}-\frac{dq}{q^2}\right)-\frac{p}{q} \\ &= \frac{dp}{q}-\frac{p\,dq}{q^2} \\ &= \frac{q\,dp-p\,dq}{q^2}. \end{aligned}$$

In chapter 6, Euler found the differentials of transcendental functions. For computing the differential of the natural logarithm (which he denoted by the single letter "ℓ" but which we will denote by the usual "log"), Euler used Mercator's series [9, p. 122]:

$$\log(1+z) = z-\frac{z^2}{2}+\frac{z^3}{3}-\cdots.$$

Given $y = \log(x)$ then

$$\begin{aligned} dy &= \log(x+dx)-\log(x) \\ &= \log\left(1+\frac{dx}{x}\right) \\ &= \frac{dx}{x}-\frac{(dx)^2}{2x^2}+\frac{(dx)^3}{3x^3}-\cdots \\ &= \frac{dx}{x}. \end{aligned}$$

To illustrate the chain rule, Euler did many examples. For instance, if $y = \log(x^n)$ then letting $p = x^n$ yields $y = \log(p)$, which implies that $dy = dp/p$ where $dp = nx^{n-1}\,dx$. Thus $dy = n\,dx/x$.

Euler's computation of dy for $y = \log(x)$ can be found in a modern nonstandard analysis text [15, p. 65]. This may seem unremarkable since nonstandard analysis was developed by Abraham Robinson in the mid-twentieth century to place the notion of infinitesimals and their manipulation on solid logical ground. In fact, it is rare to find nonstandard analysis arguments that are exactly like Euler's, because nonstandard analysis arguments are rarely done in the context of infinite series (see [11] and [16]).

As an example of Euler's work with trigonometric functions, consider the computation of dy for $y = \sin x$ [9, p. 132]. For this purpose he explicitly used the sine and cosine series

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \cdots \tag{2}$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \cdots \tag{3}$$

to show that $\sin(dx) = dx$ and $\cos(dx) = 1$. He obtained these results by substituting dx into (2) and (3) and ignoring higher-order differentials. He also employed the trigonometric identity

$$\sin(a + b) = \sin a \cos b + \sin b \cos a. \tag{4}$$

Thus, using (4):

$$\begin{aligned} dy &= \sin(x + dx) - \sin x \\ &= \sin x \cos dx + \sin dx \cos x - \sin x \\ &= \sin x + \cos x\, dx - \sin x \\ &= \cos x\, dx. \end{aligned}$$

This is the most beautifully efficient computation of all those presented, especially when compared to the usual limit computation of the derivative of $y = \sin x$. There one needs to work as follows:

$$\begin{aligned} \lim_{\Delta x \to 0} \frac{\sin(x + \Delta x) - \sin x}{\Delta x} &= \lim_{\Delta x \to 0} \frac{\sin x \cos(\Delta x) + \sin(\Delta x) \cos x - \sin x}{\Delta x} \\ &= \cos x \lim_{\Delta x \to 0} \frac{\sin(\Delta x)}{\Delta x} + \sin x \lim_{\Delta x \to 0} \frac{\cos(\Delta x) - 1}{\Delta x} \end{aligned}$$

Then $y' = \cos x$ is obtained using two limits (which must be proven):

$$\lim_{x \to 0} \frac{\sin x}{x} = 1 \tag{5}$$

and

$$\lim_{x \to 0} \frac{\cos x - 1}{x} = 0.$$

The first of these limits is captured in Euler's equation $\sin(dx) = dx$. The second limit is comparable to Euler's equation $\cos(dx) = 1$ or $\cos(dx) - 1 = 0$. Although

Euler's derivation is computationally more compact than the standard modern approach, the latter is logically sound. Any method for differentiating the sine function must deal in particular with (5). This is proven geometrically, since in the standard modern approach one defines at the outset the geometric meaning of the trigonometric functions (i.e., cosine and sine parametrize the unit circle). The proof of (5) is relatively easy when compared to the difficulty involved in showing the geometric meaning of the functions Euler defined (without regard to questions of convergence) as the sums of the power series (2) and (3).

In Euler's three-volume *Institutiones calculi integralis* (1768–1770), he defined integration, like Leibniz and Johann Bernoulli, as the formal inverse of the differential. He used the integral symbol and wrote, for example,

$$\int nx^{n-1}\,dx = x^n$$

$$\int \frac{dx}{x} = \log x$$

$$\int \cos x\,dx = \sin x$$

all plus or minus an appropriate constant. The first volume of this work reads like a modern calculus textbook chapter on techniques of integration. Integration by substitution, by parts, by partial fractions, and by trigonometric substitution are all illustrated in a logical and systematic way. Undoubtedly, Euler's well-organized and all-encompassing use of differentials in a function context did much to solidify the popularity of the differential and integral notations on the continent.

The Total Differential

Euler's *Institutiones calculi differentialis* was the first systematic exposition of the calculus of functions of several variables. He understood a function of n variables to be any finite or infinite expression involving these variables. As soon as he introduced these functions, Euler addressed the question of the relationship among the differentials of all the variables involved.

He obtained the result that if

$$V = f(x, y, z)$$

then

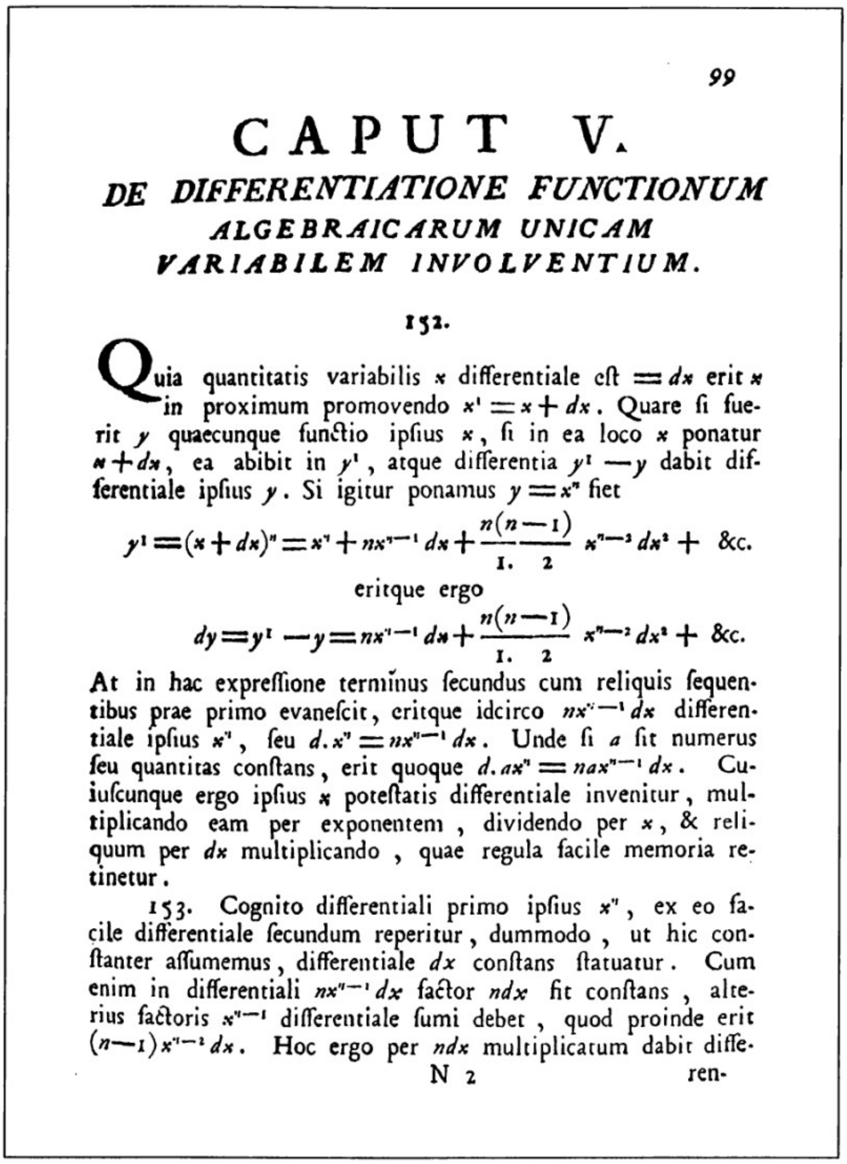
$$dV = p\,dx + q\,dy + r\,dz,$$

where p, q, and r are all functions of x, y, and z [9, pp. 144–145]. He arrived at this formula in an interesting way. If X is a function of x alone and is increased by an infinitesimal amount dx, then

$$dX = P\,dx$$

by the usual one-variable argument. Similarly, if Y and Z are functions of y alone and z alone respectively, then

$$dY = Q\,dy$$



99

Title page, Chapter 5 of *Institutiones calculi differentialis*

and

$$dZ = R\,dz.$$

If $V = X + Y + Z$ (i.e., a special function of three variables) then

$$\begin{aligned} dV &= dX + dY + dZ \\ &= P\,dx + Q\,dy + R\,dz. \end{aligned}$$

If $V = XYZ$, then

$$dV = (X + P\,dx)(Y + Q\,dy)(Z + R\,dz) - XYZ.$$

This simplifies (upon omission of higher-order differential terms such as $ZPQ\,dx\,dy$) to

$$dV = YZP\,dx + XZQ\,dy + XYR\,dz.$$

From these two examples, Euler expected that any algebraic expression of x, y, and z has differential

$$dV = p\,dx + q\,dy + r\,dz \tag{6}$$

because a function of three variables can be thought of as a sum of products of these variables. He generalized the result for any number of variables [9, p. 146].

Later in the same work, he addressed the concept of partial differentiation [9, pp. 156–157]. If y and z are held constant, then by equation (6)

$$dV = p\,dx$$

as there is no change in y or z. (Notice how, for Euler, no change in y is not the same as saying dy is the infinitesimal change in y, even though he defined infinitesimals as being zero.) He then wrote

$$p = (dV/dx),$$

where the parentheses about the quotient remind one that p equals the differential of V (with only the x being variable) divided by dx. Similar meanings apply to $q = (dV/dy)$ and $r = (dV/dz)$. This was Euler's notation and understanding of the concept of partial derivatives. The current symbol ∂ dates from the 1840's [14]. Obviously, (6) becomes

$$dV = (dV/dx)\,dx + (dV/dy)\,dy + (dV/dz)\,dz,$$

although Euler did not explicitly write this.

It is worth noting that Euler's exposition of differentials for functions of several variables immediately followed his work with differentials for functions of one variable. Exploring the differential calculus for both single and multivariable functions before passing on to integration is an old idea which I think has merit. It gives the calculus sequence a stronger focus and unity, by concentrating effort on one basic concept (the derivative) in various settings before moving on to its inverse. A recent textbook by Small and Hosack [17] takes this approach. Perhaps we will see more of this, especially since computer algebra systems such as *Derive*, *Maple*, and *Mathematica* have taken the pain out of such tasks as surface sketching.

Differentials in Multiple Integrals

Euler frequently let his readers in on his thought processes, even when the procedures seemed fruitless. This was mathematics being done for all to see, not a slick modern textbook treatment. There was no taking down the scaffolding *à la* Gauss.

Euler, in *De formulis integralibus duplicatis* (1769), gave one of the first clear discussions of double integrals. In the first half of the eighteenth century, $\iint f(x, y)\,dx\,dy$ denoted the solution of $\partial^2 z/\partial x\,\partial y = f(x, y)$ obtained by antidifferentiation. Euler supplemented this by providing a (thoroughly modern) procedure for evaluating definite double integrals over a bounded domain **R** enclosed by arcs in the xy plane. Euler used iterated integrals:

$$\iint_{\mathbf{R}} f(x, y)\, dx\, dy = \int_a^b dx \int_{f_1(x)}^{f_2(x)} z\, dy,$$

where $z = f(x, y)$. For $z > 0$, Euler saw this as a volume, since $\int z\, dy$ gives the area of a "slice" (parallel to the y-axis) of the three-dimensional region above **R** and under $z = f(x, y)$, and the following integration with respect to x "adds up the slices" to yield the volume [8, p. 293]. This is perhaps the first time Leibniz's powerful differential notation was used in tandem with a volume argument employing Cavalieri's method of indivisibles [2, p. 361].

Euler also interpreted $dx\, dy$ as an "area element" of **R**. That is, **R** is made up of an infinite set of infinitesimal area elements $dx\, dy$. This is most clearly seen when Euler attempted to change variables [8, pp. 302–303]. And it was here that Euler ran into difficulties.

He reasoned that if $dx\, dy$ is an area element and we change variables via the transformation

$$\begin{aligned} x &= x(t, v) = a + mt + v\sqrt{1 - m^2} \\ y &= y(t, v) = b + t\sqrt{1 - m^2} - mv \end{aligned}$$

(a translation by the vector (a, b), a clockwise rotation through the angle α, where $\cos\alpha = m$, and a reflection through the x-axis), then $dx\, dy$ should equal $dt\, dv$. But

$$\begin{aligned} dx &= m\, dt + dv\sqrt{1 - m^2} \\ dy &= dt\sqrt{1 - m^2} - m\, dv \end{aligned}$$

and multiplication gives

$$dx\, dy = m\sqrt{1 - m^2}\,(dt)^2 + (1 - 2m^2)\, dt\, dv - m\sqrt{1 - m^2}\,(dv)^2.$$

Euler rejected this as wrong and meaningless. (How many calculus students wonder, explicitly or implicitly, why we cannot just multiply the differential forms for dx and dy?) Euler decided to attack the problem in a formal non-geometric way, not using area elements but rather by changing variables one at a time (for details, see [13]). In this way he arrived at the correct general result:

$$\iint f(x, y)\, dx\, dy = \iint f\big(x(t, v), y(t, v)\big) \left|\frac{\partial(x, y)}{\partial(t, v)}\right| dt\, dv.$$

In 1899, another great mathematician with a computational flair, Élie Cartan, arrived at the straightforward multiplicative result Euler sought, by using Grassmann's exterior product with differential forms. This is a formal product where the usual distributive laws hold but with the conditions that

$$dx\, dx = dy\, dy = 0$$

and

$$dx\, dy = -dy\, dx$$

(see [17, p. 514], and [13]). Thus, for Euler's differentials

$$\begin{aligned} dx\,dy &= \left(m\,dt + dv\sqrt{1-m^2}\right)\left(dt\sqrt{l-m^2} - m\,dv\right) \\ &= dt\,dt\,m\sqrt{1-m^2} - m^2\,dt\,dv + (1-m^2)\,dv\,dt - dv\,dv\,m\sqrt{1-m^2} \\ &= -m^2\,dt\,dv + dv\,dt(1-m^2) \\ &= -m^2\,dt\,dv - dt\,dv(1-m^2) \\ &= -dt\,dv. \end{aligned}$$

The minus sign appears because the transformation (involving a reflection) does not preserve orientation. In general, given any transformation from the tv-plane to the xy-plane, the exterior product yields

$$dx\,dy = \frac{\partial(x,y)}{\partial(t,v)}\,dt\,dv.$$

Conclusion

Even in this rudimentary survey of Euler's work with differentials in calculus, it is fascinating to watch a genius grapple with an ambiguous concept (infinitesimal) and attempt to clarify it (absolute zero)—however flawed the attempt. Reading Euler has enriched my teaching of the calculus by keeping me mindful that my students are tackling a subject whose foundations humbled the greatest minds of the past. Even the seemingly fruitless paths can be instructive, as we have seen. It took mathematicians about 150 years to come up with the exterior product for differential forms that Euler needed for the change of variables formula in multiple integrals. How many other Eulerian dead ends may be worth pursuing? Again, the advice of Harold Edwards [7] points the way for the teacher and the researcher: "Read the masters!"

data 07.05.2020

Gravitation is by far weakest × of the three interactions at atomic scale, where electromagnetic interactions dominate.

Albert Einstein não conseguiu fazer a unificação das forças fundamentais pois considerou a gravidade como uma força fundamental e não uma consequência das 3 forças fundamentais de interação do Universo.

General relativity generalizes special relativity and refines Newton's law of universal gravitation

↳ descreveu o efeito das 3 forças fundamentais do Universo e não uma força em si mesma (independente), mas decorrentes daquelas.

providing a unified description of gravity as a geometric property of space and time (spacetime).

In particular the curvature of spacetime is directly related to the energy and momentum of whatever (tanto faz) matter and radiation are present.

Light Cone:

Geometric Newton → classical mechanics is a limiting case of special relativity

data 07.05.2020
8

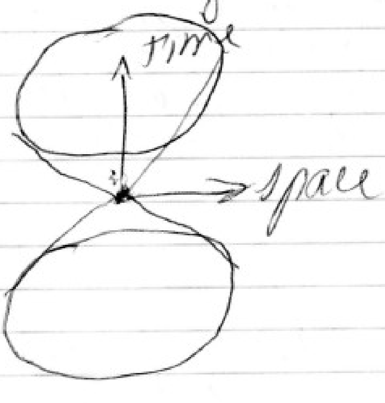
mechanics. In the language of symmetry, where gravity can be neglected, physics is Lorentz invariant (Hendrik Lorentz) as in special relativity rather than Galilei invariant as in classical mechanics.

The defining symmetry of special relativity ~~th~~ is the Poincaré group, which includes translations, rotations and boosts.

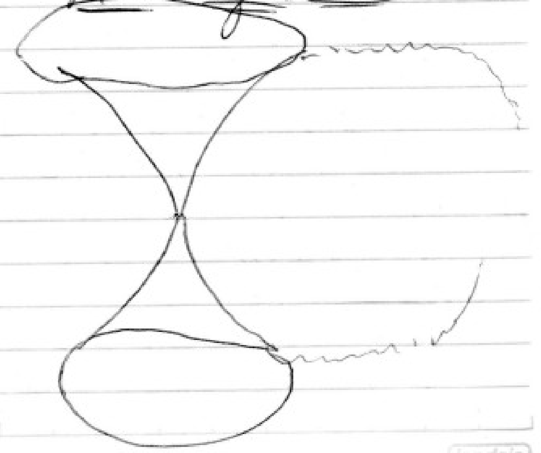
The differences between the two become significant when dealing with speeds approaching the speed of light and with high-energy phenomena.

A velocidade da luz é definida como uma constante universal, mas esta não absolutamente constante, pois a sua velocidade depende do meio em que trafega e com base nas 3 leis fundamentais de interações, aplicáveis a curvatura do espaço-tempo.

Voltando (Light cone)



Meu: light cone



07 05 2020

With Lorentz symmetry additional* structures are defined by the set of light cone. These sets are observer-independent.

In conjunction with the world lines of freely falling particles, the light-cones can be used to reconstruct the space-time's semi-Riemannian metric, at least up to a positive scalar factor.

In mathematical terms, this defines a conformal structure or conformal geometry.

↳ The conformal isometries of a domain therefore (portanto) consist of holomorphic self-maps. In particular, on the conformal compactification - the Riemann Sphere - the conformal transformation are given by the Möbius transformations

(o meu é em 3D
2 cone invertido [illegible]

reta, mas na curvatura tempo-espaço não há uma reta perpendicular ao plano em que houve a transformação.

$$z \rightarrow \frac{az+b}{cz+d}$$

where ad-bc is nonzero.

↳ can be visualized as the complex number plane wrapped around a sphere (by some form of stereographic projection).

Important:

Stereographic projection is conformal, meaning that it preserves the angles at which curves cross each other. Stereographic projection does not preserve area. In general, the area of a region of sphere does not equal the area of its projection onto the plane.

$dA = \frac{4}{(1+X^2+Y^2)^2}\, dX\,dY$. Along the unit circle $X^2+Y^2=1$, there is no inflation of area in the limit, giving a scale factor of 1. Near (0,0) areas are inflated by a factor of 4, and near infinity areas are inflated by arbitrarily small factors. The metric space is given in (X,Y) coordinates by $\frac{4}{(1+X^2+Y^2)^2}(dX^2+dY^2)$, and is the unique formula found in Bernhard Riemann's Habilitationsschrift on the foundations of geometry, delivered at Göttingen in 1854, and entitled
Über die Hypothesen welche der Geometrie zu Grunde liegen.

Source: www.maths.tcd.ie/pub/HistMath/People/Riemann/Geom/Geom.pdf.
Source: https://www.emis.de/classics/Riemann/
→ the Mathematical Papers of Georg Friedrich Bernhard Riemann.

No map from the sphere to the plane can be both conformal and area-preserving. If it were, then it would be a local isometry and would preserve Gaussian curvature.
→ is an intrinsic measure of curvature, depending only on ~~th~~ distances that are measured on the surface, not on the way it is isometrically embedded in Euclidean space. This is content of the Theorema egregium (1827).

g) Palais_Fundamental Theorem.pdf

Total Curvature (Gaussian Curvature) The surface integral of the Gaussian curvature over some region of a surface is called the total curvature. The total curvature of a geodesic triangle equals the deviation of the sum of its angles from π. The sum of the angles of a triangle on a surface of positive curvature will exceed π, while the sum of the angles of a triangle on a surface of negative curvature will be less than π. On a surface of zero curvature, such as the Euclidean plane, the angles will sum to precisely π radians. $\sum_{i=1}^{3} \theta_i = \pi + \iint_T K \, dA$

o). Gauss-Bonnet theorem
cont. ... Gaussian curvature. The sphere and the plane have different Gaussian curvatures, so this is impossible.

Circles on the sphere that do not pass through the point of projection are projected to circles on the plane. Circles on the sphere that do not pass through the point of projection are projected to straight lines on the plane. These lines are sometimes thought of as circles through the point at infinity, or circles of infinite radius. All lines in the plane, when transformed to circles on the sphere by the inverse of stereographic projection, meet at the projection point. Parallel lines, which do not intersect in the plane, are transformed to circles tangent at projection point. Intersecting lines are transformed to circles that

data 07.05.2020

intersect transversally at two points in the sphere one of which is the projection point.

Cross Section: A graph of $z=x^2+xy+y^2$. For the partial derivative at (1,1,3) that leaves y constant, the corresponding tangent line is parallel to the xz plane. Observamos uma curvatura da superfície, compare esta curvatura com as equações dA da Stereographic Projection. ✡.

observar que o ponto inicial de referência deverá ser alterado para o ponto inicial do Big Bang, ou seja para o momento em que ocorreu o Big Bang mas havendo a alteração do modelo utilizado para o desenvolvimento do Universo.

As 3 forças fundamentais de interação do Universo geram como efeito a gravidade, como uma consequência "sine qua non" da curvatura do Universo, gerada em decorrência destas 3 forças fundamentais universais e não em decorrência direta da gravidade, mas indiretamente,

07.05.2020

Speed of light: In 1865, James Clerk Maxwell proposed that light was an electromagnetic wave, and therefore travelled at the speed c appearing in his theory of electromagnetism. In 1905, Albert Einstein postulated that the speed of light c with respect to any inertial frame is a constant and is independent of the motion of the light source. c = celeritas

☆ In 1856, Wilhelm Eduard Weber and Rudolf Kohlrausch had used c for a different constant later shown to equal √2 times the speed of light in vacuum.

Poincaré group: first defined by Hermann Minkowski (1908) as the group of Minkowski spacetime isometries

↳ ignoring the effects of gravity (i.e) Minkowski space → the presence of gravity spacetime is described by a curved 4-dimensional manifold for which the tangent space to any point is a 4-dimensional Minkowski space. Thus, the structure of Minkowski space is still essential in the description of general relativity.

Hyperbolic stereographic projection

" Red circular arc is geodesic in Poincaré disk model; it projects to the brown geodesic on the green hyperboloid.

Curvature: Gaussian Curvature

Formally, Gaussian curvature only depends on the Riemann metric of the surface. This is Gauss's celebrated Theorema Egregium, which he found while concerned with geographic surveys and mapmaking.

Gaussian curvature K at the point P can be computed by the Bertrand–Diguet–Puiseux Theorem as

$$K = \lim_{r \to 0^+} 3\left(\frac{2\pi r - C(r)}{\pi r^3}\right).$$

Gauss' Theorema Egregium

One of Gauss' most important discoveries about surfaces is that the Gaussian curvature is unchanged when the surface is bent without stretching. Gauss called this result 'egregium', and the Latin word for 'remarkable' has remained attached to his theorem ever since. We shall deduce the Theorema Egregium from two results which relate the first and second fundamental forms of a surface, and which have other important consequences.

10.1 The Gauss and Codazzi–Mainardi equations

It is natural to ask if there are any relations between the first and second fundamental forms of a surface. Note that, by Examples 6.1.2, 6.1.4, 7.1.1 and 7.1.2, the plane and the unit cylinder, when suitably parametrized, have the same first fundamental form but different second fundamental forms, and so the second fundamental form certainly cannot be 'deduced' from the first. Nevertheless, there are some nontrivial relations between the two forms.

Proposition 10.1.1 (Codazzi–Mainardi Equations)

Let

$$Edu^2 + 2Fdudv + Gdv^2 \quad \text{and} \quad Ldu^2 + 2Mdudv + Ndv^2$$

Andrew Pressley, *Elementary Differential Geometry: Second Edition*,
Springer Undergraduate Mathematics Series, DOI 10.1007/978-1-84882-891-9_10,
© Springer-Verlag London Limited 2010

be the first and second fundamental forms of a surface patch $\boldsymbol{\sigma}(u, v)$, and define the Christoffel symbols as in Proposition 7.4.4. Then,

$$\begin{aligned} L_v - M_u &= L\Gamma_{12}^1 + M(\Gamma_{12}^2 - \Gamma_{11}^1) - N\Gamma_{11}^2, \\ M_v - N_u &= L\Gamma_{22}^1 + M(\Gamma_{22}^2 - \Gamma_{12}^1) - N\Gamma_{12}^2. \end{aligned} \tag{10.1}$$

Proposition 10.1.2 (Gauss Equations)

If K is the Gaussian curvature of the surface patch $\boldsymbol{\sigma}(u, v)$ in the preceding proposition, then

$$\begin{aligned} EK &= (\Gamma_{11}^2)_v - (\Gamma_{12}^2)_u + \Gamma_{11}^1\Gamma_{12}^2 + \Gamma_{11}^2\Gamma_{22}^2 - \Gamma_{12}^1\Gamma_{11}^2 - (\Gamma_{12}^2)^2 \\ FK &= (\Gamma_{12}^1)_u - (\Gamma_{11}^1)_v + \Gamma_{12}^2\Gamma_{12}^1 - \Gamma_{11}^2\Gamma_{22}^1 \\ FK &= (\Gamma_{12}^2)_v - (\Gamma_{22}^2)_u + \Gamma_{12}^1\Gamma_{12}^2 - \Gamma_{22}^1\Gamma_{11}^2 \\ GK &= (\Gamma_{22}^1)_u - (\Gamma_{12}^1)_v + \Gamma_{22}^1\Gamma_{11}^1 + \Gamma_{22}^2\Gamma_{12}^1 - (\Gamma_{12}^1)^2 - \Gamma_{12}^2\Gamma_{22}^1. \end{aligned}$$

Proof

We prove both propositions simultaneously. Write down the equation $(\boldsymbol{\sigma}_{uu})_v = (\boldsymbol{\sigma}_{uv})_u$, using Proposition 7.4.4 for $\boldsymbol{\sigma}_{uu}$ and $\boldsymbol{\sigma}_{uv}$:

$$\begin{aligned} &(\Gamma_{11}^1\boldsymbol{\sigma}_u + \Gamma_{11}^2\boldsymbol{\sigma}_v + L\mathbf{N})_v = (\Gamma_{12}^1\boldsymbol{\sigma}_u + \Gamma_{12}^2\boldsymbol{\sigma}_v + M\mathbf{N})_u, \\ \therefore \quad &\left(\frac{\partial\Gamma_{11}^1}{\partial v} - \frac{\partial\Gamma_{12}^1}{\partial u}\right)\boldsymbol{\sigma}_u + \left(\frac{\partial\Gamma_{11}^2}{\partial v} - \frac{\partial\Gamma_{12}^2}{\partial u}\right)\boldsymbol{\sigma}_v + (L_v - M_u)\mathbf{N} \\ &= \Gamma_{12}^1\boldsymbol{\sigma}_{uu} + (\Gamma_{12}^2 - \Gamma_{11}^1)\boldsymbol{\sigma}_{uv} - \Gamma_{11}^2\boldsymbol{\sigma}_{vv} - L\mathbf{N}_v + M\mathbf{N}_u \qquad (10.2) \\ &= \Gamma_{12}^1(\Gamma_{11}^1\boldsymbol{\sigma}_u + \Gamma_{11}^2\boldsymbol{\sigma}_v + L\mathbf{N}) + (\Gamma_{12}^2 - \Gamma_{11}^1)(\Gamma_{12}^1\boldsymbol{\sigma}_u + \Gamma_{12}^2\boldsymbol{\sigma}_v + M\mathbf{N}) \\ &\quad -\Gamma_{11}^2(\Gamma_{22}^1\boldsymbol{\sigma}_u + \Gamma_{22}^2\boldsymbol{\sigma}_v + N\mathbf{N}) - L\mathbf{N}_v + M\mathbf{N}_u, \end{aligned}$$

using Proposition 7.4.4 again. Now, $\mathbf{N}_u$ and $\mathbf{N}_v$ are perpendicular to $\mathbf{N}$, and so are linear combinations of $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$. Hence, equating $\mathbf{N}$ components on both sides of the last equation gives

$$L_v - M_u = L\Gamma_{12}^1 + M(\Gamma_{12}^2 - \Gamma_{11}^1) - N\Gamma_{11}^2,$$

which is the first of the Codazzi–Mainardi equations (10.1). The other equation follows in a similar way by equating coefficients of $\mathbf{N}$ in the equation $(\boldsymbol{\sigma}_{uv})_v = (\boldsymbol{\sigma}_{vv})_u$.

Now we use the formulas in the proof of Proposition 8.1.2 to express $\mathbf{N}_u$ and $\mathbf{N}_v$ in terms of $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$. Equating coefficients of $\boldsymbol{\sigma}_u$ in Eq. 10.2 then gives

$$(\Gamma_{11}^1)_v - (\Gamma_{12}^1)_u = \Gamma_{12}^2\Gamma_{12}^1 - \Gamma_{11}^2\Gamma_{22}^1 + Lc - Ma \tag{10.3}$$

in the notation of the proof of Proposition 8.1.2, from which we find that

$$a = \frac{LG - MF}{EG - F^2}, \quad c = \frac{MG - NF}{EG - F^2}$$

and hence

$$Lc - Ma = \frac{L(MG - NF) - M(LG - MF)}{EG - F^2} = -\frac{F(LN - M^2)}{EG - F^2} = -FK$$

by Corollary 8.1.3. Substituting in Eq. 10.3 and rearranging gives the second of the Gauss equations. The other three are proved in the same way, equating coefficients of $\boldsymbol{\sigma}_v$ in $(\boldsymbol{\sigma}_{uu})_v = (\boldsymbol{\sigma}_{uv})_u$ and those of $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ in $(\boldsymbol{\sigma}_{uv})_v = (\boldsymbol{\sigma}_{vv})_u$. □

The following theorem tells us that there are no other relations between the first and second fundamental forms other than those in Propositions 10.1.1 and 10.1.2.

Theorem 10.1.3

Let $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ and $\tilde{\boldsymbol{\sigma}} : U \to \mathbb{R}^3$ be surface patches with the same first and second fundamental forms. Then, there is a direct isometry M of $\mathbb{R}^3$ such that $\tilde{\boldsymbol{\sigma}} = M(\boldsymbol{\sigma})$.

Moreover, let V be an open subset of $\mathbb{R}^3$ and let E, F, G, L, M and N be smooth functions on V. Assume that $E > 0, G > 0, EG - F^2 > 0$ and that the equations in Propositions 10.1.1 and 10.1.2 hold, with $K = \frac{LN - M^2}{EG - F^2}$ and the Christoffel symbols defined as in Proposition 7.4.4. Then, if $(u_0, v_0) \in V$, there is an open set U contained in V and containing (u_0, v_0), and a surface patch $\boldsymbol{\sigma} : U \to \mathbb{R}^3$, such that $Edu^2 + 2Fdudv + Gdv^2$ and $Ldu^2 + 2Mdudv + Ndv^2$ are the first and second fundamental forms of $\boldsymbol{\sigma}$, respectively.

This theorem is an analogue for surfaces of Theorem 2.2.5, which shows that unit-speed plane curves are determined up to a direct isometry of $\mathbb{R}^3$ by their signed curvature. We shall not prove Theorem 10.1.3 here. The first part depends on uniqueness theorems for the solution of systems of ordinary differential equations, and is not particularly difficult. The second part is more sophisticated and depends on existence theorems for the solution of certain *partial* differential equations. The following example illustrates what is involved.

Example 10.1.4

Consider the first and second fundamental forms $du^2 + dv^2$ and $-du^2$, respectively. Let us first see whether a surface patch with these first and second fundamental forms exists. Since all the coefficients of these forms are constant, all the Christoffel symbols are zero and the Codazzi–Mainardi equations are obviously satisfied. The first formula in Proposition 10.1.2 gives $K = 0$, so the only other condition to be checked is $LN - M^2 = 0$, and this clearly holds since $M = N = 0$. Theorem 10.1.3 therefore tells us that a surface patch with the given first and second fundamental forms exists.

To find it, we note that the Gauss equations give

$$\boldsymbol{\sigma}_{uu} = -\mathbf{N}, \quad \boldsymbol{\sigma}_{uv} = \mathbf{0}, \quad \boldsymbol{\sigma}_{vv} = \mathbf{0}.$$

The last two equations tell us that $\boldsymbol{\sigma}_v$ is a constant vector, say $\mathbf{a}$, so

$$\boldsymbol{\sigma}(u, v) = \mathbf{b}(u) + \mathbf{a}v, \tag{10.4}$$

where $\mathbf{b}$ is a function of u only. The first equation then gives $\mathbf{N} = -\mathbf{b}''$ (a dash denoting d/du). We now need to use the expressions for $\mathbf{N}_u$ and $\mathbf{N}_v$ in terms of $\boldsymbol{\sigma}_u$ and $\boldsymbol{\sigma}_v$ in the proof of Proposition 8.1.2. The matrix of the Weingarten map with respect to the basis $\{\boldsymbol{\sigma}_u, \boldsymbol{\sigma}_v\}$ of the tangent plane is

$$\mathcal{F}_I^{-1}\mathcal{F}_{II} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}^{-1} \begin{pmatrix} -1 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} -1 & 0 \\ 0 & 0 \end{pmatrix},$$

so Proposition 8.1.2 gives

$$\mathbf{N}_u = \boldsymbol{\sigma}_u, \quad \mathbf{N}_v = \mathbf{0}.$$

The second equation tells us nothing new, since we already know that $\mathbf{N} = -\mathbf{b}''$ depends only on u. The first equation gives

$$\mathbf{b}''' + \mathbf{b}' = \mathbf{0}.$$

Hence, $\mathbf{b}'' + \mathbf{b}$ is a constant vector, which we can take to be zero by applying a translation to $\boldsymbol{\sigma}$ (see Eq. 10.4). Then,

$$\mathbf{b}(u) = \mathbf{c}\cos u + \mathbf{d}\sin u,$$

where $\mathbf{c}$ and $\mathbf{d}$ are constant vectors, and $\mathbf{N} = -\mathbf{b}'' = \mathbf{b}$. This must be a unit vector for all values of u. It is easy to see that this is possible only if $\mathbf{c}$ and $\mathbf{d}$ are perpendicular unit vectors, in which case we can arrange that $\mathbf{c} = (1, 0, 0)$ and $\mathbf{d} = (0, 1, 0)$ by applying an isometry of $\mathbb{R}^3$, giving $\mathbf{b}(u) = (\cos u, \sin u, 0)$. Finally, $\boldsymbol{\sigma}_u \times \boldsymbol{\sigma}_v = \lambda\mathbf{N}$ for some non-zero scalar λ, so $\mathbf{b}' \times \mathbf{a} = \lambda\mathbf{b}$. This forces $\mathbf{a} = (0, 0, \lambda)$, and the patch is given by

$$\boldsymbol{\sigma}(u, v) = (\cos u, \sin u, \lambda v),$$

a parametrization of the unit cylinder (which the reader had probably guessed some time ago).

EXERCISES

10.1.1 A surface patch has first and second fundamental forms

$$\cos^2 v\,du^2 + dv^2 \quad \text{and} \quad -\cos^2 v\,du^2 - dv^2,$$

respectively. Show that the surface is an open subset of a sphere of radius one. Write down a parametrization of S^2 with these first and second fundamental forms.

10.1.2 Show that there is no surface patch whose first and second fundamental forms are

$$du^2 + \cos^2 u\,dv^2 \quad \text{and} \quad \cos^2 u\,du^2 + dv^2,$$

respectively.

10.1.3 Suppose that a surface patch $\boldsymbol{\sigma}(v, w)$ has first and second fundamental forms

$$\frac{dv^2 + dw^2}{w^2} \quad \text{and} \quad L dv^2 + N dw^2,$$

respectively, where $w > 0$. Prove that L and N do not depend on v, that $LN = -1/w^4$ and that

$$Lw^5 \frac{dL}{dw} = 1 - L^2 w^4.$$

Solve this equation for L and deduce that $\boldsymbol{\sigma}$ cannot be defined in the whole of the half-plane $w > 0$. Compare the discussion of the pseudosphere in Example 9.3.3.

10.1.4 Suppose that the first and second fundamental forms of a surface patch are $Edu^2 + Gdv^2$ and $Ldu^2 + Ndv^2$, respectively. Show that the Codazzi–Mainardi equations reduce to

$$L_v = \frac{1}{2}E_v\left(\frac{L}{E} + \frac{N}{G}\right), \quad N_u = \frac{1}{2}G_u\left(\frac{L}{E} + \frac{N}{G}\right).$$

Deduce that the principal curvatures $\kappa_1 = L/E$ and $\kappa_2 = N/G$ satisfy the equations

$$(\kappa_1)_v = \frac{E_v}{2E}(\kappa_2 - \kappa_1), \quad (\kappa_2)_u = \frac{G_u}{2G}(\kappa_1 - \kappa_2).$$

10.2 Gauss' remarkable theorem

We noted after Proposition 7.4.4 that the Christoffel symbols depend only on the coefficients of the *first* fundamental form. It follows from the formulas in Proposition 10.1.2 that this is also true of the Gaussian curvature K. In view of Corollary 6.2.3, we obtain:

Theorem 10.2.1 (Gauss' Theorema Egregium)

The Gaussian curvature of a surface is preserved by local isometries.

This means, more explicitly, that if $\mathcal{S}_1$ and $\mathcal{S}_2$ are two surfaces and $f : \mathcal{S}_1 \to \mathcal{S}_2$ is a local isometry, then for any point $\mathbf{p} \in \mathcal{S}_1$ the Gaussian curvature of $\mathcal{S}_1$ at $\mathbf{p}$ is equal to that of $\mathcal{S}_2$ at $f(\mathbf{p})$. The theorem is sometimes expressed by saying that the Gaussian curvature is an *intrinsic* property of a surface, for it implies that the Gaussian curvature could be measured by a bug living in the surface.

By substituting into the equations in Proposition 10.1.2 the expressions for the Christoffel symbols in Proposition 7.4.4, we can of course find an explicit expression for K in terms of E, F and G. (It appears that we could get four such formulas, one from each of the equations in Proposition 10.1.2, but these turn out to be the same.) Here is the result.

Corollary 10.2.2

The Gaussian curvature is given by

$$K = \frac{\begin{vmatrix} -\frac{1}{2}E_{vv} + F_{uv} - \frac{1}{2}G_{uu} & \frac{1}{2}E_u & F_u - \frac{1}{2}E_v \\ F_v - \frac{1}{2}G_u & E & F \\ \frac{1}{2}G_v & F & G \end{vmatrix} - \begin{vmatrix} 0 & \frac{1}{2}E_v & \frac{1}{2}G_u \\ \frac{1}{2}E_v & E & F \\ \frac{1}{2}G_u & F & G \end{vmatrix}}{(EG - F^2)^2}.$$

We shall not go through the details of this calculation, partly because the algebra is tedious, and partly because the following special cases are often all that is needed.

Corollary 10.2.3

(i) If $F = 0$, we have

$$K = -\frac{1}{2\sqrt{EG}} \left\{ \frac{\partial}{\partial u} \left(\frac{G_u}{\sqrt{EG}} \right) + \frac{\partial}{\partial v} \left(\frac{E_v}{\sqrt{EG}} \right) \right\}.$$

(ii) If $E = 1$ and $F = 0$, we have

$$K = -\frac{1}{\sqrt{G}}\frac{\partial^2\sqrt{G}}{\partial u^2}.$$

Proof

If $F = 0$ Proposition 7.4.4 gives

$$\Gamma_{11}^1 = \frac{E_u}{2E},\ \Gamma_{11}^2 = -\frac{E_v}{2G},\ \Gamma_{12}^1 = \frac{E_v}{2E},\ \Gamma_{12}^2 = \frac{G_u}{2G},\ \Gamma_{22}^1 = -\frac{G_u}{2E},\ \Gamma_{22}^2 = \frac{G_v}{2G}.$$

Substituting into the first formula in Proposition 10.1.2 gives

$$\begin{aligned} EK &= -\left(\frac{E_v}{2G}\right)_v - \left(\frac{G_u}{2G}\right)_u + \frac{E_uG_u}{4EG} - \frac{E_vG_v}{4G^2} + \frac{E_v^2}{4EG} - \frac{G_u^2}{4G^2} \\ \text{i.e.,}\quad -2K\sqrt{EG} &= \frac{E_{vv}+G_{uu}}{(EG)^{1/2}} - \frac{E_v(EG_v+E_vG)}{2(EG)^{3/2}} - \frac{G_u(E_uG+EG_u)}{2(EG)^{3/2}} \\ &= \frac{E_{vv}}{(EG)^{1/2}} - \frac{1}{2}\frac{E_v(EG)_v}{(EG)^{3/2}} + \frac{G_{uu}}{(EG)^{1/2}} - \frac{1}{2}\frac{G_u(EG)_u}{(EG)^{3/2}} \\ &= \left(\frac{E_v}{(EG)^{1/2}}\right)_v + \left(\frac{G_u}{(EG)^{1/2}}\right)_u, \end{aligned}$$

proving the equation in (i). If, in addition, $E = 1$, the second term on the right-hand side of the formula in (i) vanishes, so

$$K = -\frac{1}{2\sqrt{G}}\frac{\partial}{\partial u}\left(\frac{G_u}{\sqrt{G}}\right) = -\frac{1}{\sqrt{G}}\frac{\partial^2\sqrt{G}}{\partial u^2}. \qquad \square$$

Example 10.2.4

For the surface of revolution

$$\boldsymbol{\sigma}(u,v) = (f(u)\cos v, f(u)\sin v, g(u)),$$

where $f > 0$ and $\dot{f}^2 + \dot{g}^2 = 1$ (a dot denoting d/du), we found in Example 6.1.3 that $E = 1$, $F = 0$, and $G = f(u)^2$. Hence, Corollary 10.2.3(ii) applies and gives

$$K = -\frac{1}{\sqrt{G}}\frac{\partial^2\sqrt{G}}{\partial u^2} = -\frac{\ddot{f}}{f},$$

in agreement with Example 8.1.4.

The Theorema Egregium provides a necessary condition for the existence of a local isometry between surfaces: if such a local isometry exists, the Gaussian curvature must be the same at corresponding points of the two surfaces. We give two examples of this idea; others can be found in the exercises.

Our first result shows that it is impossible to draw a 'perfect' map of the Earth (which is why cartography is an interesting subject).

Proposition 10.2.5

Any map of any region of the earth's surface must distort distances.

Proof

A map of a region of the earth's surface which did *not* distort distances would be a diffeomorphism from this region of a sphere to a region in a plane (the map) which multiplied all distances by the same constant factor, say C. We might as well assume that the plane passes through the origin. Then, by composing this map with the map $\mathbf{r} \mapsto C^{-1}\mathbf{r}$ from the plane to itself, we would get an *isometry* between this region of the sphere and some region of a plane. This would imply, by the Theorema Egregium, that these regions of the sphere and the plane have the same Gaussian curvature. But we know that a plane has Gaussian curvature zero everywhere, and a sphere has constant positive Gaussian curvature everywhere (if the sphere has radius R, the Gaussian curvature is $1/R^2$). So no such isometry can exist. □

Note, on the other hand, that it *is* possible to draw a map of the Earth that correctly represents angles, and a map that correctly represents areas, for we saw in Example 6.3.5 that the stereographic projection is conformal, and Archimedes' Theorem 6.4.6 shows that there is a map that correctly represents areas. However, it is not possible to represent both angles and areas correctly with the same map (Exercise 6.4.5(ii)).

Our next example shows how the Theorema Egregium can sometimes be used to determine all the isometries of a surface.

Proposition 10.2.6

The only isometries of a helicoid (Exercise 4.2.6)

$$\boldsymbol{\sigma}(u, v) = (u \cos v, u \sin v, v)$$

are S_λ, $R_x \circ S_\lambda$, $R_y \circ S_\lambda$ and $R_z \circ S_\lambda$ for some value of λ, where S_λ is the screwing motion $\boldsymbol{\sigma}(u, v) \mapsto \boldsymbol{\sigma}(u, v + \lambda)$, and R_x, R_y and R_z are rotations by π around the x-, y- and z-axes.

Proof

Suppose that an isometry of the helicoid takes $\boldsymbol{\sigma}(u,v)$ to $\boldsymbol{\sigma}(\tilde{u},\tilde{v})$, where $\tilde{u}$ and $\tilde{v}$ are smooth functions of u and v. Since the Gaussian curvature at $\boldsymbol{\sigma}(u,v)$ is $-1/(1+u^2)^2$ (see Exercise 8.1.2), the Theorema Egregium tells us that

$$\frac{-1}{(1+u^2)^2} = \frac{-1}{(1+\tilde{u}^2)^2},$$

so $\tilde{u} = \pm u$. Applying a rotation R_z by π around the z-axis changes u to $-u$ (and fixes v), so we assume that $\tilde{u} = u$. Let $\tilde{v} = f(u,v)$. By Corollary 6.2.3, the patches $\boldsymbol{\sigma}(u,v)$ and $\tilde{\boldsymbol{\sigma}}(u,v) = \boldsymbol{\sigma}(u, f(u,v))$ have the same first fundamental form. That of $\boldsymbol{\sigma}$ is $du^2 + (1+u^2)dv^2$, and that of $\tilde{\boldsymbol{\sigma}}$ is found to be

$$(1+(1+u^2)f_u^2)du^2 + 2(1+u^2)f_u f_v du dv + (1+u^2)f_v^2 dv^2.$$

Equating these, we find that $f_u = 0$ and $f_v = \pm 1$. Hence,

$$\tilde{v} = f(u,v) = \pm v + \lambda,$$

where λ is a constant. A rotation R_x by π around the x-axis changes v to $-v$ (and fixes u), so we take the $+$ sign. This gives the isometry

$$S_\lambda : \boldsymbol{\sigma}(u,v) \mapsto \boldsymbol{\sigma}(u, v+\lambda).$$

This proves the proposition (the isometry $R_y \circ S_\lambda$ arises because $R_y = R_x \circ R_z$). □

EXERCISES

10.2.1 Show that if a surface patch has first fundamental form $e^\lambda(du^2+dv^2)$, where λ is a smooth function of u and v, its Gaussian curvature K satisfies

$$\Delta\lambda + 2Ke^\lambda = 0,$$

where Δ denotes the Laplacian $\partial^2/\partial u^2 + \partial^2/\partial v^2$.

10.2.2 With the notation of Exercise 9.5.1, define $u = r\cos\theta$, $v = r\sin\theta$, and let $\tilde{\boldsymbol{\sigma}}(u,v)$ be the corresponding reparametrization of $\boldsymbol{\sigma}$. It can be shown that $\tilde{\boldsymbol{\sigma}}$ is an allowable surface patch for $\mathcal{S}$ defined on the open set $u^2+v^2 < \epsilon^2$. (Note that this is not quite obvious because $\boldsymbol{\sigma}$ is not allowable when $r = 0$.)

(i) Show that the first fundamental form of $\tilde{\boldsymbol{\sigma}}$ is $\tilde{E}du^2 + 2\tilde{F}dudv + \tilde{G}dv^2$, where

$$\tilde{E} = \frac{u^2}{r^2} + \frac{Gv^2}{r^4}, \quad \tilde{F} = \left(1 - \frac{G}{r^2}\right)\frac{uv}{r^2}, \quad \tilde{G} = \frac{v^2}{r^2} + \frac{Gu^2}{r^4}.$$

(ii) Show that $u^2(\tilde{E}-1) = v^2(\tilde{G}-1)$, and by considering the Taylor expansions of $\tilde{E}$ and $\tilde{G}$ about $u = v = 0$, deduce that

$$G(r, \theta) = r^2 + kr^4 + \text{remainder}$$

for some constant k, where remainder$/r^4$ tends to zero as r tends to zero.

(iii) Show that $k = -K(P)/3$, where $K(P)$ is the value of the Gaussian curvature of $\mathcal{S}$ at P.

10.2.3 With the notation of Exercises 9.5.1 and 10.2.2, show that:

(i) The circumference of the geodesic circle with centre P and radius R is

$$C_R = 2\pi R \left(1 - \frac{K(P)}{6} R^2 + \text{remainder}\right),$$

where remainder$/R^2$ tends to zero as R tends to zero.

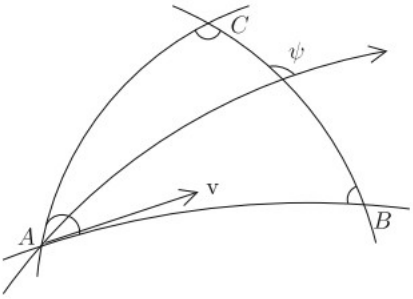
(ii) The area inside the geodesic circle in (i) is

$$A_R = \pi R^2 \left(1 - \frac{K(P)}{12} R^2 + \text{remainder}\right),$$

where the remainder satisfies the same condition as in (i).

Verify that these formulas are consistent with those in spherical geometry obtained in Exercise 6.5.3.

10.2.4 Let A, B and C be the vertices of a triangle $\mathcal{T}$ on a surface $\mathcal{S}$ whose sides are arcs of geodesics, and let α, β and γ be its internal angles (so that α is the angle at A, etc.). Assume that the triangle is contained in a geodesic patch $\boldsymbol{\sigma}$ as in Exercise 9.5.1 with $P = A$. Thus, with the notation in that exercise, if we take $\mathbf{v}$ to be tangent at A to the side passing through A and B, then the sides meeting at A are the parameter curves $\theta = 0$ and $\theta = \alpha$, and the remaining side can be parametrized by $\boldsymbol{\gamma}(\theta) = \boldsymbol{\sigma}(f(\theta), \theta)$ for some smooth function f and $0 \leq \theta \leq \alpha$.



(i) Use the geodesic equations (9.2) to show that

$$f'' - \frac{f'\lambda'}{\lambda^2} = \frac{1}{2}\frac{\partial G}{\partial r},$$

where a dash denotes $d/d\theta$ and $\lambda = \parallel \boldsymbol{\gamma}' \parallel$.

(ii) Show that, if $\psi(\theta)$ is the angle between $\boldsymbol{\sigma}_r$ and the tangent vector to the side opposite A at $\boldsymbol{\gamma}(\theta)$, then

$$\psi'(\theta) = -\frac{\partial\sqrt{G}}{\partial r}(f(\theta), \theta).$$

(iii) Show that, if K is the Gaussian curvature of $\mathcal{S}$,

$$\int_{\mathcal{T}} K \, d\mathcal{A}_{\boldsymbol{\sigma}} = \alpha + \beta + \gamma - \pi.$$

This result will be generalized in Corollary 13.2.3.

10.2.5 Show that the Gaussian curvature of the Möbius band in Example 4.5.3 is equal to $-1/4$ everywhere along its median circle. Deduce that this Möbius band *cannot* be constructed by taking a strip of paper and joining the ends together with a half-twist. (The analytic description of the 'cut and paste' Möbius band is more complicated than the version in Example 4.5.3.)

10.2.6 Show that the only isometries from the catenoid to itself are products of rotations around its axis, reflections in planes containing the axis, and reflection in the plane containing the waist of the catenoid.

10.3 Surfaces of constant Gaussian curvature

The results of the preceding two sections enable us to gain a good understanding of surfaces of constant Gaussian curvature. We begin with the following local description.

Theorem 10.3.1

Any point of a surface of constant Gaussian curvature is contained in a patch that is isometric to an open subset of a plane, a sphere or a pseudosphere.

Proof

Let $\mathbf{p}$ be a point on a surface $\mathcal{S}$ with constant Gaussian curvature K. By applying a dilation of $\mathbb{R}^3$ (see Exercise 8.1.5), we need only consider the cases $K = 0, 1$ and -1.

We take a geodesic patch $\boldsymbol{\sigma}(u, v)$ with $\boldsymbol{\sigma}(0, 0) = \mathbf{p}$. Writing $g = \sqrt{G}$, the first fundamental form is

$$du^2 + g(u, v)^2 dv^2.$$

By Corollary 10.2.3(ii),

$$\frac{\partial^2 g}{\partial u^2} + Kg = 0. \tag{10.5}$$

Note that

$$g(0, v) = 1, \quad g_u(0, v) = 0, \tag{10.6}$$

by Proposition 9.5.1.

If $K = 0$, the solution of Eq. 10.5 is $g(u, v) = \alpha u + \beta$, where α and β are smooth functions of v only. The initial conditions (10.6) give $\alpha = 0$, $\beta = 1$, so $g = 1$ and the first fundamental form of $\boldsymbol{\sigma}$ is $du^2 + dv^2$. This is the same as the first fundamental form of the usual parametrization of the plane (see Example 6.1.2), and Corollary 6.2.3 now shows that $\boldsymbol{\sigma}$ is isometric to an open subset of the plane.

If $K = 1$, the general solution of Eq. 10.5 is $g = \alpha \cos u + \beta \sin u$, where α and β only depend on v. The boundary conditions (10.6) give $\alpha = 1$, $\beta = 0$, and the first fundamental form of $\boldsymbol{\sigma}$ is $du^2 + \cos^2 u \, dv^2$. This is the first fundamental form of S^2, with u and v being latitude and longitude, respectively (see Example 6.1.3). Hence, $\boldsymbol{\sigma}$ is isometric to an open subset of S^2.

Finally, if $K = -1$, we find in the same way that the first fundamental form of $\boldsymbol{\sigma}$ is

$$du^2 + \cosh^2 u \, dv^2.$$

We have not encountered this first fundamental form before. However, let us reparametrize $\boldsymbol{\sigma}$ by defining

$$V = e^v \tanh u, \quad W = e^v \operatorname{sech} u.$$

We then find, using the formulas in Exercise 6.1.4, that the first fundamental form becomes

$$\frac{dV^2 + dW^2}{W^2}.$$

Comparing with Exercise 8.3.1, we see that this is the first fundamental form of a parametrization of the pseudosphere. $\square$

The next result gives a much more precise, though still local, description of surfaces of constant negative Gaussian curvature.

Proposition 10.3.2

Let $\mathcal{S}$ be a surface of constant Gaussian curvature -1. If $\mathbf{p} \in \mathcal{S}$, there is a surface patch of $\mathcal{S}$ containing $\mathbf{p}$ whose first and second fundamental forms are

$$du^2 + 2\cos\theta\, du dv + dv^2 \quad \text{and} \quad 2\sin\theta\, du dv, \tag{10.7}$$

respectively, where $\theta(u, v)$ is a smooth function such that $0 < \theta < \pi$ for all u, v.

Thus, the parameter curves of this parametrization form a *Chebyshev net* (see Exercises 6.1.9 and 7.4.6).

Proof

Since K is negative the surface $\mathcal{S}$ has no umbilics. Hence, there is a surface patch $\boldsymbol{\sigma}(U, V)$ containing $\mathbf{p}$ whose first and second fundamental forms are

$$EdU^2 + GdV^2 \quad \text{and} \quad LdU^2 + NdV^2,$$

respectively (Proposition 8.4.1). The principal curvatures are

$$\kappa_1 = \frac{L}{E}, \quad \kappa_2 = \frac{N}{G}. \tag{10.8}$$

Since $\kappa_1\kappa_2 = -1$, there are two cases:

(i) $\kappa_1 > 0$ and $\kappa_2 < 0$ for all U, V

(ii) $\kappa_1 < 0$ and $\kappa_2 > 0$ for all U, V

We shall concentrate on case (i), indicating briefly the modifications necessary for case (ii).

In case (i), there is a smooth function $\omega(U, V)$ such that $0 < \omega < \pi/2$ and

$$\kappa_1 = \tan\omega, \quad \kappa_2 = -\cot\omega. \tag{10.9}$$

(In case (ii), we put $\kappa_1 = -\cot\omega$, $\kappa_2 = \tan\omega$.) The first Codazzi-Mainardi equation is

$$L_V = \frac{1}{2}E_V\left(\frac{L}{E} + \frac{N}{G}\right)$$

(cf. Exercise 10.1.4). From Eqs. 10.8 and 10.9, we get

$$\begin{aligned}(E\tan\omega)_V &= \frac{1}{2}E_V(\tan\omega - \cot\omega),\\ \text{i.e.,}\quad \omega_V &= -\frac{E_V}{2E}\cot\omega.\end{aligned} \tag{10.10}$$

Then,

$$\left(\frac{\cos\omega}{\sqrt{E}}\right)_V = -\frac{\omega_V \sin\omega}{\sqrt{E}} - \frac{E_V \cos\omega}{2E^{3/2}} = -\frac{\sin\omega}{\sqrt{E}}\left(\omega_V + \frac{E_V}{2E}\cot\omega\right) = 0$$

by Eq. 10.10. Hence, there is a positive smooth function $e(U)$ such that

$$E = e(U)\cos^2\omega.$$

Similarly, the second Codazzi-Mainardi equation implies that there is a positive smooth function $g(V)$ such that

$$G = g(V)\sin^2\omega.$$

(In case (ii), we get $E = e(U)\sin^2\omega$, $G = g(V)\cos^2\omega$.)

Let $\tilde{U}(U)$ and $\tilde{V}(V)$ be smooth functions such that

$$\frac{d\tilde{U}}{dU} = \sqrt{e(U)}, \quad \frac{d\tilde{V}}{dV} = \sqrt{g(V)},$$

and let $\tilde{\boldsymbol{\sigma}}(\tilde{U},\tilde{V})$ be the corresponding reparametrization of $\boldsymbol{\sigma}(U,V)$. Then, the first fundamental form of $\tilde{\boldsymbol{\sigma}}$ is

$$\cos^2\omega\, d\tilde{U}^2 + \sin^2\omega\, d\tilde{V}^2$$

and its second fundamental form is

$$\frac{L}{e}d\tilde{U}^2 + \frac{N}{g}d\tilde{V}^2 = \sin\omega\cos\omega(d\tilde{U}^2 - d\tilde{V}^2).$$

Setting $u = (\tilde{U}+\tilde{V})/2$, $v = (\tilde{U}-\tilde{V})/2$ gives a reparametrization of $\tilde{\boldsymbol{\sigma}}$ whose first and second fundamental forms are as stated in the proposition, with $\theta = 2\omega$. (In case (ii) we set $u = (\tilde{U}+\tilde{V})/2$, $v = (\tilde{V}-\tilde{U})/2$.) □

The function $\theta(u,v)$ appearing in (10.7) is not arbitrary, as the Gauss equations (Proposition 10.1.2) must still be satisfied. As we remarked earlier, these four equations are equivalent to each other, so we need only consider one of them. The Christoffel symbols are found to be

$$\begin{aligned} \Gamma_{11}^1 = \theta_u\cot\theta,\ \ \Gamma_{12}^1 &= 0,\ \ \Gamma_{22}^1 = -\theta_v\operatorname{cosec}\theta, \\ \Gamma_{11}^2 = -\theta_u\operatorname{cosec}\theta,\ \ \Gamma_{12}^2 &= 0,\ \ \Gamma_{22}^2 = \theta_v\cot\theta. \end{aligned}$$

Substituting in the first of the Gauss equations gives

$$\begin{aligned} -1 &= (-\theta_u\operatorname{cosec}\theta)_v - \theta_u\theta_v\operatorname{cosec}\theta\cot\theta, \\ \text{i.e.,}\qquad \theta_{uv} &= \sin\theta. \end{aligned} \tag{10.11}$$

This is called the *sine-Gordon equation*; it arises in fluid mechanics and various other areas of physics.

In view of Theorem 10.1.3, we can summarize our discussion as follows.

Theorem 10.3.3

Let $\theta(u,v)$ be a smooth solution of the sine-Gordon equation (10.11) such that $0 < \theta < \pi$. Then there exists a surface, unique up to a direct isometry of $\mathbb{R}^3$, with constant Gaussian curvature -1 and first and second fundamental forms given by (10.7). Conversely, any surface of constant Gaussian curvature -1 has a parametrization with first and second fundamental forms (10.7) in which θ is a solution of the sine-Gordon equation.

We conclude this section with a beautiful global result that characterizes the *compact* surfaces of constant Gaussian curvature. Note that, by Proposition 8.6.1, the value of the constant Gaussian curvature in this case must be > 0.

Theorem 10.3.4

Every connected compact surface whose Gaussian curvature is constant is a sphere.

The proof of this theorem depends on the following lemma.

Lemma 10.3.5

Let $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ be a surface patch containing a point $\mathbf{p}$ that is not an umbilic. Let $\kappa_1 \geq \kappa_2$ be the principal curvatures of $\boldsymbol{\sigma}$ and suppose that κ_1 has a local maximum at $\mathbf{p}$ and κ_2 has a local minimum there. Then, the Gaussian curvature of $\boldsymbol{\sigma}$ at $\mathbf{p}$ is ≤ 0.

Proof 10.3.5 Since $\mathbf{p}$ is not an umbilic, $\kappa_1 > \kappa_2$ at $\mathbf{p}$, so by shrinking U if necessary, we may assume that $\kappa_1 > \kappa_2$ everywhere.

By Proposition 8.4.1, we can assume that the first and second fundamental forms of $\boldsymbol{\sigma}$ are

$$Edu^2 + Gdv^2 \quad \text{and} \quad Ldu^2 + Ndv^2,$$

respectively. By Exercise 10.1.4,

$$E_v = -\frac{2E}{\kappa_1 - \kappa_2}(\kappa_1)_v, \quad G_u = \frac{2G}{\kappa_1 - \kappa_2}(\kappa_2)_u,$$

and by Corollary 10.2.3(i), the Gaussian curvature

$$K = -\frac{1}{2\sqrt{EG}}\left(\frac{\partial}{\partial u}\left(\frac{G_u}{\sqrt{EG}}\right) + \frac{\partial}{\partial v}\left(\frac{E_v}{\sqrt{EG}}\right)\right).$$

Since $\mathbf{p}$ is a stationary point of κ_1 and κ_2, we have $(\kappa_1)_v = (\kappa_2)_u = 0$, and hence $E_v = G_u = 0$, at $\mathbf{p}$. Hence, at $\mathbf{p}$,

$$K = -\frac{1}{2EG}(G_{uu} + E_{vv}) = -\frac{1}{2EG}\left(\frac{2G}{\kappa_1 - \kappa_2}(\kappa_2)_{uu} - \frac{2E}{\kappa_1 - \kappa_2}(\kappa_1)_{vv}\right)$$

(again dropping terms involving E_v, G_u and the first derivatives of κ_1 and κ_2). Since κ_1 has a local maximum at $\mathbf{p}$, $(\kappa_1)_{vv} \leq 0$ there, and since κ_2 has a local minimum at $\mathbf{p}$, $(\kappa_2)_{uu} \geq 0$ there. Hence, the last equation shows that $K \leq 0$ at $\mathbf{p}$. □

Proof 10.3.4 The proof of Theorem 10.3.4 uses a little point set topology. We consider the continuous function on the surface $\mathcal{S}$ given by $J = (\kappa_1 - \kappa_2)^2$, where κ_1 and κ_2 are the principal curvatures. Note that this function is well defined even though κ_1 and κ_2 are not, partly because we do not know which principal curvature is to be called κ_1 and which κ_2, and partly because the principal curvatures are only well defined up to sign unless $\mathcal{S}$ has a definite orientation. We shall prove that this function is identically zero on $\mathcal{S}$, so that every point of $\mathcal{S}$ is an umbilic. Since the Gaussian curvature $K > 0$, it follows from Proposition 8.2.9 that $\mathcal{S}$ is an open subset of a sphere, say $\mathbf{S}$. In fact, $\mathcal{S}$ must be the whole of $\mathbf{S}$. For, since $\mathcal{S}$ is compact, it is necessarily a closed subset of $\mathbb{R}^3$, and hence a *closed* subset of $\mathbf{S}$. But since $\mathbf{S}$ is connected, the only non-empty subset of $\mathbf{S}$ that is both open and closed is $\mathbf{S}$ itself.

Suppose then, to get a contradiction, that J is not identically zero on $\mathcal{S}$. Since $\mathcal{S}$ is compact, J must attain its maximum value at some point $\mathbf{p} \in \mathcal{S}$, and this maximum value is > 0. Choose a patch $\boldsymbol{\sigma} : U \to \mathbb{R}^3$ of $\mathcal{S}$ containing $\mathbf{p}$, and let κ_1 and κ_2 be its principal curvatures. Since $\kappa_1\kappa_2 > 0$, by reparametrizing if necessary, we can assume that κ_1 and κ_2 are both > 0 (see Exercise 8.2.8). Suppose that $\kappa_1 > \kappa_2$ at $\mathbf{p}$; since κ_1 and κ_2 are continuous (in fact, smooth) functions on U (Exercise 8.2.8 again), by shrinking U if necessary, we can assume that $\kappa_1 > \kappa_2$ everywhere on U. Since K is a constant > 0, the function $\left(x - \frac{K}{x}\right)^2$ increases with x provided that $x > K/x > 0$. Since $\kappa_1 > K/\kappa_1 = \kappa_2 > 0$, this function is increasing at $x = \kappa_1$, so κ_1 must have a local maximum at $\mathbf{p}$, and then $\kappa_2 = K/\kappa_1$ must have a local minimum there. By Lemma 10.3.5, $K \leq 0$ at $\mathbf{p}$. This contradicts the assumption that $K > 0$. □

EXERCISES

10.3.1 Show that a compact surface with Gaussian curvature > 0 everywhere and constant *mean* curvature is a sphere.

10.3.2 Show that the solution of the sine-Gordon equation corresponding to the pseudosphere constructed in Section 8.3 is

$$\theta(u,v) = 2\tan^{-1}(\sinh(u-v+c)),$$

where c is a constant.

10.4 Geodesic mappings

We considered in Chapter 6 local diffeomorphisms between surfaces that preserve lengths, angles or areas. In the same way, it is natural to consider local diffeomorphisms that preserve geodesics. In fact, to obtain interesting results we have to consider local diffeomorphisms $F : \mathcal{S} \to \tilde{\mathcal{S}}$ from a surface $\mathcal{S}$ to a surface $\tilde{\mathcal{S}}$ such that, if $\boldsymbol{\gamma}$ is a geodesic on $\mathcal{S}$, then $F \circ \boldsymbol{\gamma}$ is a *reparametrization* of a geodesic on $\tilde{\mathcal{S}}$ (cf. Exercise 10.4.1). We recall from Exercise 9.1.2 that a curve that is a reparametrization of a geodesic is called a pre-geodesic. Thus, we are led to

Definition 10.4.1

If $\mathcal{S}$ and $\tilde{\mathcal{S}}$ are surfaces, a local diffeomorphism $F : \mathcal{S} \to \tilde{\mathcal{S}}$ is said to be *geodesic* if f takes every pre-geodesic on $\mathcal{S}$ to a pre-geodesic on $\tilde{\mathcal{S}}$.

The following result provides some examples of geodesic local diffeomorphisms.

Proposition 10.4.2

The following are geodesic local diffeomorphisms:

(i) Every local isometry.

(ii) Every dilation of $\mathbb{R}^3$.

(iii) Every composite of geodesic local diffeomorphisms.

Proof

(i) If $\boldsymbol{\gamma}$ is a pre-geodesic on a surface patch $\boldsymbol{\sigma}$ of a surface $\mathcal{S}$, then $\boldsymbol{\gamma}(t) = \boldsymbol{\gamma}_1(\varphi(t))$ for some geodesic $\boldsymbol{\gamma}_1$ and some reparametrization map φ (Exercise 9.1.2). If $F : \mathcal{S} \to \tilde{\mathcal{S}}$ is an isometry, then $\tilde{\boldsymbol{\gamma}}_1 = F \circ \boldsymbol{\gamma}_1$ is a geodesic on the surface patch $\tilde{\boldsymbol{\sigma}} = f \circ \boldsymbol{\sigma}$ of $\tilde{\mathcal{S}}$ by Corollary 9.2.7. Hence, $F \circ \boldsymbol{\gamma} = F \circ \boldsymbol{\gamma}_1 \circ \varphi = \tilde{\boldsymbol{\gamma}}_1 \circ \varphi$ is a reparametrization of the geodesic $\tilde{\boldsymbol{\gamma}}_1$, and so is a pre-geodesic.

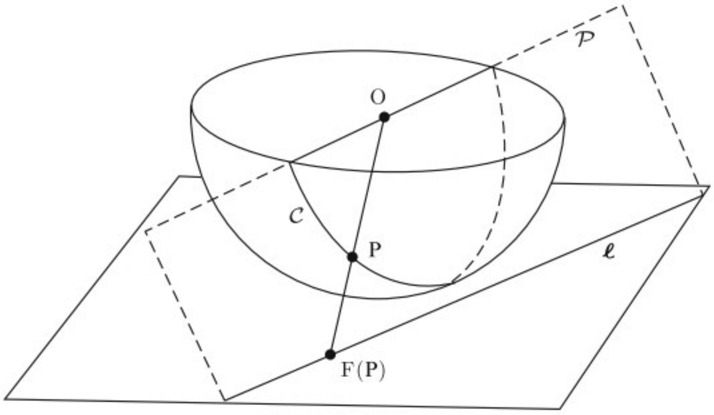
(ii) The dilation $(x, y, z) \mapsto a(x, y, z)$, where a is a non-zero constant, multiplies the first fundamental form by a^2 and hence leaves the Christoffel symbols unchanged (see Proposition 7.4.4). By Proposition 9.2.3, applying the dilation leaves the equations determining the geodesics unchanged. It follows that the dilation takes geodesics to geodesics. By the argument in part (i), it also takes pre-geodesics to pre-geodesics.

(iii) This is obvious. □

As the preceding proof made clear, local isometries and dilations take geodesics to geodesics. The following is an example of a geodesic local diffeomorphism that *does not take geodesics to geodesics*. By the preceding proposition, it cannot be a composite of local isometries and dilations.

Example 10.4.3

We consider the map F from the lower hemisphere of the unit sphere S^2 to the plane $z = -1$ given by projection from the centre of the sphere.



Every pre-geodesic $\mathcal{C}$ on S^2 is a great circle formed by the intersection of S^2 with a plane $\mathcal{P}$ passing through the origin. Central projection takes the part of $\mathcal{C}$ in the lower hemisphere to the straight line l that is the intersection of $\mathcal{P}$ with the plane $z = -1$. Hence, F is a geodesic diffeomorphism.

As a particular case, let $\mathcal{P}$ be the xz-plane, so that $\mathcal{C}$ can be parametrized by $\boldsymbol{\gamma}(t) = (\cos t, 0, \sin t)$; note that $\boldsymbol{\gamma}$ is unit-speed and so is a geodesic. It is easy to show that $F(\boldsymbol{\gamma}(t)) = (-\cot t, 0, -1)$: this curve is a parametrization of the straight line $y = 0$, $z = -1$ (hence it is a pre-geodesic), but it is *not* a geodesic as it does not have constant speed (Proposition 9.1.2).

The inverse of the diffeomorphism F in Example 10.4.3 provides a parametrization of (an open subset of) S^2 with the property that geodesics on S^2 correspond to straight lines in the parameter plane. Beltrami proved the following beautiful theorem which determines exactly which surfaces admit parametrizations with this property. It motivated him to carry out a detailed investigation of surfaces of constant Gaussian curvature, which in turn led to his work on hyperbolic geometry that we describe in Chapter 11.

Theorem 10.4.4

Let $\mathcal{S}$ be a connected surface. If there is a geodesic local diffeomorphism from $\mathcal{S}$ to a plane, then $\mathcal{S}$ has constant Gaussian curvature. Conversely, if $\mathcal{S}$ has constant Gaussian curvature, then for any point $\mathbf{p} \in \mathcal{S}$ there is a surface patch $\boldsymbol{\sigma} : U \to \mathcal{S}$ of $\mathcal{S}$ such that $\mathbf{p} \in \boldsymbol{\sigma}(U)$ and $\boldsymbol{\sigma}^{-1} : \boldsymbol{\sigma}(U) \to U$ is a geodesic diffeomorphism.

Proof

If F is a geodesic local diffeomorphism from $\mathcal{S}$ to the plane, $\boldsymbol{\sigma} = F^{-1}$ is a parametrization of an open subset of $\mathcal{S}$ with the property that $\boldsymbol{\sigma}$ takes every straight line in the plane to a pre-geodesic on $\mathcal{S}$. Denoting the parameters by u, v, we can take the line to have equation

$$v = \lambda u + \mu, \tag{10.12}$$

where λ and μ are constants. By Exercise 9.1.2, there is a parametrization $t \mapsto (u(t), v(t))$ of this line such that $\boldsymbol{\gamma}(t) = \boldsymbol{\sigma}(u(t), v(t))$ is a unit-speed geodesic on $\mathcal{S}$. By Proposition 9.2.3, we have

$$\begin{aligned} \ddot{u} + (\Gamma_{11}^1 + 2\lambda\Gamma_{12}^1 + \lambda^2\Gamma_{22}^1)\dot{u}^2 &= 0, \\ \lambda\ddot{u} + (\Gamma_{11}^2 + 2\lambda\Gamma_{12}^2 + \lambda^2\Gamma_{22}^2)\dot{u}^2 &= 0. \end{aligned}$$

Eliminating $\ddot{u}$ and noting that $\dot{u}$ cannot be zero (for then we would have $\dot{v} = 0$ too, since $\dot{v} = \lambda\dot{u}$ by Eq. 10.12, contradicting the fact that $\boldsymbol{\gamma}$ is unit-speed), we get

$$\lambda(\Gamma_{11}^1 + 2\lambda\Gamma_{12}^1 + \lambda^2\Gamma_{22}^1) = \Gamma_{11}^2 + 2\lambda\Gamma_{12}^2 + \lambda^2\Gamma_{22}^2.$$

Since *every* straight line in the uv-plane corresponds to a geodesic $\boldsymbol{\gamma}$ in this way, the preceding equation must hold for all values of the constant λ. This implies that

$$\Gamma_{11}^2 = \Gamma_{22}^1 = 0, \quad \Gamma_{11}^1 = 2\Gamma_{12}^2, \quad \Gamma_{22}^2 = 2\Gamma_{12}^1.$$

The Gauss equations (Proposition 10.1.2) now become

$$\begin{aligned}
KE &= (\Gamma_{12}^2)^2 - (\Gamma_{12}^2)_u,\\
KF &= (\Gamma_{12}^1)_u - 2(\Gamma_{12}^2)_v + \Gamma_{12}^2\Gamma_{12}^1,\\
KF &= (\Gamma_{12}^2)_v - 2(\Gamma_{12}^1)_u + \Gamma_{12}^1\Gamma_{12}^2,\\
KG &= (\Gamma_{12}^1)^2 - (\Gamma_{12}^1)_v.
\end{aligned}$$

Subtracting the middle two equations gives $(\Gamma_{12}^1)_u = (\Gamma_{12}^2)_v$, and using this the four equations become

$$KE = (\Gamma_{12}^2)^2 - (\Gamma_{12}^2)_u, \tag{10.13}$$
$$KF = -(\Gamma_{12}^2)_v + \Gamma_{12}^1\Gamma_{12}^2, \tag{10.14}$$
$$KF = -(\Gamma_{12}^1)_u + \Gamma_{12}^1\Gamma_{12}^2, \tag{10.15}$$
$$KG = (\Gamma_{12}^1)^2 - (\Gamma_{12}^1)_v. \tag{10.16}$$

Differentiating Eq. 10.13 with respect to v and Eq. 10.14 with respect to u, and then equating the expressions for $(\Gamma_{12}^2)_{uv} = (\Gamma_{12}^2)_{vu}$ gives

$$\begin{aligned}
EK_v - FK_u &= K(F_u - E_v) + 2\Gamma_{12}^2(\Gamma_{12}^2)_v - \Gamma_{12}^2(\Gamma_{12}^1)_u - \Gamma_{12}^1(\Gamma_{12}^2)_u\\
&= K(F_u - E_v) + 2\Gamma_{12}^2(\Gamma_{12}^1\Gamma_{12}^2 - KF) - \Gamma_{12}^2(\Gamma_{12}^1\Gamma_{12}^2 - KF)\\
&\quad - \Gamma_{12}^1((\Gamma_{12}^2)^2 - KE)\\
&= K(F_u - E_v) + K(E\Gamma_{12}^1 - F\Gamma_{12}^2),
\end{aligned} \tag{10.17}$$

where we used Eqs. 10.13–10.15 in passing from the first line to the second.

Using the definition of the Christoffel symbols (Proposition 7.4.4), we find that

$$E\Gamma_{12}^1 - F\Gamma_{12}^2 = \frac{(EG + F^2)E_v - 2EFG_u}{2(EG - F^2)}. \tag{10.18}$$

Now, the equations $\Gamma_{11}^2 = 0$ and $\Gamma_{11}^1 = 2\Gamma_{12}^2$ give

$$EE_v = 2EF_u - FE_u, \quad 3FE_v = 2EG_u + 2FF_u - GE_u.$$

Hence,

$$\begin{aligned}
(EG + F^2)E_v - 2EFG_u &= 2(EG - F^2)E_v + (3F^2 - EG)E_v - 2EFG_u\\
&= 2(EG - F^2)E_v + F(2EG_u + 2FF_u - GE_u)\\
&\quad - G(2EF_u - FE_u) - 2EFG_u\\
&= 2(EG - F^2)(E_v - F_u).
\end{aligned}$$

Inserting this result into Eq. 10.18 gives

$$E\Gamma_{12}^1 - F\Gamma_{12}^2 = E_v - F_u,$$

and then Eq. 10.17 gives

$$EK_v - FK_u = 0.$$

A similar calculation starting with Eqs. 10.15 and 10.16 leads to

$$FK_v - GK_u = 0.$$

Hence,

$$(EG - F^2)K_v = GFK_u - FGK_u = 0,$$

so $K_v = 0$ (since $EG - F^2 > 0$). Similarly $K_u = 0$. Hence, K is constant.

For the converse, assume that $\mathcal{S}$ has constant Gaussian curvature. By Theorem 10.3.1, each point of $\mathcal{S}$ is contained in a surface patch that is isometric to an open subset of a plane, a sphere or a pseudosphere. Since local isometries and dilations are geodesic local diffeomorphisms (Proposition 10.4.2), we have only to show that there are geodesic local diffeomorphisms from $\mathcal{S}$ to the plane in three cases:

(i) $\mathcal{S}$ is a plane, when there is nothing to prove.

(ii) $\mathcal{S}$ is the unit sphere, which is Example 10.4.3.

(iii) $\mathcal{S}$ is the pseudosphere in Section 8.3, which is Exercise 9.3.4.

The proof of Beltrami's theorem is complete. □

EXERCISES

10.4.1 Show that a local diffeomorphism between surfaces that takes unit-speed geodesics to unit-speed geodesics must be a local isometry.

10.4.2 Show that a local diffeomorphism between surfaces that is the composite of a dilation and a local isometry takes geodesics to geodesics. Is the converse of this statement true?

10.4.3 This exercise shows that a geodesic local diffeomorphism F from a surface $\mathcal{S}$ to a surface $\tilde{\mathcal{S}}$ that is also conformal is the composite of a dilation and a local isometry.

(i) Let $\mathbf{p} \in \mathcal{S}$ and let $\boldsymbol{\sigma}$ be a geodesic patch containing $\mathbf{p}$ as in Proposition 9.5.1, with first fundamental form du^2+Gdv^2. Show that $\tilde{\boldsymbol{\sigma}} = F \circ \boldsymbol{\sigma}$ is a patch of $\tilde{\boldsymbol{\sigma}}$ containing $F(\mathbf{p})$ with first fundamental form $\lambda(du^2 + Gdv^2)$ for some smooth function $\lambda(u, v)$.

(ii) Show that the parameter curves $v =$ constant are pre-geodesics on $\tilde{\boldsymbol{\sigma}}$ and deduce that λ is independent of v.

(iii) Show that if $\boldsymbol{\gamma}$ is a geodesic on $\boldsymbol{\sigma}$ and θ is the oriented angle between $\boldsymbol{\gamma}$ and the parameter curves $v =$ constant,

$$\frac{d\theta}{dv} + \frac{G_u}{2\sqrt{G}} = 0. \tag{10.19}$$

(iv) Show that

$$\frac{d\theta}{dv} + \frac{(\lambda G)_u}{2\lambda\sqrt{G}} = 0. \tag{10.20}$$

(v) Deduce from Eqs. 10.19 and 10.20 that λ is constant.

(vi) Show that $F : \boldsymbol{\sigma} \to \tilde{\boldsymbol{\sigma}}$ is the composite of a dilation and a local isometry.

DIFFERENTIAL GEOMETRY OF CURVES AND SURFACES

6. Gauss' Theorema Egregium

Question. *How can we decide if two given surfaces can be obtained from each other by "bending without stretching"?*

The simplest example is a flat strip, say of paper, which can be rolled (without stretching!) to give a cylinder; a bit more precisely, a piece of the plane can be deformed to a piece of a cylinder. On the other hand, it is intuitively clear that we cannot deform without stretching a piece of a plane to a piece of a sphere (or of an ellipse, of a hyperboloid, of a torus etc. — just try to wrap such an object!) In general, the question is hard. Let's try to translate the question into a more formal language:

- bending = *map between surfaces*
- without stretching = *preserving the distances between two points*, which is the same as *local isometry* (see the last section in chapter 4 of the notes)

Gauss came up with the idea that an answer to our question can be given by measuring curvature of curves on a surface, more precisely, the principal curvatures, but in a very ingenious way. Because if we compare the plane and the cylinder we see that their principal curvatures are $k_1^{\text{plane}} = k_2^{\text{plane}} = 0$ whereas $k_1^{\text{cylinder}} = 1$, $k_2^{\text{cylinder}} = 0$. Even though they are locally isometric, the plane and the cylinder have different principal curvatures. Nevertheless, their product is the same! Recall that the latter product is what we called the Gauss curvature. In fact, Gauss' observation was that what we noticed in the case of the deformation plane→cylinder is a very general phenomenon: if there is a deformation without stretching of the surface S_1 to the surface S_2, then the product of the principal curvatures at any point on S_1 is preserved by the deformation. Another instructive (and easy to visualize, thanks to the computer generated animation available online) example is the continuous deformation of the helicoid in the catenoid. If you follow a point on the helicoid during this process, the Gauss curvature doesn't change, even though the surface changes its shape radically during the process. Gauss' theorem can be stated as follows:

Theorema Egregium.[1] *If $f : S_1 \to S_2$ is a local isometry, then the Gauss curvature of S_1 at P equals the Gauss curvature of S_2 at $f(P)$.*

Remark. 1. The theorem can only be used to rule out (local) isometries between surfaces. By this we mean that the converse of the theorem is not true: one can find a diffeomorphism (that is, a differentiable bijective map) between surfaces which preserves the Gauss curvature at any point, but is not an isometry. You will see such an example in Homework no. 5. In the same spirit: we cannot deduce that the plane and the cylinder (or the helicoid and the catenoid) are locally isometric just because they have the same Gauss curvature!

2. In fact the importance of the theorem goes beyond the application mentioned above (that is, rule out locally isometric surfaces). Many authors consider it "the most important single theorem in differential geometry". But it's not easy to explain why, so we refer the reader to Spivak's monograph [Sp], the end of chapter 3, part B (page 143 - 144, "What does Theorema Egregium really mean?").

The rest of the chapter is devoted to the proof of this theorem. The key point is to consider a local parametrization (U, φ) and produce a formula for $K(\varphi(Q))$ (where Q is in U) which depends only on the functions E, F, and G (the coefficients of the first fundamental form).

---

[1] Gauss' original paper where this theorem was stated and proven was written in Latin. He says that this is a *remarkable theorem*, which in Latin means *theorema egregium* (egregium=remarkable).

First we note that for any Q in U, the vectors φ'_u, φ'_v, and N furnish a basis of $\mathbb{R}^3$. Thus we can consider the expansions

$$\begin{aligned}
\varphi''_{uu} &= \Gamma^1_{11}\varphi'_u + \Gamma^2_{11}\varphi'_v + L_1 N\\
\varphi''_{uv} &= \Gamma^1_{12}\varphi'_u + \Gamma^2_{12}\varphi'_v + L_2 N\\
\varphi''_{vu} &= \Gamma^1_{21}\varphi'_u + \Gamma^2_{21}\varphi'_v + L_2 N\\
\varphi''_{vv} &= \Gamma^1_{22}\varphi'_u + \Gamma^2_{22}\varphi'_v + L_3 N\\
N'_u &= a_{11}\varphi'_u + a_{21}\varphi'_v\\
N'_v &= a_{12}\varphi'_u + a_{22}\varphi'_v.
\end{aligned} \tag{1}$$

The numbers Γ^k_{ij} are called the *Christoffel symbols* of the parametrization (U, φ). Altogether, they are in number of $2 \times 2 \times 2 = 8$, but in fact, since $\varphi'_{uv} = \varphi'_{vu}$, we have

$$\Gamma^1_{12} = \Gamma^1_{21} \text{ and } \Gamma^2_{12} = \Gamma^2_{21}.$$

We take dot product of the first four equations with N and use equations (3), page 12, chapter 5 of the notes. We obtain

$$L_1 = e,\ L_2 = f,\ L_3 = g,$$

where e, f, g are the coefficients of the second fundamental form. The Christoffel symbols can be determined by taking again the first four equations and making dot products with φ'_u and φ'_v. We obtain:

$$\begin{aligned}
\Gamma^1_{11}E + \Gamma^2_{11}F &= \varphi'_{uu} \cdot \varphi'_u = \frac{1}{2}E_u\\
\Gamma^1_{11}F + \Gamma^2_{11}G &= \varphi'_{uu} \cdot \varphi'_v = F_u - \frac{1}{2}E_u
\end{aligned} \tag{2}$$

$$\begin{aligned}
\Gamma^1_{12}E + \Gamma^2_{12}F &= \varphi'_{uv} \cdot \varphi'_u = \frac{1}{2}E_v\\
\Gamma^1_{12}F + \Gamma^2_{12}G &= \varphi'_{uv} \cdot \varphi'_v = \frac{1}{2}G_u
\end{aligned} \tag{3}$$

$$\begin{aligned}
\Gamma^1_{22}E + \Gamma^2_{22}F &= \varphi'_{vv} \cdot \varphi'_u = F_v - \frac{1}{2}G_u\\
\Gamma^1_{22}F + \Gamma^2_{22}G &= \varphi'_{vv} \cdot \varphi'_v = \frac{1}{2}G_v
\end{aligned} \tag{4}$$

Each of the three groups of equations can be considered as a linear system of two equations with two unknowns. The determinant of each system is $EG - F^2$ which is strictly positive (why?). We can solve each system and obtain concrete expressions for Γ^k_{ij} in terms of E, F, G and their derivatives.

Now we consider the obvious equation

$$(\varphi''_{uu})'_v - (\varphi''_{uv})'_u = 0.$$

If we use (1), we deduce

$$\begin{aligned}
&\Gamma^1_{11}\varphi''_{uv} + \Gamma^2_{11}\varphi''_{vv} + eN'_v + (\Gamma^1_{11})'_v\varphi'_u + (\Gamma^2_{11})'_v\varphi'_v + e'_v N\\
&= \Gamma^1_{12}\varphi''_{uu} + \Gamma^2_{12}\varphi''_{vu} + fN'_u + (\Gamma^1_{12})'_u\varphi'_u + (\Gamma^2_{12})'_u\varphi'_v + f'_u N
\end{aligned}$$

We use again (1) to substitute all second order derivatives. Then we equate the coefficient of φ'_v. We obtain:

$$\Gamma^1_{11}\Gamma^2_{12} + \Gamma^2_{11}\Gamma^2_{22} + ea_{22} + (\Gamma^2_{11})'_v$$
$$= \Gamma^1_{12}\Gamma^2_{11} + \Gamma^2_{12}\Gamma^2_{12} + fa_{21} + (\Gamma^2_{12})'_u.$$

But we actually know a_{21} and a_{22}, by the Weingarten equations (see chapter 5, section 4 of the notes). By making the replacements we obtain:

$$(\Gamma^2_{12})'_u - (\Gamma^2_{11})'_v + \Gamma^1_{12}\Gamma^2_{11} + \Gamma^2_{12}\Gamma^2_{12} - \Gamma^2_{11}\Gamma^2_{22} - \Gamma^1_{11}\Gamma^2_{12}$$
$$= -E\frac{eg - f^2}{EG - F^2} = -EK$$

and this gives the desired

formula for K in terms of E, F, G and their partial derivatives of first and second order with respect to u and v.

To finish the proof, we consider the local isometry $f : S_1 \to S_2$. Take P a point of S_1. Because $d(f)_P : T_PS_1 \to T_{f(P)}S_2$ is a linear isomorphism, f is a local diffeomorphism at P, which implies that there exists a local parametrization (U, φ) of S_1 around P such that $(U, f \circ \varphi)$ is a local parametrization of S_2 around $f(P)$. For any Q in U, the canonical basis of $T_{f(\varphi(Q))}S_2$ consists of

$$(f \circ \varphi)'_u(Q) = d(f)_{\varphi(Q)}(\varphi'_u(Q)),\ (f \circ \varphi)'_v(Q) = d(f)_{\varphi(Q)}(\varphi'_v(Q)).$$

Moreover, if we denote $P = \varphi(Q)$, we have

$$\mathrm{I}_{f(P)}(d(f)_P(w)) = \mathrm{I}_P(w),$$

for all $w = w_1\varphi'_u(Q) + w_2\varphi'_v(Q)$ in T_PS_1. We also have

$$d(f)_P(w) = w_1(f \circ \varphi)'_u(Q) + w_2(f \circ \varphi)'_v(Q),$$

and

$$\mathrm{I}_P(w) = E(Q)w_1^2 + 2F(Q)w_1w_2 + G(Q)w_2^2$$

as well as

$$\mathrm{I}_{f(P)}(d(f)_P(w)) = \tilde{E}(Q)w_1^2 + \tilde{F}(Q)w_1w_2 + \tilde{G}(Q)w_2^2.$$

We deduce $E(Q) = \tilde{E}(Q)$, $F(Q) = \tilde{F}(Q)$, and $G(Q) = \tilde{G}(Q)$ for any $Q = (u, v)$ in U. Combined with the formula for K from above, these imply that the curvature of S_1 at $\varphi(Q)$ equals the curvature of S_2 at $f(\varphi(Q))$, for any Q in U. □

CURVATURE AND THE THEOREMA EGREGIUM OF GAUSS

DEANE YANG

In this note, we describe a simple way to define the second fundamental form of a hypersurface in $\mathbb{R}^n$ and use it to prove Gauss's Theorema Egregium, as well as its analogue in higher dimensions.

The basic idea is to approximate a hypersurface, near a given point, by the graph of a quadratic polynomial near its critical point. In particular, given any point p in a hypersurface $S \subset \mathbb{R}^n$, the hypersurface can be positioned so that p is at the origin and S is tangent to the hyperplane $T = \{x^n = 0\}$. It follows that S is locally the graph of a function $f(x^1, \dots, x^{n-1})$ satisfying $f(0) = 0$ and $df(0) = 0$. The second order Taylor expansion of f is therefore

$$f(v) = H(v, v) + o(|v|^2), \ v \in T,$$

where H is a symmetric tensor. The second fundamental form at p is defined to be H. The uniqueness of H implies that it is an extrinsic geometric invariant tensor of S.

The statement of the Theorem Egregium then falls out of a straightforward calculation that seeks to identify a tensor invariant, defined in terms of the second fundamental form, that is independent of the extrinsic isometric embedding. It therefore is an intrinsic geometric invariant of the hypersurface. Another straightforward tensor calculation leads to an intrinsic definition of Gauss curvature for a surface in $\mathbb{R}^3$ and, more generally, the Riemann curvature tensor.

Note that neither the Levi-Civita connection nor the Gauss map is used explicitly below.

The discussion below has a straightforward extension to submanifolds of higher codimension.

1. Rigid motions

Let $e_1, \dots, e_n$ denote the standard basis of $\mathbb{R}^n$. Given a nonzero vector $\nu \in \mathbb{R}^n$, let $\nu^\perp$ denote the linear hyperplane normal to ν.

A *rigid motion* is a map $R\colon \mathbb{R}^n \to \mathbb{R}^n$ given by

$$R(x) = A(x - p),$$

where $A \in \mathrm{SO}(n)$ and $p \in \mathbb{R}^n$.

2. Definition of a hypersurface

Define a *hypersurface* to be a subset $S \subset \mathbb{R}^n$ such that for each $x \in S$, there exists a linear subspace $T \subset \mathbb{R}^n$ of codimension 1 such that S near x is graph of a smooth function of the plane $x + T$. In other words, there exists neighborhood $N \subset \mathbb{R}^n$ of 0 and a smooth function $f : N \cap T \to \mathbb{R}$ such that

$$S \cap (x + N) = \{x + v + f(v)u \ : \ v \in T \cap N\}, \tag{1}$$

where u is a nonzero vector normal to T and $f(0) = 0$.

Date: December 31, 2015 (Revised November 13, 2019).

3. Tangent space

For each $x \in S$, there is a unique choice of T, which will be denoted T_xS and called the *tangent plane to* S *at* x, such that the corresponding function f satisfies $f(0) = 0$ and $df(0) = 0$. If S is orientable, then there exists a smooth map $u : S \to S^{n-1}$, where $u(x)$ is normal to T_xS. This is called the *Gauss map*. We will not use the Gauss map below.

4. The second fundamental form

For each $x \in S$, let f be the function be the one in (1), with $T = T_xS$. The *second fundamental form* of S at x is defined to be the Hessian $H(x)$ of f at 0. The Hessian $H(x)$ is a symmetric tensor on T_xS, where, for any $v \in T_xS$,

$$H(x)(v, v) = \left.\frac{d^2}{dt^2}\right|_{t=0} f(tv).$$

Since f is uniquely determined by S and $x \in S$, so is H. It is therefore a geometric invariant of the surface S. Since it depends on the embedding of S, it is an extrinsic invariant.

Given $x \in S$, we can apply a rigid motion to S so that $x = 0$, $u(x) = e_n$, and therefore, in a neighborhood of $0 \in \mathbb{R}^n$,

$$S = \{(x', f(x'))\},$$

where $f(0) = 0$ and $df(0) = 0$. For each $v = v^1e_1 + \cdots + v^{n-1}e_{n-1} \in T_0S (= e_n^\perp)$,

$$H(0)(v, v) = v^iv^jH(0)(e_i, e_j) = H_{ij}v^iv^j, \text{ where } H_{ij} = H_{ji} = H(0)(e_i, e_j).$$

5. Isometric hypersurfaces

Let T denote $e_n^\perp$.

Two hypersurfaces S and $\widehat{S}$ are *isometric* if there exists a smooth diffeomorphism

$$\Phi : S \to \widehat{S}$$

such that the length of any smooth curve $C \subset S$ is equal to the length of the curve $\Phi(C) \subset \widehat{S}$.

Given $x \in S$, let $\hat{x} = \Phi(x) \in \widehat{S}$. Applying rigid motions to both S and $\widehat{S}$, we can assume that that $\hat{x} = x = 0$ and the respective tangent hyperplanes are $T_{\hat{x}}\widehat{S} = T_xS = T$. This in turn defines uniquely the functions $f : T \to \mathbb{R}$, whose graph near 0 is S, and $\hat{f} : T \to \mathbb{R}$, whose graph near 0 is $\widehat{S}$.

Moreover, there is a diffeomorphism $\phi : T \to T$ such that, for each $v \in T$,

$$\Phi(v + f(v)e_n) = \phi(v) + \hat{f}(\phi(v))e_n.$$

The diffeomorphism $\Phi : S \to \widehat{S}$ preserves the lengths of all curves if and only if

$$\partial_i\hat{y} \cdot \partial_j\hat{y} = \partial_iy \cdot \partial_jy,$$

where, for each $v \in T$,

$$\begin{aligned} \hat{y}(v) &= \phi^k(v) + \hat{f}(\phi(v))e_n \\ y(v) &= v + f(v)e_n, \end{aligned}$$

for each $v \in T$. In other words,

$$\partial_i\phi \cdot \partial_j\phi + \partial_p\hat{f}\partial_i\phi^p\partial_q\hat{f}\partial_j\phi^q = \delta_{ij} + \partial_if\partial_jf. \tag{2}$$

Note that

$$\begin{aligned} \partial_i f(0) &= \partial_i \hat{f}(0) = 0 \\ \partial_i \phi^j(0) &= \delta_i^j, \end{aligned}$$

for all $1 \leq i, j \leq n-1$. Therefore, if we differentiate (2) and evaluate at $v = 0$, we get

$$\partial^2_{ik}\phi^j + \partial^2_{jk}\phi^i = 0.$$

This implies that, at $v = 0$,

$$\partial^2_{ik}\phi^j = -\partial^2_{jk}\phi^i = \partial^2_{ji}\phi^k = -\partial^2_{ik}\phi^j, \tag{3}$$

and therefore

$$\partial^2_{jk}\phi^i(0) = 0, \text{ for all } 1 \leq i, j, k \leq n-1.$$

If we differentiate (2) again, evaluate at $x = 0$, and cycle through the indices i, j, k, l, we get

$$\partial^3_{ikl}\phi^j + \partial^3_{jkl}\phi^i + \partial^2_{ik}\hat{f}\partial^2_{jl}\hat{f} + \partial^2_{il}\hat{f}\partial^2_{jk}\hat{f} = \partial^2_{ik}f\partial^2_{jl}f + \partial^2_{il}f\partial^2_{jk}f \tag{4}$$

$$\partial^3_{jli}\phi^k + \partial^3_{kli}\phi^j + \partial^2_{jl}\hat{f}\partial^2_{ki}\hat{f} + \partial^2_{ji}\hat{f}\partial^2_{kl}\hat{f} = \partial^2_{jl}f\partial^2_{ki}f + \partial^2_{ji}f\partial^2_{kl}f \tag{5}$$

$$\partial^3_{kij}\phi^l + \partial^3_{lij}\phi^k + \partial^2_{ki}\hat{f}\partial^2_{lj}\hat{f} + \partial^2_{kj}\hat{f}\partial^2_{li}\hat{f} = \partial^2_{ki}f\partial^2_{lj}f + \partial^2_{kj}f\partial^2_{li}f \tag{6}$$

$$\partial^3_{ljk}\phi^i + \partial^3_{ijk}\phi^l + \partial^2_{lj}\hat{f}\partial^2_{ik}\hat{f} + \partial^2_{lk}\hat{f}\partial^2_{ij}\hat{f} = \partial^2_{lj}f\partial^2_{ik}f + \partial^2_{lk}f\partial^2_{ij}f. \tag{7}$$

Therefore, the equation

$$(4) - (5) + (6) - (7) \tag{8}$$

eliminates ϕ and gives

$$\partial^2_{ik}\hat{f}\partial^2_{jl}\hat{f} - \partial^2_{il}\hat{f}\partial^2_{ik}\hat{f} = \partial^2_{ik}f\partial^2_{jl}f - \partial^2_{il}f\partial^2_{ik}f, \tag{9}$$

Ig follows that, if H and $\widehat{H}$ are the second fundamental forms of S and $\widehat{S}$ at 0, then

$$\widehat{R}_{ijkl} = R_{ijkl}, \tag{10}$$

where

$$R_{ijkl} = H_{ik}H_{jl} - H_{il}H_{jk} \tag{11}$$

$$\widehat{R}_{ijkl} = \widehat{H}_{ik}\widehat{H}_{jl} - \widehat{H}_{il}\widehat{H}_{jk}. \tag{12}$$

This leads to the definition of the tensor R, where, for any $v_1, v_2, v_3, v_4 \in T_xS$,

$$R(v_1, v_2, v_3, v_4) = H(v_1, v_3)H(v_2, v_4) - H(v_1, v_4)H(v_2, v_3).$$

What (10) shows is that the tensor R for a surface S depends only on its intrinsic geometry and not on the isometric embedding. The tensor R is, of course, the Riemann curvature tensor, and the equations (11) are the Gauss equations.

If $n = 2$, then the only nontrivial component of the Riemann curvature tensor is

$$K = R(e_1, e_2, e_1, e_2) = H_{11}H_{22} - H_{12}^2,$$

which is known as the Gauss curvature, and equation (10) is the Theorem Egregium of Gauss.

Example 1. We can show that the standard sphere in $\mathbb{R}^3$ is not locally isometric to the plane $x^3 = 0$ using this. Using the definition of the second fundamental form, we can verify that, for the plane, $H_{ij} = 0$ and therefore $R_{1212} = 0$. On the other hand, for the sphere, $H_{ij} = \delta_{ij}$ and therefore $R_{1212} = 1$. Therefore, the two surfaces are not locally isometric.

6. Tensor identities

Most of the proof above involves only differentiation and straightforward calculations. The only significant steps are the following:

(1) Definition of a hypersurface
(2) If a map between two hypersurfaces preserves lengths of curves, then the map satisfies equation (2).
(3) Most importantly, the tensor calculations done in (3) and (8). These are equivalent to the following tensor identities:

$$\begin{aligned}(T \otimes S^2T) \cap (\Lambda^2 T \otimes T) &= \{0\}\\ (T \otimes S^3T) \cap (\Lambda^2 T \otimes \Lambda^2 T) &= \{0\}.\end{aligned}$$

7. Intrinsic formula for Riemann curvature

The embedding of S as a graph over T is given by $v \in T \mapsto v + f(v)e_n$ and therefore, the Riemannian metric is given by

$$\begin{aligned}g_{ij}(v) &= \partial_i(v + f(v)e_n) \cdot \partial_j(v + f(v)e_n)\\ &= (e_i + \partial_i f(v)e_n) \cdot (e_k + \partial_j f(v)e_n)\\ &= \delta_{ij} + \partial_i f \partial_j f.\end{aligned}$$

Therefore, since $df(0) = 0$, it follows that at $v = 0$,

$$\begin{aligned}\partial_k g_{ij} &= \partial_k(\delta_{ij} + \partial_i f \partial_j f)\\ &= \partial^2_{ki} f \partial_j f + \partial_i f \partial^2_{kj} f\\ &= 0.\\ \partial^2_{ij} g_{kl} &= \partial^2_{ij}(\partial_k f \partial_l f)\\ &= \partial^2_{ik} f \partial^2_{jl} f + \partial^2_{il} f \partial^2_{jk} f.\end{aligned}$$

Permuting the indices, we get

$$\partial^2_{ik} g_{jl} = \partial^2_{ij} f \partial^2_{kl} f + \partial^2_{il} f \partial^2_{jk} f \tag{13}$$

$$\partial^2_{jl} g_{ik} = \partial^2_{ij} f \partial^2_{kl} f + \partial^2_{jk} f \partial^2_{il} f \tag{14}$$

$$\partial^2_{il} g_{jk} = \partial^2_{ij} f \partial^2_{kl} f + \partial^2_{ik} f \partial^2_{jl} f \tag{15}$$

$$\partial^2_{jk} g_{il} = \partial^2_{ij} f \partial^2_{kl} f + \partial^2_{jl} f \partial^2_{ik} f. \tag{16}$$

Therefore, the equation

$$-(13) - (14) + (15) + (16) \tag{17}$$

implies that, at $x = 0$,

$$\begin{aligned}-\partial^2_{ik} g_{jl} - \partial^2_{jl} g_{ik} + \partial^2_{il} g_{jk} + \partial^2_{jk} g_{il} &= -\partial^2_{il} f \partial^2_{jk} f - \partial^2_{jk} f \partial^2_{jl} f + \partial^2_{ik} f \partial^2_{jl} f + \partial^2_{jl} f \partial^2_{ik} f\\ &= 2R_{ijkl}.\end{aligned}$$

This proves, at least for a Riemannian manifold that can be isometrically embedded as a hypersurface in Euclidean space, that the Riemann curvature tensor is an intrinsic geometric invariant.

8. The Riemann curvature of an abstract Riemannian manifold

Let M be a n-manifold with Riemannian metric g. Given local coordinates $x^1, \ldots, x^n$, the metric is

$$g = g_{ij}(x)\, dx^i\, dx^j,$$

where $g_{ij}(x) = g(\partial_i, \partial_j)$. The calculations in the previous section suggest the following: Given $p \in M$, let $x = (x^1, \ldots, x^n)$ be coordinates such that $x(p) = 0$, $g_{ij}(0) = \delta_{ij}$ and $\partial_k g_{ij}(0) = 0$, for all $1 \le i, j, k \le n$. Then define the Riemann curvature tensor at p to be given by

$$R(v_1, v_2, v_3, v_4) = R_{ijkl} v_1^i v_2^j v_3^k v_4^l,$$

where, at $x = 0$,

$$R_{ijkl} = -\frac{1}{2}(\partial^2_{ik} g_{jl} + \partial^2_{jl} g_{ik} - \partial^2_{il} g_{jk} - \partial^2_{jk} g_{il}).$$

To prove that this is a well defined tensor, it suffices to prove the following lemmas, which have straightforward proofs.

Lemma 1. *Let g be a smooth Riemannian metric on an n-manifold M. For each $p \in M$, there exist local coordinates $x = (x^1, \ldots, x^n)$ such that $x(p) = 0$ and $g = g_{ij}\, dx^i\, dx^j$, where, for every $1 \le i, j, k \le n$,*

$$\begin{aligned} g_{ij}(0) &= \delta_{ij} \\ \partial_k g_{ij}(0) &= 0. \end{aligned}$$

Remark. Exponential or normal coordinates satisfy Lemma 1. However, a direct proof of Lemma 1 is a lot simpler than the construction of exponential coordinates.

Lemma 2. *Let M and N be smooth n-manifolds, h be a Riemannian metric on N, $\Phi : M \to N$ a smooth map, and $g = \Phi^* h$. Let $x = (x^1, \ldots, x^n)$ be local coordinates on a neighborhood of $p \in M$ and $y = (y^1, \ldots, y^n)$ be local coordinates on a neighborhood of $\Phi(p) \in N$ such that*

$$\begin{aligned} x(p) &= 0 \\ y(\Phi(p)) &= 0 \\ \frac{\partial y^i}{\partial x^j}(0) &= \delta^i_j \\ h_{ij}(0) &= \delta_{ij} \\ \partial_k h_{ij}(0) &= 0. \end{aligned}$$

Then at $x = y = 0$,

$$\begin{aligned} g_{ij}(0) &= \delta_{ij} \\ \partial_k g_{ij}(0) &= 0 \\ \partial^2_{ik} g_{jl} + \partial^2_{jl} g_{ik} - \partial^2_{il} g_{jk} - \partial^2_{jk} g_{il} &= \partial^2_{ik} h_{jl} + \partial^2_{jl} h_{ik} - \partial^2_{il} h_{jk} - \partial^2_{jk} h_{il}. \end{aligned}$$

PREFACE

> *Symmetry, as wide or as narrow as you may define its meaning, is one idea by which man through the ages has tried to comprehend and create order, beauty, and perfection.*
>
> —HERMANN WEYL

The unifying concept underlying fractals, chaos, and power laws is self-similarity. Self-similarity, or invariance against changes in scale or size, is an attribute of many laws of nature and innumerable phenomena in the world around us. Self-similarity is, in fact, one of the decisive symmetries that shape our universe and our efforts to comprehend it.

Symmetry itself is one of the most fundamental and fruitful concepts of human thought [Wey 81]. By symmetry we mean an *invariance* against change: something stays the same, in spite of some potentially consequential alteration. Mirror symmetry, that is, invariance against "flipping sides," is perhaps the most widely noticed symmetry. Nature built many of her organisms in nearly symmetric ways, and most fundamental laws of physics, such as Newton's law of gravitation, have an *exact* mirror symmetry: there is no difference between left and right in the attraction of heavenly (and most earthbound) bodies. However, the nonconservation of parity in radioactive decay—that is, the *violation* of point symmetry in the "weak" interactions—has finally taught even the physicists to take the distinction between right and left seriously.

Another important symmetry is invariance with respect to geometric translation. Our trust in invariance under transpositions in space and time is, in fact, so unlimited that we believe that the laws of nature are the same all over the cosmos—and that they have been, and will remain so, for all time.

An equally momentous symmetry is invariance with respect to rotation. A circle is invariant under rotation around its center by any angle. A square can be rotated only through angles that are multiples of $360°/4 = 90°$; it is said to have a fourfold symmetry axis. A regular hexagon has a sixfold symmetry. While the rotational symmetry of a flower or a starfish may be imperfect, the exact isotropy found in the fundamental laws of nature is one of the most powerful principles in elucidating the structure of individual atoms, complicated molecules, and entire crystals. Transposition, rotation, and mirror symmetries, acting together, shape crystals from diamonds to snowflakes. And the same three symmetries govern much of what we find pleasing in ornamental designs.

An even more astounding symmetry is the exact identity of like elementary particles. There simply is no difference between an electron here and an electron there—on a distant star, for example. In fact, the perfect identity of photons, the particles of light, has disqualified them from being counted as so many identifiable individuals, resulting in a new kind of particle statistics, discovered by S. N. Bose and rendered palatable by Einstein—a way of counting not heretofore encountered in a world filled with tangible objects.

It was one of the greatest mathematicians of our century, Emmy Noether, who first pointed out the connection between the symmetries of the fundamental laws of physics with respect to displacements in space and time and rotations, on the one hand, and the conservation of linear momentum, energy, and angular momentum on the other. (Noether taught at Göttingen, where David Hilbert, overcoming obstinate prejùdice, had finally secured a faculty position for her. In the dismantling of German science in 1933, she was forced to leave Gottingen. She died at Bryn Mawr in 1935.)

Other symmetries have had equally profound consequences in our understanding of the universe we inhabit. Invariance against uniform motion has given us special relativity, a fusion of space and time into space-time and, as its best-known consequence, the equation $E = mc^2$. The equivalence of acceleration and gravity postulated by Einstein is the basis of his general theory of relativity, which further revolutionized our appreciation of space, time, and matter.

Yet, among all these symmetries flowering in the Garden of Invariance, there sprouts one that, until recently, has not been sufficiently cherished: the ubiquitous invariance against changes in size, called *self-similarity* or, if more than one scale factor is involved, *self-affinity*. The enormously fruitful concepts of self-similarity and self-affinity pervade nature from the distribution of atoms in matter to that of the galaxies in the universe. And in mathematics, too, self-similarity is deeply entrenched. Some 300 years ago the German philosopher and polymath Gottfried Wilhelm Leibniz used the scaling invariance of the infinitely long straight line for its definition. Cantor sets and Weierstrass functions are other early examples—albeit less smooth—of self-similar structures in mathematics, later joined by Julia sets and other marvels of set theory.

It is perhaps symptomatic that with *set theory* still another abstract branch of mathematics has penetrated the real world. There simply seems to be no limit to Eugene Wigner's "unreasonable effectiveness" of mathematics. Indeed, who would have thought that such utterly mathematical constructions as *Cantor sets*, invented solely to reassure the skeptics that sets could both have zero measure and still be uncountable, would make a real difference in any practical realm, let alone become a pivotal concept? Yet this is precisely what happened for many natural phenomena from gelation, polymerization, and coagulation in colloidal physics and chemistry to nonlinear systems in innumerable branches of science. Percolation, dendritic growth, fracture surfaces, electrical discharges (lightnings and Lichtenberg figures), and the composition of quasicrystals are best described by set-theoretic constructs.

Or take the weird functions Karl Weierstrass invented a hundred years ago purely to prove that a function could be both everywhere continuous and yet nowhere differentiable. The fact that such an analytic pathology describes something in the real world—nay, is *elemental* to understanding the strange attractors of nonlinear dynamic systems (such as the double swing and the three-body problem)—gives one pause.

The word *symmetric* is of ancient Greek parentage and means well-proportioned, well-ordered—certainly nothing even remotely chaotic. Yet, paradoxically, self-similarity, the topic of this tome, alone among all the symmetries gives birth to its very antithesis: *chaos*, a state of utter confusion and disorder. As we shall endeavor to show, the genesis of chaos is, in fact, closely related to self-similarity and its inherent lack of "smoothness."

Perhaps not surprisingly, self-similarity entails numerous paradoxes in measurements of time, length, and even musical pitch. Think of Zeno's tardy turtle, pursued—but never overtaken—by swift Achilles. Why do certain lengths increase without bound when we measure them with ever smaller yardsticks? How would Euclid have explained plane geometric figures whose areas scale not as the squares of their apparent perimeters but as some lesser power, such as 1.77 and other fractional exponents? What should we think of musical sounds that, when scaled *up* in frequency, sound—incredibly—*lower* in pitch? How are such monstrosities possible? And how can we describe them in a consistent, meaningful manner?

Here a particularly felicitous thought by Felix Hausdorff comes to the rescue. His and Abram Besicovitch's new ways of looking at dimension dethrones it from its integer position and propels it into the realm of real numbers, giving us one of the sharpest tools—the *Hausdorff dimension* and its ramifications—with which to attack the strange sets that self-similarity breeds.

And while recalling some of the glorious names of the past, we should never forget our great contemporary, the inimitable Benoit B. Mandelbrot, who, single-handed, rescued set theory's most brittle functions and "dustiest" sets from near-oblivion and planted them right in the middle of our daily experience and consciousness. Yes, for all these years, we *have* been living with fractal arteries, not far from fractal river systems draining fractal mountainscapes under fractal clouds, toward fractal coastlines. But, kin to Molière's would-be gentleman, we lacked the proper prose—*fractal*, noun and adjective—that Benoit B. begot.

But our story also has a silent and immobile hero: the digital computer. There can be little doubt that computers have acted as the most forceful forceps in extracting fractals from the dark recesses of abstract mathematics and delivering their geometric intricacies into bright daylight. In fact, the impact of fractal images, often of unimagined beauty and appeal, has given computer graphics a surprising new dimension.

Synopsis

We open our treatise with one of the most charming uses that similarity was ever put too: the young Einstein's proof of Pythagoras's theorem. By adding just a single straight line, in the right place, to a right triangle and applying plenty of similarity, the popular theorem is proved without further prodding.

We then invade the unlimited domain of *self*-similarity as manifest in fractals, multifractals, and the scaling laws of physics, psychophysics, and boundless other fields.

In phase spaces, we encounter deterministic chaos and strange attractors. Percolation and other phase transitions lead us to critical exponents and a hierarchy of different dimensions. Following Poincaré, we immerse ourselves in the self-similarities of iterated mappings, from baker transformations and Bernoulli shifts to logistic parabolas and circle maps. Neither tori, *cantori*, nor Arnold tongues will faze us as we (sur)mount devil's staircases to unwind among the rational winding numbers festooning Farey trees.

And when we talk about nonlinear dynamics we must remember some of the great contributors of recent vintage: Siegel, Moser, Lorenz, Wilson, Feigenbaum, and—last but not least—the great Russian "school" exemplified by such names as Lyapunov, Arnol'd, Sinai, Chirikov, Alexeev, Anosov, Pesin, and the recently deceased master mathematician Kolmogorov.

Cayley trees, also known as Bethe lattices, will provide us with a fitting point of departure for many a practical fractal, such as our bronchial and vascular systems. Cellular automata concern us as models of both biological growth and chemical reactions.

We are also strangely attracted to symbolic dynamics, kneading (and needing) the Morse-Thue sequence and, especially, the Fibonacci rabbit sequence and their discrete self-similarities that, indiscreetly, tell us so much about period doubling, mode locking, frustrated Ising spins, and fivefold symmetric quasicrystals. Many of these subjects were shrouded in mystery and beset by paradoxes before the sharp scalpels, fashioned by scaling and renormalization theories, revealed the underlying tissue and made them tractable. In fact, it is no accident that viable fundamental field theories in physics are renormalizable, as they must be if they are to shun sham scales.

And, of course, we will not hesitate to run down random fractals, from Brownian motion to diffusion-limited aggregation and stock market hiccups (some hiccups of late!). The poor gambler's ruin and the St. Petersburg paradox will provide further food for fractal reflections.

These, then, are some of the exciting, and sobering, themes sounded in the present volume. The aim of this exposition is to enhance the reader's understanding of self-similarity, perhaps the most pregnant of all of nature's symmetries, and to illustrate the wide-ranging applications of scaling invariance in physics, chemistry, biology, music, and—particularly—the visual arts, as manifested in the recent renaissance of computer graphics through fractal images and their iterative beauty.

Acknowledgments

This book owes its existence to many sources. Apart from a brief encounter, in my dissertation, with chaos among the normal modes of concert halls, a "nonintegrable" system if there ever was one, my main stimulus came from the early demonstrations by Heinz-Otto Peitgen and Peter Richter of fractal Julia sets. Their beautiful images, and the intriguing mathematics which underlies them, as epitomized in their book *The Beauty of Fractals*, have made a lasting impression on me.

My first meeting with Mandelbrot's work was his analysis of word frequencies in natural and artificial languages, which touched upon my own interests in computer speech synthesis and recognition. Mandelbrot's monumental monograph *The Fractal Geometry of Nature* influenced me immeasurably, as it did so many other people.

I have also greatly benefited from Robert Devaney's books and lectures on chaos, Jens Feder's *Fractals*, Michael Barnsley's *Fractals Everywhere*, and Dietrich Stauffer's charming *Introduction to Percolation Theory*.

I learned a lot about new developments during the 1988 Gordon Conference on Fractals, organized by Richard Voss and Paul Meakin, which brought together many of the world's outstanding experts in the field.

At the University of Göttingen, it was mainly through the work of Werner Lauterborn that I saw chaos in action in nonlinear dynamic systems from cavitation bubbles to Toda chains. My own students at the Drittes Physikalisches Institut provided both stimulus and rectification during a series of lecture courses on self-similarity, fractals, and chaos. Heinrich Henze and Karl Lautscham made skillful additions to the demonstrations that accompanied these lectures. Holger Behme, Wolf Dieter Brandt, and Tino Gramss contributed many of the computer graphics in this book.

The late Walter Kaufmann-Bühler of Springer Verlag, New York, and Ronald Graham, a longtime colleague at Bell Laboratories, provided early encouragement.

Hildegard Franks and Esperanza Plata in Murray Hill, New Jersey, supported by Maija Sutter and Irena Schönke in Göttingen, converted nearly illegible

CHAPTER

Introduction

> *I want to know how God created this world. I am not interested in this or that phenomenon, in the spectrum of this or that element. I want to know His thoughts; the rest are details.*
>
> —ALBERT EINSTEIN

Nature abounds with periodic phenomena: from the motion of a swing to the oscillations of atoms, from the chirping of a grasshopper to the orbits of the heavenly bodies. And our terrestrial bodies, too, participate in this universal minuet—from the heart beat and circadian rhythms to monthly and even longer cycles.

Of course, nothing in nature is *exactly* periodic. All motion has a beginning and an end, so that, in the mathematical sense, strict periodicity does not exist in the real world. Nevertheless, periodicity has proved to be a supremely useful concept in elucidating underlying laws and mechanisms in many fields.

One reason for the universality of simple harmonic motion is the linearity—or near-linearity—of many physical systems and the invariance with displacement in space and time of the laws governing their behavior.

But there are numerous other phenomena in which linearity breaks down and, instead of periodicity, we get aperiodic or even chaotic motion: the smooth waves on a well-behaved lake turn to violent turbulence in the mountain brook, and the daily sunrise, the paradigm of predictability, is overshadowed by cloud formations, a haven for *chaos*—albeit *deterministic* chaos.

But no matter how chaotic life gets, with all regularity gone to bits, another fundamental bulwark often remains unshaken, rising above the turbulent chaos: *self-similarity*, an invariance with respect to *scaling*; in other words, invariance not with *additive* translations, but invariance with *multiplicative* changes of scale. In short, a self-similar object appears unchanged after increasing or shrinking its size. Indeed, in turbulent flows, large eddies beget smaller ones, and these spawn smaller ones still—and so on *ad infinitum* (almost). In general, one of the conspicuous consequences of self-similarity is the appearance of exceedingly fine-grained structures, now generally called *fractals* after Benoit B. Mandelbrot, the father of fractals [Man 83].[1]

Many laws of nature are independent, or nearly so, of a scaling factor. The fact that scaling usually has a limit (Planck's constant, when things get too small, or the speed of light, when objects fly too fast) does no harm to the usefulness of "thinking self-similar," just as the lack (outside mathematics) of strict periodicity is no great impediment in the real world. In a sense, self-similarity is akin to periodicity on a *logarithmic* scale.

Self-similarity, strict or otherwise, reigns in many fields in many guises, and in this book we shall explore some of the many manifestations of self-similarity in the world around us. Among the topics treated are the following:

- Scaling laws and their exponents in physics, psychophysics, and physiology
- Random walks in the stock market and under the microscope; floods, forest fires, the distribution of galaxies, and other "accidents" with statistical self-similarity
- Scaling invariance, self-similarity, and some of their mathematical models, such as Cantor sets and Julia sets
- Fractals and their characterization by Hausdorff, and other noninteger dimensions; fractal paradoxes and their resolution; Weierstrass functions and Hilbert curves; Koch flakes, Sierpinski gaskets, and other non-Euclidean constructions in two and more dimensions; fat fractals and multifractals
- Iterated mappings and a selection of the ensuing self-similarities
- The logistic parabola and other unimodal maps with universal scaling laws; period-doubling bifurcation to chaos; the Feigenbaum constant, symbolic dynamics and the Morse-Thue sequence; Sharkovskii's universal ordering of orbits
- Complexification of the quadratic map and the Mandelbrot set
- Devil's staircases, Farey trees, Arnold tongues, and modelocking; the "rabbit sequence" and the quasi-periodic route to temporal and spatial chaos; Ising spins and quasicrystals
- Laplace's triangle and cellular automata

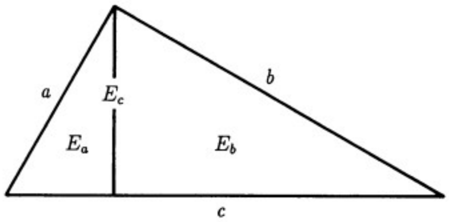

Figure 1 Pythagoras's theorem: sketch for proof by the 11-year-old Einstein based on similarity.

In this chapter some of these topics are introduced informally, together with the leading dramatis personae.

Einstein, Pythagoras, and Simple Similarity

I will a little think.
—ALBERT EINSTEIN, in America

When Jacob Einstein taught (Euclidean) geometry to his 11-year-old nephew Albert, the young Einstein—even then striving for utmost parsimony—felt that some of Euclid's proofs were unnecessarily complicated.[2] For example, in a typical proof of Pythagoras's theorem $a^2 + b^2 = c^2$, was it really mandatory to have all those extra lines, angles, and squares in addition to the basic right triangle with hypotenuse, c and sides a and b?

After "a little thinking," the sharp youngster came up with a proof that required only *one* additional line, the altitude above the hypotenuse (see Figure 1). This height divides the large triangle into two smaller triangles that are *similar* to each other and similar to the large triangle. (Triangles are similar if their angles are the same, which is easily seen to be the case in Figure 1.)

Now, in Euclidean geometry, the area ratio of two similar (closed) figures is equal to the *square* of the ratio of corresponding *linear* dimensions. Thus, the areas E_a, E_b, and E_c (E as in German *Ebene*) of the three triangles in Figure 1 are related to their hypotenuses a, b, and c by the following equations:

$$E_a = ma^2 \tag{1}$$

---

[2] I have the story from Schneior Lifson of the Weizmann Institute in Tel Aviv, who has it from Einstein's assistant Ernst Strauss, to whom it was told by old Albert himself.

$$E_b = mb^2 \tag{2}$$

$$E_c = mc^2 \tag{3}$$

where m is a dimensionless nonzero multiplier that is the *same in all three equations.*

Now a second look at Figure 1 will reveal that the area of the large triangle is, of course, the sum of the areas of the two smaller triangles,

$$E_a + E_b = E_c$$

or, with equations 1 to 3,

$$ma^2 + mb^2 = mc^2$$

Dividing this identity by the common measure m promptly produces Pythagoras's renowned result

$$a^2 + b^2 = c^2$$

proved here by an 11-year old person[3] by combining two fertile scientific principles that were going to stand the grown-up Einstein in good stead: simplicity and symmetry, of which self-similarity is a special case. Yet the true beauty of Einstein's proof is not that it is so simple, but that it exposes the true essence of Pythagoras's theorem: *similarity* and *scaling*.

The resemblance of equation 3 to Einstein's later discovery, his famous $E = mc^2$, is of course entirely fortuitous. The equivalence of mass m and energy E, which is at the basis of nuclear power in all its guises, is a consequence of Lorentz invariance. This invariance, which underlies special relativity, was predicted by Einstein in 1905 after, it seems, several false starts and a "little more thinking" (see Figure 2).

A Self-Similar Array of Self-Preserving Queens

One of numerous chess problems is the placement of as many queens as possible on a chessboard of a given size so that no queen "attacks" (shares a row, column, or $\pm 45°$ diagonal with) any other queen. For a $k \times k$ square board, there can be at most k nonattacking queens. But are k peacefully coexisting queens always possible? What if k is very large? Doesn't the complexity of placing the queens grow exponentially with the size of the board? As we shall see, the placement is actually very simple, even for arbitrarily large boards, if we focus our attention

---

[3] Really a "nonperson" at that stage, considering the neglect he suffered in his Munich high school [Pye 85].

' $! ,
;B<C< D A A / ;* E / ; ; !

' / %$ D8D <)CF &<D 88)B&D<CF G CF

and given by

$$\int_V \partial_i f\, dV = \oint_S f\, dS_i, \tag{1.139a}$$

$$\int_S \varepsilon_{ijk}\partial_k f\, dS_j = \oint_\Gamma f\, dx^i, \tag{1.139b}$$

where, as in the case of the divergence and curl theorems, S is the boundary of V for the first equation, while Γ is the boundary of S in the second. The proofs of these relations are completely analogous to those of the earlier theorems. In the case of the divergence theorem, the only modification is that we only need to consider one term, and we integrate in the x^i direction first. In fact, we could prove the divergence theorem by first proving the more general form and afterwards letting f be the jth component of a vector $\vec{v}$. We would obtain

$$I_i^j = \int_V \partial_i v^j dV = \oint_S v^j dS_i \tag{1.140}$$

and upon letting $i = j$ and summing

$$I_i^i = \int_V \partial_i v^i dV = \int_V \nabla \cdot \vec{v}\, dV = \oint_S v^i dS_i = \oint_S \vec{v} \cdot d\vec{S}. \tag{1.141}$$

Proving the generalised curl theorem starting from the regular curl theorem is left as Problem 1.44.

1.6 NON-CARTESIAN COORDINATE SYSTEMS

While Cartesian coordinate systems provide a solid basis for dealing with scalars, vectors, and later on tensors, in affine spaces, we will encounter problems that are easier to describe and solve using a different set of coordinates that are not necessarily linear or even orthogonal. In several cases, we will also be able to apply symmetry arguments in a particular set of coordinates that are not as easily applicable in other coordinate systems.

1.6.1 General theory

A coordinate system of an N dimensional affine space is a labelling of all the points in the space by N numbers, which we call *coordinates*. Each combination of possible coordinates should uniquely define a point in the space. Each y^a is a continuous function called a *coordinate function* from the N dimensional space to the real numbers. From this point on, we will adopt the convention of using early letters in the alphabet (a, b, c, ...) as indices for general coordinate systems and reserve letters from the middle of the alphabet (i, j, k, ...) for indices in Cartesian coordinates.

Example 1.25 Given an affine N dimensional space, we can always define a Cartesian coordinate system as we have done previously. We do so by selecting one point in the affine space as the origin O and selecting a set of orthonormal basis vectors $\vec{e}_i$. The coordinates are then defined by mapping the coordinates x^i onto the point P such that

$$\overrightarrow{OP} = \vec{x} = \vec{e}_i x^i, \tag{1.142}$$

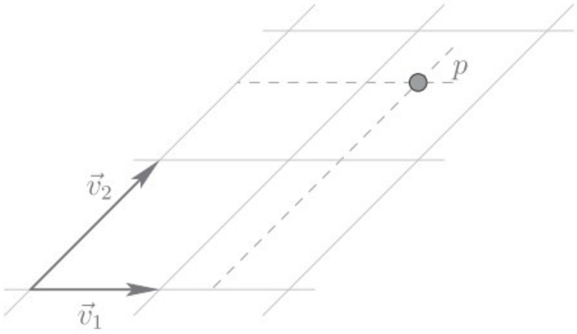

Figure 1.16 A coordinate system for a two-dimensional affine space may be based on the linearly independent, but not orthogonal, set of vectors $\vec{v}_1$ and $\vec{v}_2$. In this case, the coordinates of the point p would be $y^1 = 1.4$, $y^2 = 1.6$.

where $\overrightarrow{OP}$ is the difference vector between P and O. The coordinate functions are given by

$$x^i(P) = \vec{e}_i \cdot \overrightarrow{OP}. \tag{1.143}$$

Since we can always start by writing down a Cartesian coordinate system for an affine space, the coordinates of a more general coordinate system may be written in terms of these Cartesian coordinates for simplicity.

Example 1.26 We can create a coordinate system that is not based on orthogonal basis vectors in a similar way to how we created the Cartesian coordinate system. Instead of a set of orthonormal basis vectors, it suffices to pick a set of linearly independent vectors $\vec{v}_a$. The mapping of the coordinates y^a to the point P is given by

$$\overrightarrow{OP} = \vec{x} = \vec{v}_a y^a. \tag{1.144}$$

However, note that the coordinate functions are not given by $y^a = \vec{v}_a \cdot \overrightarrow{OP}$ in this case as the vectors $\vec{v}_a$ are not necessarily orthogonal or even normalised. For concreteness, let us take a two-dimensional space parametrised using the basis $\vec{v}_1 = \vec{e}_1$ and $\vec{v}_2 = \vec{e}_1 + \vec{e}_2$, where $\vec{e}_1$ and $\vec{e}_2$ form an orthonormal basis, see Fig. 1.16. We obtain

$$\vec{x} = y^1\vec{e}_1 + y^2(\vec{e}_1 + \vec{e}_2) = \vec{e}_1(y^1 + y^2) + \vec{e}_2 y^2. \tag{1.145}$$

From this we can deduce that the coordinate functions are given by

$$y^1 = (\vec{e}_1 - \vec{e}_2) \cdot \vec{x} = x^1 - x^2 \neq \vec{v}_1 \cdot \vec{x}, \tag{1.146a}$$

$$y^2 = \vec{e}_2 \cdot \vec{x} = x^2 \neq \vec{v}_2 \cdot \vec{x}. \tag{1.146b}$$

Equivalently, we could have used

$$y^1 = x^1 - x^2, \tag{1.147a}$$

$$y^2 = x^2, \tag{1.147b}$$

to *define* the coordinate functions y^1 and y^2. In what follows we will discuss how this applies to the general setting with an arbitrary coordinate system.

1.6.1.1 Tangent vector basis

As indicated above, we will now assume that the coordinate functions y^a are known functions of the Cartesian coordinates x^i. Given these functions, we define the *coordinate lines* for the y^a coordinate as the curves for which y^b is constant for all $b \neq a$. The *tangent vector* of this coordinate line is given by

$$\vec{E}_a = \frac{\partial \vec{x}}{\partial y^a} = \frac{\partial x^i}{\partial y^a}\vec{e}_i, \tag{1.148}$$

where $\vec{e}_i$ are the Cartesian basis vectors, which are constant. The partial derivative in this expression is the partial derivative of the Cartesian coordinate functions expressed as functions of the y coordinates. In order for the coordinate system to uniquely define a point, the tangent vectors $\vec{E}_a$ must be linearly independent. We can use this fact in order to use the $\vec{E}_a$ vectors as a set of basis vectors and express any vector as a linear combination of these basis vectors. This presents us with a conundrum as the vectors $\vec{E}_a$ may generally depend on the coordinates. The way forward here is to realise that most vectors are defined only at a given point in space. In particular, for vector fields, it is natural to use the basis defined at a particular spatial point as the basis for the fields at that point. In terms of components, we would write

$$\vec{v}(\vec{x}) = v^a(\vec{x})\vec{E}_a(\vec{x}). \tag{1.149}$$

In what follows, we will often suppress the explicit mention of the spatial dependence of both vector components and basis vectors, i.e., we will assume that $v^a \equiv v^a(\vec{x})$ and $\vec{E}_a \equiv \vec{E}_a(\vec{x})$.

The set of vectors $\vec{E}_a$ is called a *tangent vector basis* and the vector components v^a are called *contravariant vector components*. The reason for this nomenclature is that a vector is not dependent upon the basis used to represent it and in order to ensure that this is the case, the vector components must transform in the opposite way as compared to the basis vectors under a coordinate change. In particular for a vector $\vec{v}$

$$\vec{v} = v^a\vec{E}_a = v^a\frac{\partial x^i}{\partial y^a}\vec{e}_i = v^i\vec{e}_i. \tag{1.150}$$

Scalar multiplication with $\vec{e}_j$ now leads to

$$v^j = \frac{\partial x^j}{\partial y^a}v^a \quad \Longrightarrow \quad v^b = \frac{\partial y^b}{\partial x^j}\frac{\partial x^j}{\partial y^a}v^a = \frac{\partial y^b}{\partial x^j}v^j. \tag{1.151}$$

Here we have used the chain rule and the fact that

$$\frac{\partial y^b}{\partial x^j}\frac{\partial x^j}{\partial y^a} = \delta^b_a. \tag{1.152}$$

Note that we have here introduced a slightly new notation for the δ symbol, namely that it has one index up and one index down. As we shall see, the position of the indices (up or down), that we have so far been quite flexible with, plays a crucial role for non-Cartesian coordinate systems. In Eq. (1.151), we have found that the vector components v^a transform with the partial derivative of the y coordinates with respect to the x coordinates instead of vice versa, as the tangent vector basis does.

We also note that the form of Eq. (1.151) is not restricted to when one of the coordinate systems is Cartesian. If we have two coordinate systems with coordinates y^a and $y'^{a'}$, respectively, we obtain

$$v^{a'} = \frac{\partial y'^{a'}}{\partial x^j} v^j = \frac{\partial y'^{a'}}{\partial x^j} \frac{\partial x^j}{\partial y^a} v^a = \frac{\partial y'^{a'}}{\partial y^a} v^a, \tag{1.153}$$

where we have again applied the chain rule for the derivatives.

Example 1.27 In Example 1.26, we used the vectors $\vec{v}_1$ and $\vec{v}_2$ to define a new coordinate system on a two-dimensional affine space. Towards the end of the example, we noted that the coordinate system could also be defined by specifying the coordinate functions as in Eqs. (1.147). Inverting these equations leads to

$$x^1 = y^1 + y^2, \quad x^2 = y^2. \tag{1.154}$$

It follows directly that the tangent vector basis is given by

$$\vec{E}_1 = \frac{\partial \vec{x}}{\partial y^1} = \vec{e}_1 = \vec{v}_1, \quad \vec{E}_2 = \frac{\partial \vec{x}}{\partial y^2} = \vec{e}_1 + \vec{e}_2 = \vec{v}_2. \tag{1.155}$$

Thus, the tangent vector basis is the basis we used to define the coordinate system in Example 1.26. Note that this is a particular result for the situation when the coordinate functions are linear, we call this type of coordinates *affine coordinates*.

1.6.1.2 Dual basis

Apart from the tangent vector basis, there is a different set of basis vectors which we can define using a given coordinate system. As we move on to more advanced topics, the need shall arise to separate the following concept further from the concept of tangent vectors, but for now let us define a set of vector fields by taking the gradient of the coordinate functions

$$\vec{E}^a = \nabla y^a. \tag{1.156}$$

These vector fields also form a basis at each point in the base space and their relation to the Cartesian basis is

$$\vec{e}_i \cdot \vec{E}^a = \frac{\partial y^a}{\partial x^i} \quad \Longrightarrow \quad \vec{E}^a = \frac{\partial y^a}{\partial x^i} \vec{e}_i. \tag{1.157}$$

Note that the vectors $\vec{E}^a$ follow the very same transformation rule as the contravariant vector components and thus transforms in the opposite fashion as compared to the tangent vector basis. This new set of basis vectors is called the *dual basis* and has a set of interesting properties. The first one that we note is that the vectors in the dual basis are not necessarily parallel to the corresponding tangent vectors.

Example 1.28 Returning again to Example 1.26, Eqs. (1.147) directly gives us

$$\vec{E}^1 = \vec{e}_1 - \vec{e}_2, \quad \vec{E}^2 = \vec{e}_2, \tag{1.158}$$

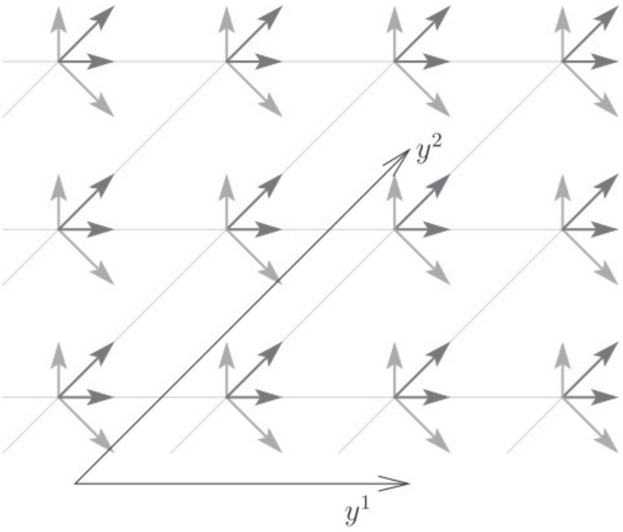

Figure 1.17 The two-dimensional coordinate system $y^1 = x^1 - x^2$, $y^2 = x^2$ along with the associated tangent vector basis (dark) and dual basis (light). The coordinate lines of y^1 are at the same time the level surfaces of y^2. By definition, the tangent vector field $\vec{E}_1$ is tangent to the y^1 coordinate lines while the dual field $\vec{E}^2$ is normal to the y^2 level surfaces. Thus, we must have $\vec{E}_1 \cdot \vec{E}^2 = 0$. The corresponding argument can be made for $\vec{E}_2$ and $\vec{E}^1$.

which are clearly not parallel to $\vec{E}_1$ and $\vec{E}_2$, respectively. The two different bases are illustrated in Fig. 1.17. However, as shown in the figure, the tangent vector field $\vec{E}_1$ is orthogonal to the dual vector field $\vec{E}^2$.

The fact that $\vec{E}_1 \cdot \vec{E}^2 = 0$ in the above example is by no means a coincidence. From the properties of the tangent vector and dual fields, we generally obtain

$$\vec{E}_a \cdot \vec{E}^b = \vec{e}_i \cdot \vec{e}_j \frac{\partial x^i}{\partial y^a} \frac{\partial y^b}{\partial x^j} = \frac{\partial x^i}{\partial y^a} \frac{\partial y^b}{\partial x^i} = \frac{\partial y^b}{\partial y^a} = \delta^b_a. \tag{1.159}$$

Thus, although $\vec{E}^a$ is not generally parallel with $\vec{E}_a$, it is the only dual basis vector that has a non-zero scalar product with $\vec{E}_a$ and this scalar product is equal to one.

Example 1.29 While the tangent vector basis and dual basis are not necessarily parallel to each other, there is an important class of coordinate systems in which they are. An example of this is the coordinate system

$$s = \sinh(x^1), \quad t = \sinh(x^2), \tag{1.160}$$

where we have called the new coordinates s and t rather than y^1 and y^2 in order to avoid confusion in later examples. This coordinate system has the same coordinate lines and coordinate level surfaces as the original Cartesian system as it only rescales the coordinates.

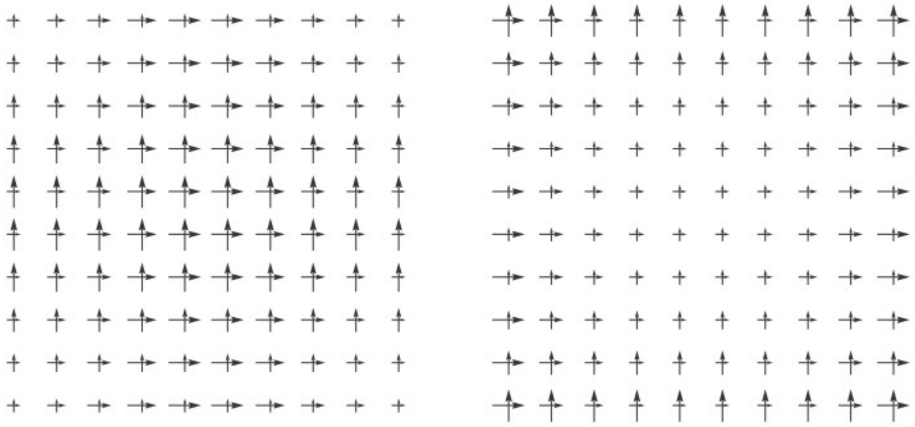

Figure 1.18 The tangent vector basis (left) and dual basis (right) for the coordinate system $s = \sinh(x^1)$, $t = \sinh(x^2)$ with $s = t = 0$ in the middle of the figures (not to scale between the figures). When the magnitude of the tangent vector basis is large, then the magnitude of the dual basis is small and vice versa.

We find that

$$\vec{E}_s = \vec{e}_1 \frac{1}{\sqrt{1+s^2}}, \quad \vec{E}_t = \vec{e}_2 \frac{1}{\sqrt{1+t^2}} \tag{1.161a}$$

$$\vec{E}^s = \vec{e}_1 \sqrt{1+s^2}, \quad \vec{E}^t = \vec{e}_2 \sqrt{1+t^2}, \tag{1.161b}$$

where we have taken the habit of using the coordinate names rather than numbers when speaking about specific components. In Fig. 1.18, we show the tangent vector and dual basis fields for this coordinate system. Another difference from our previous example is that the basis vectors depend on the coordinates, something which is often the case for non-Cartesian coordinate systems.

When it comes to decomposing an arbitrary vector $\vec{v}$ into a linear combination of $\vec{E}^a$ we find that, with $\vec{v} = v_a \vec{E}^a$,

$$\vec{E}_a \cdot \vec{v} = \vec{E}_a \cdot v_b \vec{E}^b = \delta_a^b v_b = v_a. \tag{1.162}$$

Using the expression for $\vec{E}_a$ in Cartesian coordinates, we find that

$$v_a = \frac{\partial x^i}{\partial y^a} \vec{e}_i \cdot \vec{v} = \frac{\partial x^i}{\partial y^a} v^i. \tag{1.163}$$

The components v_a thus transform in the same way as the tangent vector basis under coordinate changes and are therefore called *covariant vector components*.

Before specialising to coordinate systems that fulfil an additional orthogonality criterion, let us examine how to express the scalar product of two general vectors $\vec{v}$ and $\vec{w}$ in a general coordinate system. Writing $\vec{v}$ in terms of the tangent vector basis and $\vec{w}$ in the dual basis, we find that

$$\vec{v} \cdot \vec{w} = v^a w_b \vec{E}_a \cdot \vec{E}^b = v^a w_b \delta^a_b = v^a w_a. \tag{1.164}$$

The scalar product of the two vectors is therefore given by the sum of the products of the covariant and contravariant components of the vectors, respectively. Naturally, there is nothing stopping us from instead expressing $\vec{v}$ in the dual basis and $\vec{w}$ in the tangent vector basis and arriving at $\vec{v} = \vec{w} = v_a w^a$.

1.6.2 Orthogonal coordinates

As we have seen, the tangent vector basis $\vec{E}_a$ need not be orthogonal and, depending on the coordinates, we may end up with $\vec{E}_a \cdot \vec{E}_b \neq 0$ for $a \neq b$. However, there is an important class of coordinate systems where the tangent vector basis is orthogonal as we saw in Example 1.29. A coordinate system where this is the case is called an *orthogonal coordinate system* and in such systems

$$\vec{E}_a \cdot \vec{E}_b = h_a^2 \delta_{ab}, \qquad \text{(no sum)} \tag{1.165}$$

where we have introduced the *scale factors* $h_a = |\vec{E}_a|$, which are the moduli of the tangent vector basis. Since the vectors $\vec{E}_a$ are orthogonal, we can define an *orthonormal basis* $\vec{e}_a$ according to

$$\vec{e}_a = \frac{1}{h_a}\vec{E}_a = \frac{1}{h_a}\frac{\partial \vec{x}}{\partial y^a}. \qquad \text{(no sum)} \tag{1.166}$$

The normalisation condition gives

$$h_a = \sqrt{\sum_i \left(\frac{\partial x^i}{\partial y^a}\right)^2}. \tag{1.167}$$

For our purposes, it is not relevant to work with covariant and contravariant indices once we have established the orthonormal basis $\vec{e}_a$. For the remainder of this chapter, we will therefore use a notation similar to that used for Cartesian coordinates, with the only difference being in the indices used. Naturally, any vector can be written as a linear combination of the $\vec{e}_a$ basis

$$\vec{v} = \tilde{v}_a \vec{e}_a = \sum_a \tilde{v}_a \frac{1}{h_a}\vec{E}_a, \tag{1.168}$$

which leads to the relation $\tilde{v}_a = h_a v^a$ (no sum), where $\tilde{v}_a$ are the *physical components* of the vector $\vec{v}$ in the orthonormal basis, since they are directly related to the projection of the vector onto the basis unit vectors.

Example 1.30 In Example 1.29 we introduced an orthogonal coordinate system with

$$\vec{E}_s = \frac{1}{\sqrt{1+s^2}}\vec{e}_1, \quad \vec{E}_t = \frac{1}{\sqrt{1+t^2}}\vec{e}_2. \tag{1.169}$$

Taking the modulus of these two tangent vectors gives us

$$h_s = \frac{1}{\sqrt{1+s^2}}, \quad h_t = \frac{1}{\sqrt{1+t^2}} \tag{1.170}$$

and thus

$$\vec{e}_s = \vec{e}_1, \quad \vec{e}_t = \vec{e}_2. \tag{1.171}$$

In the above example, the orthonormal basis turned out to be the same as the Cartesian one, but the $\vec{e}_a$ generally depend on the point in the base space, just as $\vec{E}_a$ does, due to the possibility of $\vec{E}_a$ changing direction from point to point.

Let us now find the relation between the dual basis $\vec{E}^a$ and the orthonormal basis $\vec{e}_a$. In order to do this, we expand $\vec{E}^a$ in the orthonormal basis as $\vec{E}^a = \tilde{E}^a_b \vec{e}_b$ and obtain

$$\tilde{E}^a_b = \vec{e}_b \cdot \vec{E}^a = \frac{1}{h_b}\vec{E}_b \cdot \vec{E}^a = \frac{1}{h_b}\delta^a_b. \qquad \text{(no sum)} \tag{1.172}$$

It follows directly that

$$\vec{e}_a = \frac{1}{h_a}\vec{E}_a = h_a \vec{E}^a. \qquad \text{(no sum)} \tag{1.173}$$

Thus, not only is the tangent vector basis orthogonal, it is also parallel to the dual basis, with the only difference between the two being a factor of h_a^2. This also means that we could just as well construct the orthonormal basis starting from the dual basis.

1.6.2.1 Integration in orthogonal coordinates

It is worth spending some time and effort on discussing line, surface and volume integrals in orthogonal coordinate systems. In all cases, the relevant quantity will be

$$\frac{\partial \vec{x}}{\partial y^a} = \vec{E}_a = h_a \vec{e}_a. \qquad \text{(no sum)} \tag{1.174}$$

The form of a line integral does not change significantly, we only need to note that

$$\int_\Gamma \vec{v} \cdot d\vec{x} = \int_\Gamma \vec{v} \cdot \vec{E}_a \dot{y}^a d\tau, \tag{1.175}$$

where $\dot{y}^a = dy^a/d\tau$ and τ is a curve parameter. This lets us express the integral as

$$\int_\Gamma \vec{v} \cdot d\vec{x} = \int_\Gamma \sum_a \tilde{v}_a h_a \dot{y}^a d\tau. \tag{1.176}$$

In particular, if integrating along the y^b coordinate line, we would use y^b as a parameter and thus have

$$\int_\Gamma \vec{v} \cdot d\vec{x} = \int_\Gamma \sum_a \tilde{v}_a h_a \frac{\partial y^a}{\partial y^b} dy^b = \int_\Gamma \tilde{v}_b h_b dy^b. \qquad \text{(no sum)} \tag{1.177}$$

Similar to the above, if we have a surface integral over a coordinate level surface S_c with $y^c =$ constant and the other coordinates being y^a and y^b, which we can use for parametrising the surface, then the surface element will be given by

$$\begin{aligned} d\vec{S} &= \frac{\partial \vec{x}}{\partial y^a} \times \frac{\partial \vec{x}}{\partial y^b} dy^a dy^b = \vec{E}_a \times \vec{E}_b \, dy^a dy^b \\ &= h_a h_b (\vec{e}_a \times \vec{e}_b) dy^a dy^b = h_a h_b \vec{e}_c dy^a dy^b, \qquad \text{(no sum)} \end{aligned} \tag{1.178}$$

assuming that $\vec{e}_a$, $\vec{e}_b$, and $\vec{e}_c$ form a right-handed triplet. Since $\vec{e}_c$ is a unit vector, it is the unit normal and the surface area is $dS = h_a h_b dy^a dy^b$ (no sum). A flux integral over this surface is therefore given by

$$\int_{S_c} \vec{v} \cdot d\vec{S} = \int_{S_c} \tilde{v}_c h_a h_b dy^a dy^b. \qquad \text{(no sum)} \tag{1.179}$$

Finally, parametrising a volume with the coordinates, the volume element dV may be expressed as

$$\begin{aligned} dV &= \frac{\partial \vec{x}}{\partial y^1} \cdot \left(\frac{\partial \vec{x}}{\partial y^2} \times \frac{\partial \vec{x}}{\partial y^3} \right) dy^1 dy^2 dy^3 = \vec{E}_1 \cdot (\vec{E}_2 \times \vec{E}_3) dy^1 dy^2 dy^3 \\ &= h_1 h_2 h_3 dy^1 dy^2 dy^3, \end{aligned} \tag{1.180}$$

with a similar generalisation of $dV = \prod_a h_a dy^a$ in an arbitrary number of dimensions. For ease of notation, we introduce the *Jacobian determinant*

$$\mathcal{J} = \prod_a h_a = h_1 h_2 h_3, \tag{1.181}$$

where the last equality holds in three dimensions, which is the product of all of the scale factors. However, it should be noted that the Jacobian determinant also appears in non-orthogonal coordinates, although it does not take the simple form shown above. In general coordinates, we would have

$$\mathcal{J} = \vec{E}_1 \cdot (\vec{E}_2 \times \vec{E}_3), \tag{1.182}$$

again with a straightforward generalisation to an arbitrary number of dimensions. As a result, a volume integral expressed in an arbitrary coordinate system takes the form

$$\int_\Omega \ldots dV = \int_{\Omega_p} \ldots \mathcal{J}\, dy^1 dy^2 dy^3, \tag{1.183}$$

where Ω_p is the set of coordinates corresponding to the volume Ω.

Example 1.31 There is an intuitive interpretation of the integral expressions derived above. The tangent vector $\vec{E}_a = h_a \vec{e}_a$ (no sum) is the change in the position vector associated to an infinitesimal change in the coordinate y^a. A line element therefore becomes directly proportional to $\vec{E}_a dy^a$. Due to the orthogonality of these changes, a surface element spanned by two of the $\vec{E}_a$ will be equal to the product of the scale factors in magnitude and directed in the third direction and the volume spanned by all three of them will be the product of all of the side lengths of the spanned rectangular box.

As an important final comment on integration in orthogonal coordinate systems, it must be noted that if the integrand is a vector quantity, then the result cannot be obtained by integrating the components of the orthonormal basis $\vec{e}_a$ one by one. The reason for this is that the basis vectors themselves are not constant and may therefore not be taken outside of the integral as in the case of Cartesian coordinates.

1.6.2.2 Differentiation in orthogonal coordinates

Just as integration takes a slightly different form in general coordinate systems as compared to Cartesian coordinates, the differential operators acting on scalar and vector fields take on a slightly modified form, with the appearance of scale factors slightly simplifying the results. The operator that is easiest to transform to orthogonal coordinates is the gradient of a scalar field φ, which will be given by

$$\nabla \varphi = \vec{e}_i \partial_i \varphi = \vec{e}_i \frac{\partial y^a}{\partial x^i} \partial_a \varphi = \vec{E}^a \partial_a \varphi, \tag{1.184}$$

which holds in any coordinate system. It follows that the partial derivatives $\partial_a \varphi$ are naturally covariant vector components as they will follow the covariant transformation rules. Writing this in terms of the orthonormal basis, the *gradient in orthogonal coordinates* is

$$\nabla \varphi = \sum_a \frac{1}{h_a} \vec{e}_a \partial_a \varphi. \tag{1.185}$$

Due to the appearance of scale factors, expressing the divergence and curl in terms of the orthonormal basis $\vec{e}_a$ and its vector components poses a bit more of a challenge and we will be greatly helped by the following argumentation: Let us consider the dual basis $\vec{E}^a = \nabla y^a = \vec{e}_a / h_a$ (no sum). Taking the cross product between two of these vectors, we obtain

$$\vec{E}^a \times \vec{E}^b = \frac{1}{h_a h_b} \vec{e}_a \times \vec{e}_b = \frac{1}{h_a h_b} \sum_c \varepsilon_{abc} \vec{e}_c = \sum_c \frac{h_c}{\mathcal{J}} \varepsilon_{abc} \vec{e}_c, \tag{1.186}$$

where ε_{abc} has the same properties as the permutation symbol in Cartesian coordinates, i.e., it is completely anti-symmetric and equal to one when $\vec{e}_a$, $\vec{e}_b$, and $\vec{e}_c$ form a right-handed system. Taking the divergence of the original expression leads to

$$\nabla \cdot (\vec{E}^a \times \vec{E}^b) = \nabla \cdot (\nabla y^a \times \nabla y^b) = \nabla y^b \cdot (\nabla \times \nabla y^a) - \nabla y^a \cdot (\nabla \times \nabla y^b) = 0, \tag{1.187}$$

due to $\nabla \times \nabla \varphi = 0$ for all functions φ, and thus also for the coordinate functions. Inserting the expression for $\vec{E}^a \times \vec{E}^b$ in terms of the orthonormal basis into this gives the result

$$\sum_c \nabla \cdot \frac{h_c}{\mathcal{J}} \varepsilon_{abc} \vec{e}_c = 0. \tag{1.188}$$

Multiplying this with ε_{dab}, summing over a and b, and making use of the ε-δ-relation we finally arrive at

$$\sum_{abc} \varepsilon_{dab} \varepsilon_{abc} \nabla \cdot \frac{h_c}{\mathcal{J}} \vec{e}_c = 2 \nabla \cdot \frac{h_d}{\mathcal{J}} \vec{e}_d = 0. \tag{1.189}$$

Equipped with this relation, we move on to expressing the *divergence in orthogonal coordinates*. By expanding the vector $\vec{v}$ as $\vec{v} = \tilde{v}_a \vec{e}_a$, we obtain

$$\begin{aligned} \nabla \cdot \vec{v} = \nabla \cdot \tilde{v}_a \vec{e}_a &= \sum_a \nabla \cdot \left(\frac{\tilde{v}_a \mathcal{J}}{h_a} \frac{h_a}{\mathcal{J}} \vec{e}_a \right) = \sum_a \left[\frac{h_a}{\mathcal{J}} \vec{e}_a \cdot \nabla \left(\frac{\tilde{v}_a \mathcal{J}}{h_a} \right) + \frac{\tilde{v}_a \mathcal{J}}{h_a} \nabla \cdot \left(\frac{h_a}{\mathcal{J}} \vec{e}_a \right) \right] \\ &= \sum_a \frac{h_a}{\mathcal{J}} \vec{e}_a \cdot \nabla \left(\frac{\tilde{v}_a \mathcal{J}}{h_a} \right) = \frac{1}{\mathcal{J}} \sum_a \partial_a \left(\frac{\tilde{v}_a \mathcal{J}}{h_a} \right), \end{aligned} \tag{1.190}$$

where in the last step we have used Eq. (1.185) to express the gradient in terms of the orthonormal basis.

Before moving on with the curl, we note that the *Laplace operator in orthogonal coordinates* can be expressed by combining Eqs. (1.185) and (1.190) into

$$\nabla^2 \varphi = \nabla \cdot \nabla \varphi = \frac{1}{\mathcal{J}} \sum_a \partial_a \left(\frac{\mathcal{J}}{h_a^2} \partial_a \varphi \right). \tag{1.191}$$

Finally, the *curl in orthogonal coordinates* can be expressed using the scale factors and vector components $\tilde{v}_a$ by noting that

$$\nabla \times \vec{v} = \nabla \times v_a \vec{E}^a = -\vec{E}^a \times \nabla v_a + v_a \nabla \times \vec{E}^a = -\vec{E}^a \times \nabla v_a. \tag{1.192}$$

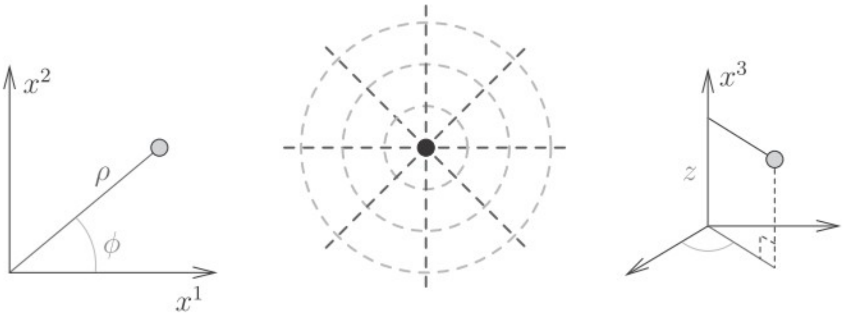

Figure 1.19 The left figure shows the relation between polar coordinates ρ and ϕ and a Cartesian coordinate system in two dimensions. The middle figure shows coordinate lines of ρ (dark) and ϕ (light) based on a polar coordinate system with the black point as origin. A cylinder coordinate system can be created by adding a third direction perpendicular to the plane as shown in the right figure.

Expressing $\vec{E}^a$ in terms of $\vec{e}_a$ and using Eq. (1.185), we find

$$\nabla \times \vec{v} = \sum_{abc} \vec{e}_a \varepsilon_{abc} \frac{1}{h_b h_c} \partial_b \left(h_c \tilde{v}_c \right) = \frac{1}{\mathcal{J}} \sum_{abc} \vec{e}_a \varepsilon_{abc} h_a \partial_b (h_c \tilde{v}_c). \tag{1.193}$$

In matrix determinant notation, this can schematically be written as

$$\nabla \times \vec{v} = \frac{1}{\mathcal{J}} \begin{vmatrix} h_1\vec{e}_1 & \partial_1 & h_1\tilde{v}_1 \\ h_2\vec{e}_2 & \partial_2 & h_2\tilde{v}_2 \\ h_3\vec{e}_3 & \partial_3 & h_3\tilde{v}_3 \end{vmatrix}, \tag{1.194}$$

where the partial derivatives are taken to act on the quantities $h_a\tilde{v}_a$ (no sum) in the third column.

1.6.3 Polar and cylinder coordinates

With the general theory in place, we will now turn our attention to some specific coordinate systems that are highly relevant in several physical applications. The first such system is the set of *polar coordinates* in two dimensions, which are defined by

$$x^1 = \rho \cos(\phi), \tag{1.195a}$$

$$x^2 = \rho \sin(\phi), \tag{1.195b}$$

see Fig. 1.19. This set of coordinates is uniquely defines any point in a Cartesian coordinate system based on the coordinates ρ and ϕ with $0 \leq \rho < \infty$ and ϕ being 2π periodic. We may also extend this to a three dimensional space by mapping the third Cartesian coordinate x^3 to a third coordinate z according to

$$x^3 = z, \tag{1.195c}$$

which along with the earlier definitions of ρ and ϕ defines *cylinder coordinates*. Below we will assume that we are working in three dimensions with cylinder coordinates, remembering that the polar coordinates may be recovered by omitting the z direction, with the obvious exception of the curl, where three dimensions are necessary in order for it to be defined. Using the definition of the tangent vector basis in Eq. (1.148), we find that

$$\vec{E}_\rho = \vec{e}_1 \cos(\phi) + \vec{e}_2 \sin(\phi), \tag{1.196a}$$

$$\vec{E}_\phi = -\vec{e}_1 \rho \sin(\phi) + \vec{e}_2 \rho \cos(\phi), \tag{1.196b}$$

$$\vec{E}_z = \vec{e}_3. \tag{1.196c}$$

It is straightforward to verify that these vectors are orthogonal and therefore we can apply the full framework we have developed for orthogonal coordinate systems. In particular, taking the modulus of these vectors, we find the scale factors for cylinder coordinates

$$h_\rho = 1, \quad h_\phi = \rho, \quad h_z = 1 \tag{1.197}$$

and the orthonormal basis is given by

$$\vec{e}_\rho = \vec{E}_\rho = \vec{e}_1 \cos(\phi) + \vec{e}_2 \sin(\phi), \tag{1.198a}$$

$$\vec{e}_\phi = \frac{1}{\rho}\vec{E}_\phi = -\vec{e}_1 \sin(\phi) + \vec{e}_2 \cos(\phi), \tag{1.198b}$$

$$\vec{e}_z = \vec{E}_z = \vec{e}_3. \tag{1.198c}$$

It should be noted that the position vector $\vec{x}$ can be expressed in cylinder coordinates as

$$\vec{x} = \rho \vec{e}_\rho + z \vec{e}_z. \tag{1.199}$$

Applying the theory developed in Section 1.6.2, we can immediately express the gradient, divergence, curl, and Laplace operator in cylinder coordinates

$$\nabla f = \vec{e}_\rho \partial_\rho f + \vec{e}_\phi \frac{1}{\rho} \partial_\phi f + \vec{e}_z \partial_z f, \tag{1.200a}$$

$$\nabla \cdot \vec{v} = \frac{1}{\rho}(\partial_\rho \rho \tilde{v}_\rho + \partial_\phi \tilde{v}_\phi) + \partial_z \tilde{v}_z, \tag{1.200b}$$

$$\nabla \times \vec{v} = \vec{e}_\rho \left(\frac{1}{\rho} \partial_\phi \tilde{v}_z - \partial_z \tilde{v}_\phi \right) + \vec{e}_\phi \left(\partial_z \tilde{v}_\rho - \partial_\rho \tilde{v}_z \right) + \frac{1}{\rho} \vec{e}_z \left(\partial_\rho \rho \tilde{v}_\phi - \partial_\phi \tilde{v}_\rho \right), \tag{1.200c}$$

$$\nabla^2 f = \frac{1}{\rho} \partial_\rho (\rho \partial_\rho f) + \frac{1}{\rho^2} \partial_\phi^2 f + \partial_z^2 f. \tag{1.200d}$$

Example 1.32 An important vector field which is most easily described in cylinder coordinates is

$$\vec{v} = \frac{1}{\rho} \vec{e}_\phi. \tag{1.201}$$

It can be used to describe the magnetic field strength around an infinite conductor carrying a current in magnetostatics, but for our current purposes it is sufficient to notice that its divergence and curl both vanish as

$$\nabla \cdot \vec{v} = \frac{1}{\rho} \partial_\phi \frac{1}{\rho} = 0, \tag{1.202}$$

$$\nabla \times \vec{v} = -\vec{e}_\rho \partial_z \frac{1}{\rho} + \vec{e}_z \frac{1}{\rho} \partial_\rho \left(\frac{\rho}{\rho} \right) = 0. \tag{1.203}$$

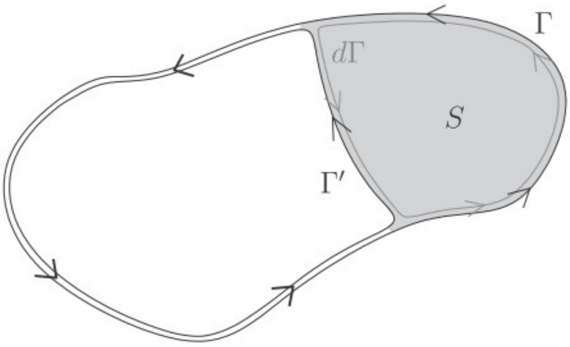

Figure 1.20 The change of contour from Γ to Γ′ does not change the value of the circulation integral of $\vec{v}$ as long as $\nabla \times \vec{v} = 0$ on the area S.

These relations are true for all $\rho > 0$, but may not be generally true at the line $\rho = 0$, where the cylinder coordinate system is singular and this vector field will require special treatment. Taking the circulation integral of $\vec{v}$ around a closed curve Γ, we may rewrite it as a circulation integral around Γ′ according to Fig. 1.20 as long as $\nabla \times \vec{v} = 0$ on an area with the difference contour as a border, in this case as long as the z-axis does not pass through the loop $d\Gamma$. We may therefore change the shape of the contour as long as we do not change the number of times it winds around the z-axis. For a curve that winds around the z-axis once, it may be deformed into a circle of radius R in the plane $z = 0$. We parametrise this circle by $\rho = R$, $\phi = t$, and $z = 0$, with $0 < t < 2\pi$ and the circulation integral becomes

$$\oint_\Gamma \vec{v} \cdot d\vec{x} = \int_0^{2\pi} \frac{R}{R} dt = 2\pi. \tag{1.204}$$

In the above example, we might have been tempted to apply the curl theorem and ended up with

$$\oint_\Gamma \vec{v} \cdot d\vec{x} = \int_S (\nabla \times \vec{v}) \cdot d\vec{S} = 0, \tag{1.205}$$

where S is the disc with the circle Γ as border. Obviously, $0 \neq 2\pi$ and it would seem that something is amiss. However, this is precisely an effect of the vector field $\vec{v}$ being singular at $\rho = 0$, implying that $\nabla \times \vec{v}$ is in some way related to a δ function along $\rho = 0$, since everywhere else the relation $\nabla \times \vec{v} = 0$ holds true.

1.6.4 Spherical coordinates

The second coordinate system we will have a closer look at is that of *spherical coordinates*. It is most useful whenever a problem exhibits complete rotational symmetry in three dimensions, as is the case for a point charge or a spherically symmetric mass distribution, as we will see in the examples of this section. While the cylinder coordinates in three dimensions introduced polar coordinates in a plane and left the third coordinate untouched, spherical coordinates introduces two angles θ and φ, which uniquely define the direction to a point from the origin, and a radius r, which uniquely defines the distance. The spherical

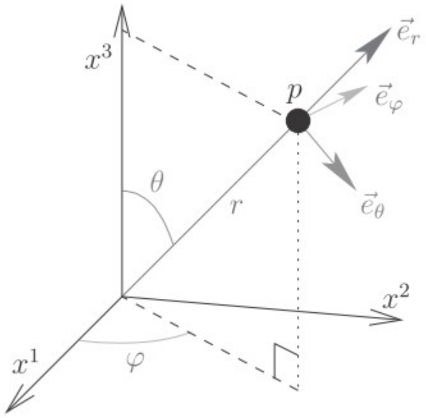

Figure 1.21 The definition of the spherical coordinates in relation to a Cartesian coordinate system. Two angles and a distance uniquely identifies the point p. The unit vectors $\vec{e}_r$, $\vec{e}_\theta$, and $\vec{e}_\varphi$ represent the directions in which p would move when the corresponding coordinates change.

coordinates are defined by

$$x^1 = r\sin(\theta)\cos(\varphi), \tag{1.206a}$$

$$x^2 = r\sin(\theta)\sin(\varphi), \tag{1.206b}$$

$$x^3 = r\cos(\theta), \tag{1.206c}$$

and they are graphically represented in Fig. 1.21. The angle θ is the angle the position vector $\vec{x}$ makes with the x^3-axis, while φ measures the angle between the projection of $\vec{x}$ onto the x^1-x^2-plane and the x^1-axis, much like the polar coordinate ϕ.

From the definition of spherical coordinates, we can find the tangent vector basis in terms of the original Cartesian basis vectors

$$\vec{E}_r = \vec{e}_1\sin(\theta)\cos(\varphi) + \vec{e}_2\sin(\theta)\sin(\varphi) + \vec{e}_3\cos(\theta), \tag{1.207a}$$

$$\vec{E}_\theta = r[\vec{e}_1\cos(\theta)\cos(\varphi) + \vec{e}_2\cos(\theta)\sin(\varphi) - \vec{e}_3\sin(\theta)], \tag{1.207b}$$

$$\vec{E}_\varphi = r\sin(\theta)[-\vec{e}_1\sin(\varphi) + \vec{e}_2\cos(\varphi)]. \tag{1.207c}$$

As in the case of cylinder coordinates, it is straightforward to show that this set of basis vectors is orthogonal and the scale factors

$$h_r = 1, \quad h_\theta = r, \quad \text{and} \quad h_\varphi = r\sin(\theta) \tag{1.208}$$

are found by computing their moduli. Dividing the tangent vector basis by the scale factors provides us with the orthonormal basis

$$\vec{e}_r = \vec{E}_r = \vec{e}_1\sin(\theta)\cos(\varphi) + \vec{e}_2\sin(\theta)\sin(\varphi) + \vec{e}_3\cos(\theta), \tag{1.209a}$$

$$\vec{e}_\theta = \frac{1}{r}\vec{E}_\theta = \vec{e}_1\cos(\theta)\cos(\varphi) + \vec{e}_2\cos(\theta)\sin(\varphi) - \vec{e}_3\sin(\theta), \tag{1.209b}$$

$$\vec{e}_\varphi = \frac{1}{r\sin(\theta)}\vec{E}_\varphi = -\vec{e}_1\sin(\varphi) + \vec{e}_2\cos(\varphi). \tag{1.209c}$$

This set of basis vectors is also illustrated in Fig. 1.21. Furthermore, we obtain the relation

$$\vec{x} = r\vec{e}_r \tag{1.210}$$

for the position vector at each point in space. This is a natural consequence of the selection of the angular parameters as defining the direction to a given point and the coordinate r giving the distance, just as $\vec{x} = \rho\vec{e}_\rho$ in polar coordinates for two dimensions. In fact, polar and spherical coordinates are the two and three dimensional versions of a more general set of spherical coordinates in N dimensions.

The gradient, divergence, curl, and Laplace operators are expressed in spherical coordinates according to

$$\nabla f = \vec{e}_r\partial_r f + \frac{1}{r}\vec{e}_\theta\partial_\theta f + \frac{1}{r\sin(\theta)}\vec{e}_\varphi\partial_\varphi f, \tag{1.211a}$$

$$\nabla\cdot\vec{v} = \frac{1}{r^2}\partial_r(r^2\tilde{v}_r) + \frac{1}{r\sin(\theta)}\partial_\theta(\sin(\theta)\tilde{v}_\theta) + \frac{1}{r\sin(\theta)}\partial_\varphi\tilde{v}_\varphi, \tag{1.211b}$$

$$\begin{aligned}\nabla\times\vec{v} = {} & \frac{1}{r\sin(\theta)}\vec{e}_r(\partial_\theta\sin(\theta)\tilde{v}_\varphi - \partial_\varphi\tilde{v}_\theta) + \frac{1}{r}\vec{e}_\theta\left(\frac{1}{\sin(\theta)}\partial_\varphi\tilde{v}_r - \partial_r r\tilde{v}_\varphi\right)\\ & + \frac{1}{r}\vec{e}_\varphi(\partial_r r\tilde{v}_\theta - \partial_\theta\tilde{v}_r),\end{aligned} \tag{1.211c}$$

$$\nabla^2 f = \frac{1}{r^2}\left[\partial_r\left(r^2\partial_r f\right) + \frac{1}{\sin(\theta)}\partial_\theta\left(\sin(\theta)\partial_\theta f\right) + \frac{1}{\sin^2(\theta)}\partial_\varphi^2 f\right]. \tag{1.211d}$$

Example 1.33 An important vector field in physics is the field of a *point source* in three dimensions, which is most easily expressed in spherical coordinates as

$$\vec{v} = \frac{1}{r^2}\vec{e}_r. \tag{1.212}$$

Inserting $\tilde{v}_r = 1/r^2$ into the expressions for the divergence and curl, respectively, we obtain

$$\nabla\cdot\vec{v} = \frac{1}{r^2}\partial_r\frac{r^2}{r^2} = 0, \tag{1.213}$$

$$\nabla\times\vec{v} = \frac{1}{r}\vec{e}_\theta\left(\frac{1}{\sin(\theta)}\partial_\varphi\frac{1}{r^2}\right) - \frac{1}{r}\vec{e}_\varphi\partial_\theta\frac{1}{r^2} = 0. \tag{1.214}$$

As for the field in Example 1.32, this field is both divergence and curl free everywhere where the coordinate system is not singular, in this case at $r = 0$, where the field has a singularity.

If we perform the flux integral over a closed surface S with outward pointing normal vector, the divergence theorem now tells us that the flux Φ through S is given by

$$\Phi = \oint_S \vec{v}\cdot d\vec{S} = \int_V \nabla\cdot\vec{v}\,dV = 0, \tag{1.215}$$

where V is the volume enclosed by S as long as the point $r = 0$ is not part of this volume. If $r = 0$ is enclosed by S, then we can add and subtract the flux integral over a small sphere S_ε of radius ε to the original integral without changing its value, since we are adding and subtracting the same thing, see Fig. 1.22. As a result, the flux through S is given by

$$\Phi = \left(\oint_S \vec{v}\cdot d\vec{S} - \oint_{S_\varepsilon}\vec{v}\cdot d\vec{S}\right) + \oint_{S_\varepsilon}\vec{v}\cdot d\vec{S} = \int_{V_\varepsilon}\nabla\cdot\vec{v}\,dV + \oint_{S_\varepsilon}\vec{v}\cdot d\vec{S}, \tag{1.216}$$

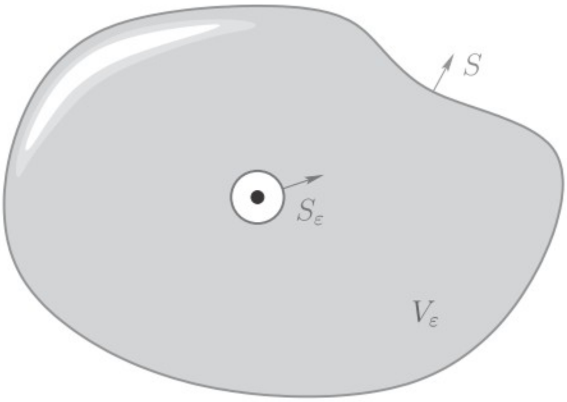

Figure 1.22 By adding and subtracting the flux through the small sphere S_ε, we can rewrite the flux integral over S as the flux integral over S_ε and a volume integral over the volume V_ε in between the S and S_ε.

where V_ε is the volume in between S and S_ε. We have here used the fact that the negative of the integral over S_ε is equal to the integral over S_ε with reversed normal vector, i.e., a normal vector pointing out of the volume V_ε. Since $r = 0$ is not in V_ε, the field $\vec{v}$ is divergence free in this volume and we therefore obtain

$$\Phi = \oint_{S_\varepsilon} \vec{v} \cdot d\vec{S}. \tag{1.217}$$

The surface element $d\vec{S}$ is given by Eq. (1.178) as

$$d\vec{S} = \vec{e}_r h_\theta h_\varphi d\theta\, d\varphi = \vec{e}_r \varepsilon^2 \sin(\theta)\, d\theta\, d\varphi, \tag{1.218}$$

where we have evaluated the scale factors at $r = \varepsilon$ in the last step. We find that

$$\Phi = \oint_{S_\varepsilon} \vec{v} \cdot d\vec{S} = \int_0^\pi \sin(\theta) d\theta \int_0^{2\pi} d\varphi = 4\pi. \tag{1.219}$$

Thus, the flux of the field $\vec{v}$ through a closed surface S is zero if it does not contain the point $r = 0$ and 4π if it does. In order for the divergence theorem to hold, this implies that

$$\nabla \cdot \vec{v} = 4\pi \delta^{(3)}(\vec{x}), \tag{1.220}$$

where $\delta^{(3)}(\vec{x})$ is the three dimensional *delta function* defined by

$$\int_V \delta^{(3)}(\vec{x})\, dV = \begin{cases} 1, & (\vec{x} = 0 \text{ is in } V) \\ 0, & (\text{otherwise}) \end{cases}. \tag{1.221}$$

For the time being, we will just accept that this is the case, but we shall return to this relation when we discuss Green's functions in Chapter 7.

Example 1.34 You may have realised that the vector field in the previous example has a form that reminds us of the gravitational field outside a spherically symmetric mass distribution

$$\vec{g} = -\vec{e}_r \frac{GM}{r^2} \tag{1.222}$$

or the electric field outside a spherically symmetric charge distribution

$$\vec{E} = \vec{e}_r \frac{kQ}{r^2}, \tag{1.223}$$

where G is Newton's gravitational constant, M the total mass of the mass distribution, k is Coulomb's constant, and Q the total charge of the charge distribution. From Gauss's law on differential form, we have

$$\nabla \cdot \vec{E} = \frac{\rho}{\varepsilon_0}. \tag{1.224}$$

Taking the electric field to be given by Eq. (1.223) in all of space, the resulting charge density must be

$$\rho = \varepsilon_0 \nabla \cdot \vec{E} = 4\pi\varepsilon_0 kQ\delta^{(3)}(\vec{x}) = Q\delta^{(3)}(\vec{x}), \tag{1.225}$$

where the last step applies the fact that $k = 1/4\pi\varepsilon_0$. Thus, the charge density is zero everywhere except for in the origin and the total charge, obtained by integrating the charge density over all of space, is Q. The charge distribution therefore corresponds to a single point charge Q in the origin. Similar arguments can be made for the gravitational field.

Even if the charge distribution is not confined to the origin, but still spherically symmetric, the fields above are still solutions to the field equations outside the charge distribution. This can be derived by using the rotational symmetry of the problem. If the charge distribution is rotated around any axis through the center, then the new charge distribution is equivalent to the original one. However, if we take the rotation axis to be the x^3-axis, then the rotation would have rotated the components of the field orthogonal to $\vec{e}_3$, leading to a different solution for the same charge distribution unless those components are zero, see Fig. 1.23. From this we can draw the conclusion that the field will be of the form $\vec{E} = E(r)\vec{e}_r$, since the solution must be unique and the rotational symmetry also implies that the magnitude of the field cannot depend on the angles θ and φ. If we now take a sphere S_r of radius r such that the entire charge distribution is contained within it, then the integral form of Gauss's law states

$$\oint_{S_r} \vec{E} \cdot d\vec{S} = E(r) \oint_{S_r} dS = E(r) 4\pi r^2 = \frac{Q}{\varepsilon_0}. \tag{1.226}$$

Solving for $E(r)$ results in

$$E(r) = \frac{1}{4\pi\varepsilon_0} \frac{Q}{r^2} = \frac{kQ}{r^2} \tag{1.227}$$

as expected. Solving vector equations by using symmetry arguments in this fashion is not always straightforward and will generally involve special cases or complicated integrals. This will be somewhat simplified by the use of potential theory, which is introduced in the next section.

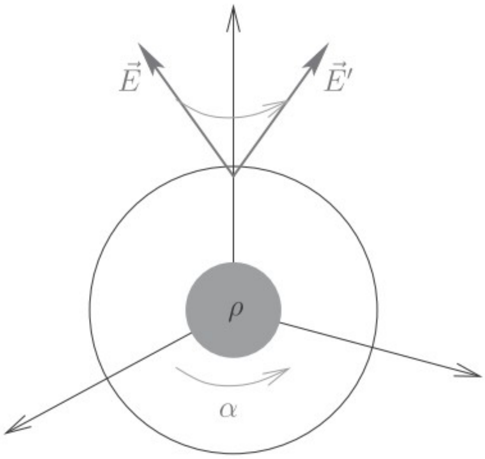

Figure 1.23 Under a rotation by an angle α, if there are components of the electric field $\vec{E}$ orthogonal to the axis of rotation, they will be changed by the rotation to $\vec{E}'$, even if the charge distribution remains the same. This would lead to a different solution unless the orthogonal components are identically zero.

1.7 POTENTIALS

It is sometimes very useful to consider vector fields that can be constructed as derivatives of other fields, both in order to solve differential equations involving fields and in order to make statements of physical importance without having to perform longer calculations. In this section, we will discuss such vector fields, the underlying theory, and some of the physical applications. There are essentially two ways of writing a vector field $\vec{v}$ as a derivative of a different field, either

$$\vec{v} = -\nabla\phi, \tag{1.228a}$$

where ϕ is a scalar field, or

$$\vec{v} = \nabla \times \vec{A}, \tag{1.228b}$$

where $\vec{A}$ is a vector field. The fields ϕ and $\vec{A}$ are known as the *scalar potential* and *vector potential*, respectively. The minus sign in the equation for the scalar potential is purely conventional, but it will appear in this fashion in many physics applications, which is why we adhere to this convention.

1.7.1 Scalar potentials

Vector fields with scalar potentials are typically encountered at very early stages of physics education although it will generally not be stated in the language of vector analysis.

Example 1.35 The gravitational potential Φ is the scalar potential of the gravitational field $\vec{g}$

$$\vec{g} = -\nabla\Phi. \tag{1.229}$$

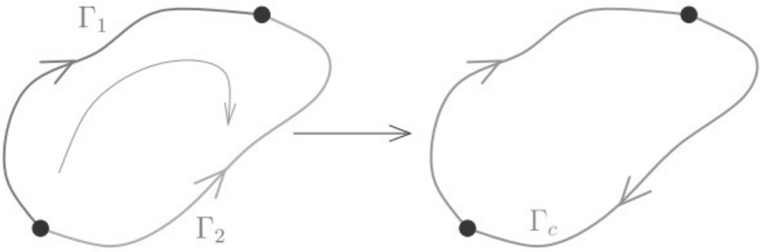

Figure 1.24 The two curves Γ_1 and Γ_2 have the same endpoints. The closed curve Γ_c can be constructed by first going along Γ_1 in the original direction and then along Γ_2 in the opposite direction. This results in a relation between the line integrals along Γ_1 and Γ_2 to the circulation integral along Γ_c.

From Eq. (1.222), we find that, outside a spherical mass distribution,

$$\vec{e}_r \cdot \vec{g} = -\frac{GM}{r^2} = -\partial_r \Phi, \tag{1.230}$$

leading to

$$\Phi = -\frac{GM}{r} \tag{1.231}$$

up to an integration constant that is chosen to be zero by convention, such that the gravitational potential approaches zero as $r \to \infty$.

Coming back to the results of Section 1.4.3, we immediately find that any vector field $\vec{v}$ with a scalar potential ϕ is curl free, as follows from

$$\nabla \times \vec{v} = -\nabla \times \nabla\phi = 0, \tag{1.232}$$

where we have used that $\nabla \times \nabla$ is zero for all scalar fields. It turns out that being curl free is also a sufficient condition for having a scalar potential. Before showing this by explicitly constructing a scalar potential for a curl free vector field, let us examine the properties and physical applications of these fields.

A *conservative vector field* is a vector field $\vec{v}$ for which the line integral

$$L = \int_\Gamma \vec{v} \cdot d\vec{x} \tag{1.233}$$

only depends on the endpoints of the curve Γ. In particular, if we take two different curves Γ_1 and Γ_2 with the same endpoints (see Fig. 1.24), then we can construct a closed curve Γ_c by first going along Γ_1 in the original direction and then along Γ_2 in the opposite direction. This gives us the relation

$$\oint_{\Gamma_c} \vec{v} \cdot d\vec{x} = \int_{\Gamma_1} \vec{v} \cdot d\vec{x} - \int_{\Gamma_2} \vec{v} \cdot d\vec{x} \equiv L_1 - L_2, \tag{1.234}$$

for any vector field $\vec{v}$. Using the curl theorem, we obtain the relation

$$L_1 - L_2 = \int_S (\nabla \times \vec{v}) \cdot d\vec{S}, \tag{1.235}$$

where S is a surface with Γ_c as boundary. If $\nabla \times \vec{v} = 0$, it therefore holds that $L_1 = L_2$, meaning that $\vec{v}$ is conservative if it is curl free. As we have seen that all vector fields with a scalar potential are curl free, they are therefore also conservative. This is also reflected in Eq. (1.106), where we saw that the line integral of a gradient was only dependent on the endpoints of the curve.

Example 1.36 A homogeneous electric field $\vec{E}$ is independent of the position. Naturally this implies that

$$\nabla \times \vec{E} = 0 \tag{1.236}$$

and the field is therefore conservative. The line integral between the two points $\vec{x}_A$ and $\vec{x}_B$ is therefore independent of the path taken and we can take a straight path parametrised by $\vec{x}(t) = \vec{x}_A + t(\vec{x}_B - \vec{x}_A)$, where $t = 0$ represents the start of the curve and $t = 1$ represents the end. Along this curve, $d\vec{x}/dt = \vec{x}_B - \vec{x}_A$, leading to

$$\int_{\vec{x}_A}^{\vec{x}_B} \vec{E} \cdot d\vec{x} = \int_0^1 \vec{E} \cdot (\vec{x}_B - \vec{x}_A)\, dt = \vec{E} \cdot (\vec{x}_B - \vec{x}_A). \tag{1.237}$$

Since $\vec{E}$ is conservative, this will be the result for the line integral of any curve starting in $\vec{x}_A$ and ending in $\vec{x}_B$. We also note that if we define $V = -\vec{E} \cdot (\vec{x} - \vec{x}_A)$, then

$$-\nabla V = \nabla E^i(x^i - x^i_A) = \vec{e}_j E^i \partial_j (x^i - x^i_A) = \vec{e}_j E^i \delta_{ij} = \vec{E}. \tag{1.238}$$

Therefore, the constant field $\vec{E}$ has the potential V.

The above example provides a hint to how we can construct a potential for any conservative field. Assuming a conservative vector field $\vec{v}$, we can construct the scalar field

$$\varphi(\vec{x}) = -\int_{\vec{x}_0}^{\vec{x}} \vec{v}(\vec{\xi}) \cdot d\vec{\xi}, \tag{1.239}$$

which is a line integral along any curve connecting $\vec{x}_0$ and $\vec{x}$. This is well defined due to $\vec{v}$ being conservative, meaning that the integral does not depend on the particular curve chosen. In order to compute the gradient of this scalar field, we need to express the partial derivatives $\partial_i \varphi$ in terms of $\vec{v}$. By definition, the partial derivatives are given by

$$\partial_i \varphi = \lim_{\varepsilon \to 0} \left(\frac{\varphi(\vec{x} + \varepsilon \vec{e}_i) - \varphi(\vec{x})}{\varepsilon} \right). \tag{1.240}$$

We now note that

$$\varphi(\vec{x} + \varepsilon \vec{e}_i) - \varphi(\vec{x}) = -\int_{\vec{x}_0}^{\vec{x}+\varepsilon\vec{e}_i} \vec{v} \cdot d\vec{x} + \int_{\vec{x}_0}^{\vec{x}} \vec{v} \cdot d\vec{x} = -\int_{\vec{x}}^{\vec{x}+\varepsilon\vec{e}_i} \vec{v} \cdot d\vec{x}, \tag{1.241}$$

where we have used that we can select a curve first passing through $\vec{x}$ and then continuing to $\vec{x} + \varepsilon \vec{e}_i$ when computing $\varphi(\vec{x} + \varepsilon \vec{e}_i)$. Again, due to $\vec{v}$ being conservative, we can select the curve $\vec{x}(t) = \vec{x} + t\varepsilon \vec{e}_i$, with t going from 0 to 1, when evaluating the remaining integral. We find that

$$-\int_{\vec{x}}^{\vec{x}+\varepsilon\vec{e}_i} \vec{v} \cdot d\vec{x} = -\varepsilon \int_0^1 \vec{v} \cdot \vec{e}_i dt = -\varepsilon \int_0^1 v^i dt = -\varepsilon v^i(\vec{x} + \varepsilon t_* \vec{e}_i), \tag{1.242}$$

where $0 \leq t_* \leq 1$, and we have used the mean value theorem of integration in the last step. Taking the limit, we obtain

$$\partial_i \varphi = -\lim_{\varepsilon \to 0} \left(v^i(\vec{x} + \varepsilon t_* \vec{e}_i) \right) = -v^i(\vec{x}). \tag{1.243}$$

It follows that

$$-\nabla\varphi = -\vec{e}_i \partial_i \varphi = \vec{e}_i v^i = \vec{v} \tag{1.244}$$

and thus φ is a scalar potential of $\vec{v}$, meaning that a scalar potential of $\vec{v}$ exists as long as $\vec{v}$ is conservative.

Collecting our results, we find that the following three statements are equivalent:

1. The vector field $\vec{v}$ is curl free, $\nabla \times \vec{v} = 0$.
2. The vector field $\vec{v}$ is conservative.
3. The vector field $\vec{v}$ has a scalar potential φ such that $\vec{v} = -\nabla\varphi$.

Example 1.37 A *conservative force field* is a force field $\vec{F}$ for which the work W done by moving an object from $\vec{x}_A$ to $\vec{x}_B$, given by the line integral

$$W = \int_{\vec{x}_A}^{\vec{x}_B} \vec{F} \cdot d\vec{x}, \tag{1.245}$$

does not depend on the path taken. By definition, this force field is a conservative vector field, meaning that it has a scalar potential V and is curl free. The scalar potential is the *potential energy* of the force field and we have

$$\vec{F} = -\nabla V. \tag{1.246}$$

Conservative force fields play a central role in classical mechanics.

In the construction of the scalar potential of a conservative vector field, we introduced the arbitrary point $\vec{x}_0$. As any choice of $\vec{x}_0$ results in a valid scalar potential, the resulting scalar potential is not unique. For the conservative vector field $\vec{v}$, we can define two scalar potentials

$$\varphi_1 = -\int_{\vec{x}_1}^{\vec{x}} \vec{v} \cdot d\vec{x} \quad \text{and} \quad \varphi_2 = -\int_{\vec{x}_2}^{\vec{x}} \vec{v} \cdot d\vec{x}. \tag{1.247}$$

Both of these scalar fields have the property $-\nabla\varphi_i = \vec{v}$ and are therefore scalar potentials of $\vec{v}$. However, they differ by

$$\varphi_2(\vec{x}) - \varphi_1(\vec{x}) = \int_{\vec{x}_1}^{\vec{x}_2} \vec{v} \cdot d\vec{x} \tag{1.248}$$

which is a constant independent of $\vec{x}$. In general, if $\vec{v}$ has the scalar potential φ, then $\phi = \varphi + k$, where k is a constant, will fulfil

$$-\nabla\phi = -\nabla(\varphi + k) = -\nabla\varphi - \nabla k = \vec{v} \tag{1.249}$$

and also be a scalar potential of $\vec{v}$. Any scalar potential is therefore only defined up to a constant and scalar potentials differing by a constant will give the same vector field.

It is also worth noting that the construction of the scalar potential as an integral of the vector field may not always be the easiest way of computing the potential. In general, finding the potential amounts to solving a set of differential equations

$$\partial_i \varphi = -v^i, \tag{1.250}$$

which can often be done in a straightforward fashion, as in Example 1.35.

Example 1.38 In Example 1.36 we found the potential of a constant electric field $\vec{E}$ by integration along a selected curve. We could also have integrated the equation $\partial_i V = -E^i$ directly. Restricting ourselves to two dimensions and starting with $i = 1$, we find that

$$\partial_1 V = -E^1 \quad \Longrightarrow \quad V = -E^1 x^1 + f(x^2), \tag{1.251}$$

where f is only a function of x^2 and thus $\partial_1 f(x^2) = 0$. Inserting this into $\partial_2 V = -E^2$ gives us

$$\partial_2(-E^1 x^1 + f(x^2)) = f'(x^2) = -E^2 \quad \Longrightarrow \quad f(x^2) = -E^2 x^2 + V_0, \tag{1.252}$$

where V_0 is a constant. It follows that

$$V = -E^1 x^1 - E^2 x^2 + V_0 = -\vec{E} \cdot \vec{x} + V_0, \tag{1.253}$$

where V_0 is an arbitrary integration constant. This example has a straightforward generalisation to any number of dimensions.

1.7.2 Vector potentials

Unlike scalar potentials, vector potentials are generally not encountered in physics education until the study of magnetostatics.

Example 1.39 A static magnetic field $\vec{B}$ has a vector potential $\vec{A}$ such that

$$\vec{B} = \nabla \times \vec{A}. \tag{1.254}$$

As we shall see, this follows from *Gauss's law of magnetism*, which on differential form is given by

$$\nabla \cdot \vec{B} = 0. \tag{1.255}$$

In analogy to curl free vector fields having scalar potentials, we shall see that divergence free vector fields have vector potentials.

For any vector field $\vec{v}$ with a vector potential $\vec{A}$, we find that

$$\nabla \cdot \vec{v} = \nabla \cdot (\nabla \times A) = 0. \tag{1.256}$$

All fields with vector potentials are therefore divergence free. This is analogous to what we found in the scalar potential case, where all fields with scalar potentials were found to be curl free. Furthermore, just as vector fields with scalar potentials having line integrals depending only on the curve endpoints, the flux of a field with a vector potential through a surface S only depends on the boundary curve, which follows directly from the curl theorem (see Eq. (1.136)).

In order to show that $\nabla \cdot \vec{v} = 0$ implies the existence of a vector potential, we will proceed with an explicit construction of the potential $\vec{A}$. Unfortunately, the construction cannot proceed in a way similar to the construction of a scalar potential based on a curl free field, mainly due to the loss of a path independent line integral. Instead, we start by considering the scalar field

$$\phi(\vec{x}) = \frac{1}{r}, \tag{1.257}$$

where r is the spherical coordinate. By taking the gradient of this field, we obtain

$$-\nabla\phi = -\vec{e}_r \partial_r \frac{1}{r} = \frac{1}{r^2}\vec{e}_r, \tag{1.258}$$

which is exactly the point source vector field considered in Example 1.33. Using the results from this example, we find that

$$-\nabla^2\phi = 4\pi\delta^{(3)}(\vec{x}). \tag{1.259}$$

By making the translation $\vec{x} \to \vec{x} - \vec{x}_0$, we obtain the relation

$$-\nabla^2 \frac{1}{|\vec{x} - \vec{x}_0|} = 4\pi\delta^{(3)}(\vec{x} - \vec{x}_0). \tag{1.260}$$

Furthermore, for any vector field $\vec{v}$, we can use the defining property of $\delta^{(3)}$ in order to obtain

$$\vec{v}(\vec{x}) = \int \delta^{(3)}(\vec{x} - \vec{x}_0)\vec{v}(\vec{x}_0)dV_0 = -\frac{1}{4\pi}\int \vec{v}(\vec{x}_0)\left(\nabla^2 \frac{1}{|\vec{x} - \vec{x}_0|}\right)dV_0, \tag{1.261}$$

where the integral is taken over all of space and the fields will be assumed to go to zero sufficiently fast as $r \to \infty$. By moving the Laplace operator out of the integral, we obtain

$$\vec{v}(\vec{x}) = -\frac{1}{4\pi}\nabla^2 \int \frac{\vec{v}(\vec{x}_0)}{|\vec{x} - \vec{x}_0|}dV_0 = -\frac{1}{4\pi}\nabla^2\vec{w}, \tag{1.262}$$

where

$$\vec{w} = \int \frac{\vec{v}(\vec{x}_0)}{|\vec{x} - \vec{x}_0|}dV_0. \tag{1.263}$$

From Eq. (1.97), it follows that

$$\vec{v}(\vec{x}) = \frac{1}{4\pi}\nabla \times (\nabla \times \vec{w}) - \frac{1}{4\pi}\nabla(\nabla \cdot \vec{w}). \tag{1.264}$$

We can now rewrite $\nabla \cdot \vec{w}$ according to

$$\nabla \cdot \vec{w} = \int \nabla \cdot \frac{\vec{v}(\vec{x}_0)}{|\vec{x} - \vec{x}_0|}dV_0 = \int \vec{v}(\vec{x}_0) \cdot \nabla \frac{1}{|\vec{x} - \vec{x}_0|}dV_0. \tag{1.265}$$

We now note that $\nabla f(\vec{x} - \vec{x}_0) = -\nabla_0 f(\vec{x} - \vec{x}_0)$, where ∇_0 is taken to be the gradient with respect to $\vec{x}_0$, which leads to

$$\nabla \cdot \vec{w} = -\int \vec{v}(\vec{x}_0) \cdot \nabla_0 \frac{1}{|\vec{x} - \vec{x}_0|}dV_0 = -\int \nabla_0 \cdot \left(\frac{\vec{v}(\vec{x}_0)}{|\vec{x} - \vec{x}_0|}\right)dV_0 = 0, \tag{1.266}$$

where we have used the fact that $\vec{v}$ was taken to be divergence free and again assumed that the $\vec{v}$ goes to zero sufficiently fast as $r \to \infty$ for the surface integral in the divergence theorem to vanish as we integrate over the entire space. It follows that

$$\vec{v} = \nabla \times \vec{A}, \tag{1.267}$$

where

$$\vec{A} = \frac{1}{4\pi}\nabla \times \vec{w} = \frac{1}{4\pi}\nabla \times \int \frac{\vec{v}(\vec{x}_0)}{|\vec{x} - \vec{x}_0|} dV_0, \tag{1.268}$$

and thus $\vec{v}$ has $\vec{A}$ as a vector potential.

While the above tells us of the existence of a vector potential, it is not necessarily the most convenient way of computing it. Again in analogy to the scalar potential case, it is often more advantageous to solve the set of differential equations obtained when demanding that $\vec{v} = \nabla \times \vec{A}$.

Example 1.40 Following Example 1.18, we know that the constant vector field $\vec{\omega} = 2\omega\vec{e}_3$ has the vector potential $\vec{A} = \omega(-x^2\vec{e}_1 + x^1\vec{e}_2)$ (note that $\vec{A}$ was called $\vec{v}$ in Example 1.18) and we now set out to reproduce this result. Starting from $\nabla \cdot \vec{\omega} = 0$, which follows directly from $\vec{\omega}$ being constant, we know that the vector potential exists. We therefore write

$$\begin{aligned}\nabla \times \vec{A} &= \left(\partial_2 A^3 - \partial_3 A^2\right)\vec{e}_1 + \left(\partial_3 A^1 - \partial_1 A^3\right)\vec{e}_2 + \left(\partial_1 A^2 - \partial_2 A^1\right)\vec{e}_3 \\ &= 2\omega\vec{e}_3.\end{aligned} \tag{1.269}$$

The vector field components A^i are generally too many to solve for in a unique way and we therefore try to find a solution such that $A^3 = 0$. It follows that

$$\partial_3 A^1 = 0 \quad \Longrightarrow \quad A^1 = f^1(x^1, x^2), \tag{1.270a}$$

$$\partial_3 A^2 = 0 \quad \Longrightarrow \quad A^2 = f^2(x^1, x^2), \tag{1.270b}$$

$$\partial_1 f^2 - \partial_2 f^1 = 2\omega. \tag{1.270c}$$

The last of these equations also has several possible solutions, one of which is

$$f^1 = -2\omega x^2, \quad f^2 = 0, \tag{1.271a}$$

which is different from the vector potential we already saw. However, another solution is clearly

$$f^1 = -\omega x^2, \quad f^2 = \omega x^1, \tag{1.271b}$$

which leads to precisely the potential already obtained in Example 1.18. Both of these solutions are perfectly valid vector potentials for $\vec{\omega}$ and it follows that the vector potential is not unique. This is a general result that will hold for any divergence free vector field.

The procedure in the above example can be generally applied to any divergence free vector field $\vec{v}$. We can start by making the ansatz that the vector potential $\vec{A}$ is of the form

$$\vec{A} = A^1\vec{e}_1 + A^2\vec{e}_2, \tag{1.272}$$

which is assuming that the $\vec{e}_3$ component is identically zero. The first component of the relation $\vec{v} = \nabla \times \vec{A}$ is now given by

$$-\partial_3 A^2 = v^1 \quad \Longrightarrow \quad A^2 = -\int_{x_0^3}^{x^3} v^1(x^1, x^2, z)\, dz + f^2(x^1, x^2), \tag{1.273}$$

for each set of x^1 and x^2. Similarly, we obtain

$$A^1 = \int_{x_0^3}^{x^3} v^2(x^1, x^2, z)\, dz + f^1(x^1, x^2). \tag{1.274}$$

The third component will now be of the form

$$v^3 = \partial_1 A^2 - \partial_2 A^1 = -\int_{x_0^3}^{x^3} [\partial_1 v^1(\vec{x}_z) + \partial_2 v^2(\vec{x}_z)] dz + \partial_1 f^2 - \partial_2 f^1, \tag{1.275}$$

where $\vec{x}_z = x^1\vec{e}_1 + x^2\vec{e}_2 + z\vec{e}_3$ and f^1 and f^2 are functions of x^1 and x^2. However, since $\vec{v}$ is divergence free, we can replace $\partial_1 v^1 + \partial_2 v^2$ with $-\partial_3 v^3$. We now obtain

$$v^3(\vec{x}) = \int_{x_0^3}^{x^3} \partial_3 v^3(\vec{x}_z) dz + \partial_1 f^2 - \partial_2 f^1 = v^3(\vec{x}) - v^3(x^1, x^2, x_0^3) + \partial_1 f^2 - \partial_2 f^1 \tag{1.276}$$

or, cancelling $v^3(\vec{x})$ from both sides,

$$v^3(x^1, x^2, x_0^3) = \partial_1 f^2 - \partial_2 f^1. \tag{1.277}$$

As in the example, this differential equation can be solved by

$$f^1 = -\int_{x_0^2}^{x^2} v^3(x^1, y, x_0^3)\, dy, \quad f^2 = 0 \tag{1.278}$$

and we obtain a vector potential

$$\vec{A} = \vec{e}_1 \left[\int_{x_0^3}^{x^3} v^2(x^1, x^2, z)\, dz - \int_{x_0^2}^{x^2} v^3(x^1, y, x_0^3)\, dy \right] + \vec{e}_2 \int_{x_0^3}^{x^3} v^1(x^1, x^2, z)\, dz. \tag{1.279}$$

Apart from giving us an alternative way of showing that the vector potential exists, this explicit construction gives us a straightforward recipe for computing a vector potential for any divergence free vector field without applying our original construction.

Note that this explicit construction of a vector potential only depends on the local properties of the vector field $\vec{v}$ and does not require it to go to zero sufficiently fast as $r \to \infty$.

Example 1.41 Another example of a divergence free vector field can be found in fluid dynamics. For any fluid, the local velocity field $\vec{v}$ tells us how fast the fluid is moving at each point in space. For an *incompressible fluid*, i.e., a fluid for which the density is constant regardless of external pressure or forces, we must have $\nabla \cdot \vec{v} = 0$, implying the existence of a vector potential for the fluid flow. While this may not be exactly true for any fluid, it is often a good approximation and we will return to the rationale behind this condition for an incompressible fluid in Section 3.9.3.

As we have seen, the vector potential, like the scalar potential for curl free fields, is not unique. In the scalar potential case, we found that any scalar fields that differed by a constant had the same gradient. In the case of a field with a vector potential, we can clearly also add a constant vector field to the potential without affecting the field itself. However, this is not the most general way of obtaining equivalent vector potentials. Let us assume that the vector field $\vec{v}$ is divergence free and that it has two different vector potentials $\vec{A}_1$ and $\vec{A}_2$. By taking the curl of the difference of these vector potentials, we can deduce that

$$\nabla \times (\vec{A}_1 - \vec{A}_2) = \nabla \times \vec{A}_1 - \nabla \times \vec{A}_2 = \vec{v} - \vec{v} = 0. \tag{1.280}$$

Thus, the difference vector field $\delta\vec{A} = \vec{A}_1 - \vec{A}_2$ is curl free. From the previous section, it directly follows that $\delta\vec{A}$ has a scalar potential φ such that $\delta\vec{A} = -\nabla\varphi$. Therefore, for any two vector potentials of the same field, we must have

$$\vec{A}_2 = \vec{A}_1 + \nabla\varphi, \tag{1.281}$$

for some φ. In addition, if we know one vector potential $\vec{A}$, then also

$$\nabla \times (\vec{A} + \nabla\varphi) = \nabla \times \vec{A} + \nabla \times \nabla\varphi = \vec{v} \tag{1.282}$$

for any scalar field φ. It follows that any difference between two vector potentials of the same divergence free field is a gradient and that adding a gradient to the vector potential of a vector field will give a new vector potential of the same field.

1.7.3 Scalar and vector potentials

So far we have seen that curl free vector fields have scalar potentials and that divergence free vector fields have vector potentials. The natural question arises whether or not anything can be said for fields that are neither curl nor divergence free. We shall find that any vector field, regardless of its curl and divergence, may be written using a scalar and a vector potential. In fact, we will be able to decompose any vector field into two parts, where one is curl free and the other divergence free according to

$$\vec{v} = \vec{v}_s + \vec{v}_v, \quad \text{where} \quad \vec{v}_s = -\nabla\varphi, \quad \vec{v}_v = \nabla \times \vec{A}. \tag{1.283}$$

The existence of such a decomposition is known as *Helmholtz's theorem* (or the *fundamental theorem of vector analysis*) and the decomposition itself is called a *Helmholtz decomposition*.

Helmholtz's theorem can be stated in the following way: If V is a volume in three dimensional space, a vector field $\vec{v}$ may be decomposed in a curl free and a divergence free component. We will show that this is true by explicitly constructing such a decomposition in a similar fashion to when we showed that any divergence free field has a vector potential. Starting from $\phi = 1/\left|\vec{x} - \vec{x}_0\right|$, we follow the same steps as in Eqs. (1.258) to (1.264), but with the integration domain being V rather than all of space. The scalar and vector potentials are given by $\varphi = \nabla \cdot \vec{w}/4\pi$ and $\vec{A} = \nabla \times \vec{w}/4\pi$, respectively. We find that

$$\begin{aligned}
\varphi &= \frac{1}{4\pi}\int_V \vec{v}(\vec{x}_0) \cdot \nabla \frac{1}{|\vec{x} - \vec{x}_0|} dV_0 = -\frac{1}{4\pi}\int_V \vec{v}(\vec{x}_0) \nabla_0 \frac{1}{|\vec{x} - \vec{x}_0|} dV_0 \\
&= -\frac{1}{4\pi}\int_V \nabla_0 \left(\vec{v}(\vec{x}_0) \frac{1}{|\vec{x} - \vec{x}_0|} \right) dV_0 + \frac{1}{4\pi}\int_V \frac{1}{|\vec{x} - \vec{x}_0|} \nabla_0 \cdot \vec{v}(\vec{x}_0) dV_0 \\
&= \frac{1}{4\pi}\int_V \frac{1}{|\vec{x} - \vec{x}_0|} \nabla_0 \cdot \vec{v}(\vec{x}_0) dV_0 - \frac{1}{4\pi}\oint_S \frac{\vec{v}(\vec{x}_0)}{|\vec{x} - \vec{x}_0|} \cdot d\vec{S}_0, \qquad (1.284) \\
\vec{A} &= -\frac{1}{4\pi}\int_V \vec{v}(\vec{x}_0) \times \nabla \frac{1}{|\vec{x} - \vec{x}_0|} dV_0 = \frac{1}{4\pi}\int_V \vec{v}(\vec{x}_0) \times \nabla_0 \frac{1}{|\vec{x} - \vec{x}_0|} dV_0 \\
&= -\frac{1}{4\pi}\int_V \nabla_0 \times \left(\frac{\vec{v}(\vec{x}_0)}{|\vec{x} - \vec{x}_0|} \right) dV_0 + \frac{1}{4\pi}\int_V \frac{1}{|\vec{x} - \vec{x}_0|} \nabla_0 \times \vec{v}(\vec{x}_0) dV_0
\end{aligned}$$

$$= \frac{1}{4\pi}\int_V \frac{1}{|\vec{x}-\vec{x}_0|}\nabla_0 \times \vec{v}(\vec{x}_0)dV_0 + \frac{1}{4\pi}\oint_S \frac{\vec{v}(\vec{x}_0)}{|\vec{x}-\vec{x}_0|} \times d\vec{S}_0. \tag{1.285}$$

Note that in order to compute these potentials, we only need to know the divergence and curl of $\vec{v}$ in V as well as the value of $\vec{v}$ on the surface S, which is the boundary surface of V.

Just as for scalar and vector potentials, the Helmholtz decomposition is generally not unique. Given a decomposition

$$\vec{v} = -\nabla\varphi_1 + \nabla \times \vec{A}_1, \tag{1.286}$$

we can try to find another pair of potentials φ_2 and $\vec{A}_2$ satisfying the same relation. Such a pair of potentials must fulfil

$$\vec{v} - \vec{v} = -\nabla(\varphi_1 - \varphi_2) + \nabla \times (\vec{A}_1 - \vec{A}_2) = 0. \tag{1.287}$$

Taking the divergence of this relation gives

$$-\nabla^2(\varphi_1 - \varphi_2) = 0, \tag{1.288}$$

implying that the difference of the scalar potentials $f = \varphi_1 - \varphi_2$ must fulfil *Laplace's equation*

$$\nabla^2 f = 0. \tag{1.289}$$

For the difference of the vector potentials, we find that

$$\nabla \times (\vec{A}_1 - \vec{A}_2) = \nabla f. \tag{1.290}$$

Since ∇f is divergence free, it has a vector potential and this equation therefore has a solution. We can therefore add any function satisfying Laplace's equation to the scalar potential as long as we modify the vector potential accordingly.

Example 1.42 In the Helmholtz decomposition above, we will end up with a scalar potential

$$\varphi = -\frac{1}{4\pi}\oint_S \frac{\vec{v}(\vec{x}_0)}{|\vec{x}-\vec{x}_0|} \cdot d\vec{S}_0 \tag{1.291}$$

even in the case when $\nabla \cdot \vec{v} = 0$. However, by the arguments of the previous section, we should be able to write the divergence free vector field $\vec{v}$ as $\vec{v} = \nabla \times \vec{A}$ for some vector potential $\vec{A}$. We note that

$$\nabla^2\varphi = -\frac{1}{4\pi}\oint_S \left(\nabla^2 \frac{1}{|\vec{x}-\vec{x}_0|}\right)\vec{v}(\vec{x}_0)\cdot d\vec{S}_0 = \oint_S \delta^{(3)}(\vec{x}-\vec{x}_0)\vec{v}(\vec{x}_0)\cdot d\vec{S}_0 = 0, \tag{1.292}$$

where we have assumed $\vec{x}$ is an interior point of V so that $\delta^{(3)}(\vec{x}-\vec{x}_0)$ is zero on the boundary S. Since φ fulfils $\nabla^2\varphi = 0$, we can choose a new scalar potential $\varphi_2 = 0$ which fulfils $\nabla^2(\varphi_2 - \varphi) = 0$ and find a corresponding vector potential $\vec{A}_2$ such that

$$\nabla \times (\vec{A}_2 - \vec{A}) = -\nabla\varphi, \quad \nabla \times \vec{A}_2 = -\nabla\varphi + \nabla \times \vec{A} = \vec{v}. \tag{1.293}$$

Thus, we can still construct a vector potential of $\vec{v}$ as per the previous section.

Example 1.43 We have seen that a constant electric field $\vec{E} = E^i \vec{e}_i$ has a scalar potential $V = -\vec{E} \cdot \vec{x}$, the existence of which was implied by $\nabla \cdot \vec{E} = 0$. However, since $\vec{E}$ is constant, we also have

$$\nabla \cdot \vec{E} = \partial_i E^i = 0, \tag{1.294}$$

implying that $\vec{E} = \nabla \times \vec{A}$ for some vector potential $\vec{A}$. Such a vector potential can be constructed by letting

$$\vec{A} = \frac{1}{2}\vec{E} \times \vec{x}, \tag{1.295}$$

which gives us

$$\nabla \times \vec{A} = \frac{1}{2}\nabla \times (\vec{E} \times \vec{x}) = \frac{1}{2}[\vec{E}(\nabla \cdot \vec{x}) - (\vec{E} \cdot \nabla)\vec{x}] = \frac{1}{2}(3\vec{E} - \vec{E}) = \vec{E}. \tag{1.296}$$

This is also consistent with $\nabla^2 \varphi = 0$ implying that the scalar potential can be removed by a redefinition of the vector potential.

Often, the potentials are not physically observable quantities, but the vector fields they describe are. In these situations the potentials can be changed freely as long as they give rise to the same fields. This freedom also means that, when solving physical problems, we may impose additional constraints on the potentials in such a way that the problem is as easy to solve as possible. This can be done as long as our imposed conditions are not so stringent that they imply that the problem has no solution.

1.8 PROBLEMS

Problem 1.1. Write down the following vector expressions in component form using the Einstein summation convention:

a) $\vec{v} \cdot (k\vec{w} + \vec{u})$

b) $[(k\vec{v}) \times \vec{w}](\ell + m)$

c) $\vec{v} \times (\vec{w} \times \vec{u})$

d) $(\vec{v} \times \vec{w}) \times \vec{u}$

Here, $\vec{u}$, $\vec{v}$, and $\vec{w}$ are vectors while k, ℓ, and m are scalars. Your answers may contain at most one permutation symbol ε_{ijk}.

Problem 1.2. Verify that the cross product satisfies Eq. (1.7) when written on component form.

Problem 1.3. Check that the components of a vector $\vec{v}$ can be found through the use of Eq. (1.10).

Problem 1.4. Consider the three vectors

$$\vec{v}_1 = 3\vec{e}_1 - \vec{e}_2, \quad \vec{v}_2 = 2\vec{e}_2, \quad \vec{e}_3 = -\vec{e}_1 + \vec{e}_2 + 5\vec{e}_3. \tag{1.297}$$

Compute the following:

a) The magnitude of each of the vectors.

b) The inner product between any pair of the vectors.

c) The cross product between any pair of the vectors.

d) The angles between the vectors.

e) The volume of the parallelepiped spanned by the vectors.

Problem 1.5. Show, using only Eq. (1.6), that the cross product $\vec{v} \times \vec{w}$ is orthogonal to both $\vec{v}$ and $\vec{w}$, i.e., show that

$$\vec{v} \cdot (\vec{v} \times \vec{w}) = \vec{w} \cdot (\vec{v} \times \vec{w}) = 0. \tag{1.298}$$

Problem 1.6. Consider the three vectors

$$\vec{e}_{1'}' = \frac{\vec{e}_1}{\sqrt{2}} - \frac{\vec{e}_3}{\sqrt{2}}, \quad \vec{e}_{2'}' = \frac{\vec{e}_1}{\sqrt{3}} + \frac{\vec{e}_2}{\sqrt{3}} + \frac{\vec{e}_3}{\sqrt{3}}, \quad \vec{e}_{3'}' = \frac{\vec{e}_1}{\sqrt{6}} - \sqrt{\frac{2}{3}}\vec{e}_2 + \frac{\vec{e}_3}{\sqrt{6}}. \tag{1.299}$$

Show that this set of vectors is orthogonal and normalised. Determine whether they form a right- or left-handed set and compute the corresponding transformation coefficients.

Problem 1.7. Show that the Kronecker delta fulfils the relation

$$\delta_{ii} = N, \tag{1.300}$$

where N is the dimensionality of the space.

Problem 1.8. Show that Eq. (1.26) turns into Eq. (1.6) when writing out the sums explicitly by making use of Eq. (1.24).

Problem 1.9. Prove the ε-δ-relation Eq. (1.41) and use it to derive the bac-cab rule Eq. (1.40). *Hint:* In order to prove the ε-δ-relation, you do not need to perform the sum explicitly for all possible indices. It is sufficient to do it for some combinations of free indices and then use the symmetries and anti-symmetries of the expression.

Problem 1.10. Use the ε-δ-relation to express the quantity $\varepsilon_{ijk}\varepsilon_{jk\ell}$ in terms of the Kronecker delta.

Problem 1.11. Consider the vector fields $\vec{v} = x^2\vec{e}_1 - x^1\vec{e}_2$ and $\vec{w} = x^3\vec{e}_1 - x^1\vec{e}_3$ in three dimensions. Compute the following quantities:

a) $\vec{v} \cdot \vec{w}$

b) $\vec{v} \times \vec{w}$

c) $\vec{v} \cdot (\vec{w} \times \vec{x})$

where $\vec{x}$ is the position vector $\vec{x} = x^i\vec{e}_i$.

Problem 1.12. Consider the parallelogram spanned by the vectors $\vec{v}$ and $\vec{w}$, see Fig. 1.25. Show that the diagonals $\vec{v} + \vec{w}$ and $\vec{v} - \vec{w}$ of this parallelogram are orthogonal if and only if $\vec{v}$ and $\vec{w}$ have the same magnitude.

Problem 1.13. A cube of side length ℓ is spanned by the three vectors $\vec{v}_1 = \ell\vec{e}_1$, $\vec{v}_2 = \ell\vec{e}_2$, and $\vec{v}_3 = \ell\vec{e}_3$. Compute the angle between two of the cube diagonals by using the inner product of the displacement vectors between opposite corners.

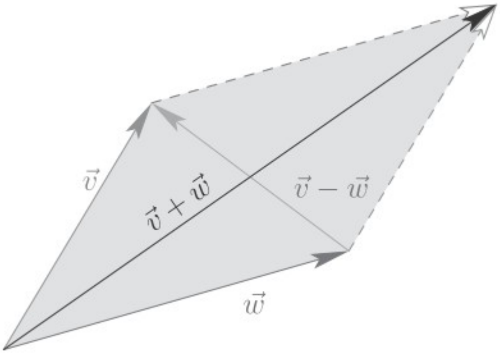

Figure 1.25 A parallelogram spanned by the vectors $\vec{v}$ and $\vec{w}$. The aim of Problem 1.12 is to show that the diagonal vectors $\vec{v}+\vec{w}$ and $\vec{v}-\vec{w}$ are orthogonal only if $\vec{v}$ and $\vec{w}$ have the same magnitude.

Problem 1.14. Find an expression for the squared magnitude of the vector $\vec{v}\times\vec{w}$ in terms of the components of $\vec{v}$ and $\vec{w}$. Also express the magnitudes of $\vec{v}$ and $\vec{w}$ and use your results to find an expression for the sine of the angle between $\vec{v}$ and $\vec{w}$.

Problem 1.15. Consider the two lines given by

$$\vec{x}_1(t) = t\vec{e}_1 + (2-t)\vec{e}_2 \quad \text{and} \quad \vec{x}_2(s) = 2s\vec{e}_1 - \vec{e}_2 - s\vec{e}_3, \tag{1.301}$$

respectively. Define the difference vector between two points on the lines $\vec{d}(t,s) = \vec{x}_1(t) - \vec{x}_2(s)$ and use it to find the shortest distance between the lines. Show that for the points defining the shortest distance, $\vec{d}$ is orthogonal to the tangent vectors of both lines.

Problem 1.16. An object moves in such a fashion that its position as a function of time t may be described by

$$\vec{x}(t) = r_0\cos(\omega t)\vec{e}_1 + r_0\sin(\omega t)\vec{e}_2 + v_0 t\vec{e}_3. \tag{1.302}$$

a) What is the distance from the origin at an arbitrary time t?

b) What are the velocity and acceleration vectors associated to this motion?

Problem 1.17. Many physical situations involving precession, such as the precession of a spinning top or magnetic spin precession, can be described by the vectorial differential equation

$$\frac{d\vec{L}}{dt} = \vec{v}\times\vec{L}, \tag{1.303}$$

where $\vec{L}$ is an angular momentum and $\vec{v}$ is a constant vector. Show that the magnitude of the angular momentum $\vec{L}$ and its inner product with $\vec{v}$ are constants in time.

Problem 1.18. Compute the divergence and curl of the following vector fields:

a) $\vec{x} = x^i\vec{e}_i$

b) $\vec{v}_1 = \vec{a}\times\vec{x}$

c) $\vec{v}_2 = x^2\vec{e}_1 - x^1\vec{e}_2$

where $\vec{a}$ is a constant vector $\vec{a} = a^i \vec{e}_i$.

Problem 1.19. Rewrite the following expressions in terms of the scalar field ϕ and its derivatives only, i.e., leave no derivatives of the position vector $\vec{x}$ or derivatives of products:

a) $\nabla \cdot (\phi \vec{x})$

b) $\nabla \cdot (\vec{x} \times \nabla\phi)$

c) $\nabla \cdot (\phi \nabla \phi)$

d) $\nabla \times (\vec{x} \times \nabla\phi)$

Problem 1.20. Confirm that if the partial derivatives of a scalar field ϕ commute, i.e., $\partial_i \partial_j \phi = \partial_j \partial_i \phi$, and if the partial derivatives of a vector field $\vec{v}$ commute, then Eqs. (1.91) are satisfied.

Problem 1.21. Express $\nabla \times (\nabla \times \vec{v})$ in terms of the permutation symbol and use the ε-δ-relation to prove Eq. (1.97).

Problem 1.22. Starting from the definition in Eq. (1.36), show that the vector $\vec{S}$ defined in this equation is orthogonal to all $\vec{v}_i$.

Problem 1.23. Consider the following surfaces:

a) $\phi_1(\vec{x}) = x^1 + x^2 + x^3 = 5$

b) $\phi_2(\vec{x}) = (x^1)^2 + (x^2)^2 - x^3 = 0$

c) $\phi_3(\vec{x}) = x^3 - r_0 \cos(kx^1) = -4$

For each surface, parametrise it using the parameters $t = x^1$ and $s = x^2$ and find an expression for the directed area element $d\vec{S}$. Use the fact that the area element is orthogonal to the surface to find a normal vector $\vec{n}$ with magnitude one. Verify that the surface normal in each case is parallel to $\nabla\phi_k$.

Problem 1.24. Show that for a general scalar field $\phi(\vec{x})$, the relation

$$[(\vec{x} \times \nabla) \times (\vec{x} \times \nabla)]\phi = -\vec{x} \times \nabla\phi \tag{1.304}$$

is satisfied.

Problem 1.25. Let $\phi(\vec{x})$ be a scalar field and find the conditions that it has to fulfil in order to satisfy the relation

$$\nabla \times (\nabla\phi \times \vec{a}) = \nabla(\nabla\phi \cdot \vec{a}), \tag{1.305}$$

where $\vec{a}$ is a constant non-zero vector.

Problem 1.26. For a vector field $\vec{v}(\vec{x})$ that fulfils the relation

$$\vec{v}(k\vec{x}) = k^n \vec{v}(\vec{x}), \tag{1.306}$$

where k and n are constants, show that

$$(\vec{x} \cdot \nabla)\vec{v}(\vec{x}) = n\vec{v}(\vec{x}) \tag{1.307a}$$

and compute

$$\nabla \cdot \{\vec{x}[\vec{x} \cdot \vec{v}(\vec{x})]\}. \tag{1.307b}$$

Problem 1.27. For the motion of a rigid body rotating around the point $\vec{x}_0$, the velocity field of the body may be written as

$$\vec{v}(\vec{x}, t) = \vec{\omega}(t) \times (\vec{x} - \vec{x}_0), \tag{1.308}$$

where $\vec{\omega}(t)$ describes the angular velocity of the rotation. Determine an expression for the acceleration $\vec{a}(\vec{x}, t) = d\vec{v}/dt$ and compute the quantities $\nabla \cdot \vec{v}$, $\nabla \times \vec{v}$, $\nabla \cdot \vec{a}$, and $\nabla \times \vec{a}$. *Hint:* When determining the acceleration field, consider the motion $\vec{x}(t)$ of a point in the body that satisfies $d\vec{x}(t)/dt = \vec{v}$.

Problem 1.28. A particle is moving in a force field $\vec{F} = k(x^1\vec{e}_2 - x^2\vec{e}_1)$ from the position $\vec{x} = r_0\vec{e}_1$ to the position $\vec{x} = r_0\vec{e}_2$. Compute the work done by the force when the particle takes the path

a) along a circle of constant radius r_0 and

b) along the straight line between the endpoints.

Determine whether or not the force field is conservative.

Problem 1.29. The *Lorentz force* on a particle with electric charge q in a magnetic field $\vec{B}(\vec{x})$ is given by

$$\vec{F} = q\vec{v} \times \vec{B}, \tag{1.309}$$

where $\vec{v}$ is the particle's velocity $\vec{v} = d\vec{x}/dt$. Show that the total work

$$W = \int \vec{F} \cdot d\vec{x} \tag{1.310}$$

done by the magnetic field on the particle is equal to zero.

Problem 1.30. The half-sphere of radius R defined by $x^3 > 0$ and $\vec{x}^{\,2} = R^2$ can be parametrised by the cylinder coordinates ρ and ϕ as

$$x^1 = \rho\cos(\phi), \quad x^2 = \rho\sin(\phi), \quad x^3 = \sqrt{R^2 - \rho^2}, \tag{1.311}$$

for $\rho < R$. Use this parametrisation to compute the total area of the half-sphere according to

$$A = \int dS. \tag{1.312}$$

Problem 1.31. Consider the vector field

$$\vec{v} = (x^1)^k\vec{e}_1 + (x^2)^k\vec{e}_2 + (x^3)^k\vec{e}_3, \tag{1.313}$$

where k is a positive integer. Compute the flux integral

$$\Phi = \oint_S \vec{v} \cdot d\vec{S}, \tag{1.314}$$

where S is the sphere of radius R with the surface normal pointing away from the origin.

Problem 1.32. In a region where the matter density is given by

$$\rho(\vec{x}) = \frac{\rho_0}{L^2}\vec{x}^{\,2}, \tag{1.315}$$

compute the total mass contained in the volumes given by

a) the cube $0 < x^i < L$ $(i = 1, 2, 3)$ and

b) the sphere $r < L$ in spherical coordinates.

Problem 1.33. Consider a fluid with constant density ρ_0 and the velocity field

$$\vec{v} = \frac{v_0}{L}(x^1\vec{e}_2 - x^2\vec{e}_1 + L\vec{e}_3). \tag{1.316}$$

a) Verify that the velocity field is divergence free $\nabla \cdot \vec{v} = 0$.

b) Compute the total momentum inside the cube $0 < x^i < L$ $(i = 1, 2, 3)$.

Problem 1.34. For the fluid in Problem 1.33, compute the mass flux of the fluid

$$\Phi = \int_S \rho_0 \vec{v} \cdot d\vec{S} \tag{1.317}$$

when the surface S in cylinder coordinates is given by

a) the disc $z = z_0$, $\rho < r_0$, $0 < \phi < 2\pi$, with surface normal $\vec{n} = \vec{e}_3$,

b) the cylinder $0 < z < z_0$, $\rho = r_0$, $0 < \phi < 2\pi$, with surface normal $\vec{n} = \vec{e}_\rho$,

c) the ϕ coordinate surface $0 < z < z_0$, $0 < \rho < r_0$, $\phi = \phi_0$, with surface normal $\vec{n} = \vec{e}_\phi$.

Note: We have here used ρ_0 to denote a density, be careful not to confuse it with the cylinder coordinate ρ.

Problem 1.35. A small element $d\vec{x}$ of a conductor carrying a current I in a magnetic field $\vec{B}$ will be subjected to a force

$$d\vec{F} = -I\vec{B} \times d\vec{x}. \tag{1.318}$$

In a constant magnetic field $\vec{B} = \vec{B}_0$

a) compute the total force $\vec{F}$ acting on the closed loop given by

$$x^1 = r_0\cos(t), \quad x^2 = r_0\sin(t), \quad x^3 = 0, \qquad (0 < t < 2\pi) \tag{1.319}$$

b) compute the total torque $\vec{M}$ relative to the origin for the same loop. The torque due to a force $d\vec{F}$ is given by $d\vec{M} = \vec{x} \times d\vec{F}$.

Problem 1.36. For a static electromagnetic field, the electric field $\vec{E}$ has a scalar potential ϕ and the magnetic field $\vec{B}$ is divergence free. Assuming that S is a closed equipotential surface, i.e., that ϕ takes a constant value ϕ_0 on S, compute the volume integral

$$I = \int_V \vec{E} \cdot \vec{B}\, dV, \tag{1.320}$$

where V is the volume enclosed by S, by using the divergence theorem.

Problem 1.37. Compute the closed surface integral

$$\vec{I} = \oint_S \vec{x} \times d\vec{S} \tag{1.321}$$

by rewriting it as an integral over the volume V enclosed by S and simplifying the resulting expression.

Problem 1.38. Use the generalised version of the curl theorem to rewrite the circulation integral

$$\vec{I} = \oint_\Gamma \vec{x} \times d\vec{x} \tag{1.322}$$

around the closed loop Γ as an integral over a surface S bounded by Γ. Simplify your result as far as possible without knowing the loop Γ and then apply your result to the loop given by

$$x^1(t) = r_0 \cos(t), \quad x^2(t) = r_0 \sin(t), \quad x^3(t) = 0. \tag{1.323}$$

Verify that you obtain the same result from the circulation integral as you get from the surface integral.

Problem 1.39. Given that the scalar field $\phi(\vec{x})$ is constant on the boundary curve of a surface S, show that

$$\int_S [(\nabla\phi) \times (\nabla\psi)] \cdot d\vec{S} = 0 \tag{1.324}$$

for any scalar field $\psi(\vec{x})$.

Problem 1.40. Consider again the fluid treated in Problems 1.33 and 1.34. Rewrite the mass flux out of the closed surface S composed of the cylinder area $-z_0 < z < z_0$, $\rho = r_0$, $0 < \phi < 2\pi$ and the two discs $z = \pm z_0$, $\rho < r_0$, $0 < \phi < 2\pi$ as an integral over the enclosed volume and compute the volume integral. Verify that the flux is equivalent to the flux resulting from adding up the fluxes through S (use your results from Problem 1.34).

Problem 1.41. Compute the integral expression

$$I = \int_V \vec{v} \cdot \vec{w}\, dV, \tag{1.325}$$

where $\vec{v}$ is curl free in the volume V and $\vec{w}$ is orthogonal to the surface normal at the boundary of V and divergence free inside V.

Problem 1.42. The surface integral

$$\vec{\Phi} = \oint_S \frac{\vec{x}}{r^5} \vec{x} \cdot d\vec{S} \tag{1.326}$$

can be rewritten as a volume integral

$$\vec{\Phi} = \int_V \vec{x}\phi(\vec{x})\, dV. \tag{1.327}$$

Determine an expression for the scalar field $\phi(\vec{x})$ assuming that $\vec{x} = 0$ is not within the volume V.

Problem 1.43. Let $\vec{A}$ be a vector field satisfying the relation $\nabla \times (\nabla \times \vec{A}) = 0$ in the volume V and $\vec{n} \cdot [\vec{A} \times (\nabla \times \vec{A})] = 0$ on the boundary surface S of V, where $\vec{n}$ is the surface normal. Show that

$$\int_V (\nabla \times \vec{A})^2 dV = 0. \tag{1.328}$$

Problem 1.44. Use the regular curl theorem to prove the generalised curl theorem, given by Eq. (1.139b).

Problem 1.45. The vector potential $\vec{A}$ of a magnetic dipole with the constant dipole moment $\vec{m}$ is given by

$$\vec{A} = \frac{\mu_0}{4\pi} \frac{\vec{m} \times \vec{x}}{r^3}. \tag{1.329}$$

Compute the corresponding magnetic field $\vec{B} = \nabla \times \vec{A}$ for $r > 0$. Also compute the curl of this magnetic field.

Problem 1.46. With the dual basis at hand, show that the contravariant vector components v^a of a vector $\vec{v}$ may be found as

$$v^a = \vec{E}^a \cdot \vec{v}, \tag{1.330}$$

similar to how the covariant vector components were computed using the tangent vector basis in Eq. (1.162).

Problem 1.47. Verify that the tangent vector bases in cylinder coordinates (see Eqs. (1.196)) and in spherical coordinates (see Eqs. (1.207)) are orthogonal bases.

Problem 1.48. Compute the divergence and curl of the vector field $\vec{v} = \frac{1}{\rho}\vec{e}_\phi$, given in cylinder coordinates, for $\rho > 0$. Use your result to compute the circulation integral

$$I = \oint_\Gamma \vec{v} \cdot d\vec{x}, \tag{1.331}$$

where Γ is the closed curve given by

$$\rho(t) = \rho_0[2 + \sin(t)], \quad \phi(t) = t, \quad z(t) = t(t - 4\pi), \tag{1.332}$$

where $0 < t < 4\pi$.

Problem 1.49. *Hyperbolic coordinates* u and v in two dimensions may be introduced to parametrise the region $x^1, x^2 > 0$ according to

$$x^1 = ve^u, \quad x^2 = ve^{-u}. \tag{1.333}$$

a) Sketch the coordinate lines corresponding to u and v.

b) Find the inverse transformation that expresses u and v as functions of x^1 and x^2.

c) Compute the tangent vector and dual bases.

d) Determine whether or not hyperbolic coordinates form an orthogonal coordinate system. If they do, compute the scale factors. If they do not, compute the inner products $\vec{E}_u \cdot \vec{E}_v$ and $\vec{E}^u \cdot \vec{E}^v$.

Problem 1.50. The *parabolic coordinates* t and s in two dimensions are defined through the relations

$$x^1 = ts, \quad x^2 = \frac{1}{2}(t^2 - s^2), \tag{1.334a}$$

where $t, s > 0$.

a) Sketch the coordinate lines corresponding to t and s.

b) Find the inverse transformation that expresses t and s as functions of x^1 and x^2.

c) Compute the tangent vector and dual bases.

d) Determine whether or not hyperbolic coordinates form an orthogonal coordinate system. If they do, compute the scale factors. If they do not, compute the inner products $\vec{E}_t \cdot \vec{E}_s$ and $\vec{E}^t \cdot \vec{E}^s$.

e) Find the expressions for the gradient, divergence, curl, and Laplace operators in three dimensions when also parametrising the third direction with an additional coordinate z as

$$x^3 = z. \tag{1.334b}$$

f) Express the position vector $\vec{x}$ in parabolic coordinates.

Problem 1.51. A screened point charge at the origin may be described by the Yukawa potential

$$\phi(\vec{x}) = \frac{q}{4\pi r} e^{-kr}, \tag{1.335}$$

where k is a constant and r is the radial spherical coordinate. Compute the flux of the corresponding vector field $\vec{v} = -\nabla\phi$ out of the sphere of radius R both by directly performing the surface integral and by applying the divergence theorem. What can be said about $\nabla^2\phi(\vec{x})$ at the origin?

Problem 1.52. Compute $\nabla \cdot \vec{x}$ and $\nabla \times \vec{x}$ using the expressions for the divergence and curl in cylinder and spherical coordinates. Verify that the results are the same as the result you would find doing the same computation in Cartesian coordinates.

Problem 1.53. Verify that the vector field

$$\vec{v} = \frac{1}{r^2}\vec{e}_r \tag{1.336}$$

is divergence free for $r > 0$. According to our discussion on potentials, this implies that $\vec{v}$ has a vector potential $\vec{A}$ such that

$$\vec{v} = \nabla \times \vec{A}. \tag{1.337}$$

Find a vector potential $\vec{A}$ of $\vec{v}$ that has the form $\vec{A} = A_\varphi \vec{e}_\varphi$ and is divergence free.

Problem 1.54. Assume that the vector fields $\vec{v}(\vec{x})$ and $\vec{w}(\vec{x})$ satisfy

$$\nabla \cdot \vec{v} = \nabla \cdot \vec{w} \quad \text{and} \quad \nabla \times \vec{v} = \nabla \times \vec{w} \tag{1.338a}$$

within a volume V and that

$$\vec{n} \cdot \vec{v} = \vec{n} \cdot \vec{w} \tag{1.338b}$$

on the boundary surface of V. Show that $\vec{v}(\vec{x}) = \vec{w}(\vec{x})$ within the volume V.

Problem 1.55. The force on a charge q at position $\vec{x} \neq 0$ from an electric dipole of dipole moment $\vec{p} = p\vec{e}_3$ at the origin is given by

$$\vec{F} = pq\left(\frac{2\cos(\theta)}{r^3}\vec{e}_r + \frac{\sin(\theta)}{r^3}\vec{e}_\theta\right) \tag{1.339}$$

in spherical coordinates. Compute $\nabla \cdot \vec{F}$ and $\nabla \times \vec{F}$. Does this force field have a corresponding scalar and vector potential?

2.3.5 Orthogonal coordinates

Let us briefly examine some of the above ideas applied to an orthogonal coordinate system. The first observation we can make is that, due to the orthogonality, the metric tensor is diagonal by definition

$$(g_{ab}) = \mathrm{diag}(h_1^2, h_2^2, \ldots, h_N^2), \tag{2.130}$$

where the h_a are the scale factors. This follows directly from the relation $g_{ab} = \vec{E}_a \cdot \vec{E}_b$ while keeping in mind that the coordinate system is orthogonal. Inserting this into the expression for the Christoffel symbols in Eq. (2.86), we find that

$$\Gamma^c_{ab} = \delta_{cb}\partial_a \ln(h_b) + \delta_{ca}\partial_b \ln(h_a) - \frac{\delta_{ab}}{2h_c^2}\partial_c h_a^2, \qquad \text{(no sum)} \tag{2.131}$$

where we have used that $(\partial_a h_b^2)/h_b^2 = 2\partial_a \ln(h_b)$. As can be seen from this expression, only Christoffel symbols that contain at least two of the same index can be non-zero. Furthermore, the scale factor belonging to that index must depend on the remaining index. In particular, we obtain

$$\Gamma^c_{ab} = \begin{cases} \partial_b \ln(h_a), & (c = a) \\ -\frac{1}{2h_c^2}\partial_c h_a^2, & (a = b \neq c) \end{cases}. \tag{2.132}$$

Due to the metric being diagonal, the metric determinant is given by the product of the diagonal elements

$$g = \prod_{a=1}^{N} h_a^2 \quad \Longrightarrow \quad \sqrt{g} = \prod_{a=1}^{N} h_a. \tag{2.133}$$

We note that the expression for $\sqrt{g}$ is exactly the same as that for the Jacobian determinant $\mathcal{J}$ in Eq. (1.181) for transformations to an orthogonal coordinate system from a Cartesian one. Naturally, this is no coincidence since $\sqrt{g} = 1$ in any Cartesian system and $\sqrt{g}$ is a scalar density of weight one.

Example 2.23 The polar coordinates ρ and ϕ in $\mathbb{R}^2$ constitute an orthogonal coordinate system as discussed in Section 1.6.3, where it was also found that

$$h_\rho = 1, \quad h_\phi = \rho. \tag{2.134}$$

From this follows that

$$g_{\rho\rho} = 1, \quad g_{\phi\phi} = \rho^2, \quad g_{\rho\phi} = g_{\phi\rho} = 0. \tag{2.135}$$

As we only have two coordinates, the argumentation above does not reduce the possible number of non-zero Christoffel symbols. However, since none of the scale factors depend on ϕ, the Christoffel symbols containing derivatives with respect to ϕ are all identically equal to zero. This includes

$$\Gamma^\phi_{\phi\phi} = \partial_\phi \ln(h_\phi) = 0, \tag{2.136a}$$

$$\Gamma^\phi_{\rho\rho} = -\frac{1}{2h_\phi}\partial_\phi h_\rho^2 = 0, \tag{2.136b}$$

$$\Gamma^\rho_{\rho\phi} = \Gamma^\rho_{\phi\rho} = \partial_\phi \ln(h_\rho) = 0. \tag{2.136c}$$

At the same time, the scale factor h_ρ is constant, which gives us

$$\Gamma^\rho_{\rho\rho} = \partial_\rho \ln(h_\rho) = 0. \tag{2.136d}$$

Finally, the non-zero Christoffel symbols are

$$\Gamma^{\rho}_{\phi\phi} = -\frac{1}{2h_\rho}\partial_\rho h_\phi^2 = -\rho, \tag{2.136e}$$

$$\Gamma^{\phi}_{\phi\rho} = \Gamma^{\phi}_{\rho\phi} = \partial_\rho \ln(h_\phi) = \frac{1}{\rho}. \tag{2.136f}$$

These results are in accordance with the derivatives of the tangent vector basis

$$\partial_\rho \vec{E}_\rho = 0, \quad \partial_\phi \vec{E}_\rho = \frac{1}{\rho}\vec{E}_\phi, \quad \partial_\rho \vec{E}_\phi = \frac{1}{\rho}\vec{E}_\phi, \quad \partial_\phi \vec{E}_\phi = -\rho\vec{E}_\rho, \tag{2.137}$$

which can be derived starting from Eq. (1.196). Note that it will often be easier to compute the Christoffel symbols directly from their definition in terms of the partial derivatives of the tangent vector basis.

2.4 TENSORS IN CARTESIAN COORDINATES

As mentioned in the beginning of this chapter, many texts will start the discussion on tensors by considering the special case of tensors in Cartesian coordinates, much in the same way as we first discussed scalars and vectors in Cartesian coordinates in Chapter 1. Instead, we choose to start by discussing the full framework of tensors in arbitrary coordinate systems, using the definition in terms of the outer product in order to build a deeper foundation for our upcoming discussion of more general spaces in Chapter 9, where the discussion on arbitrary coordinate systems will provide us with some additional intuition. However, before jumping into the more general framework, let us take a step back and look at the special case of Cartesian coordinate systems.

We start this endeavour by taking a set of constant orthonormal unit vectors $\vec{e}_i$ and fixing an origin. Any point in space is then described by the coordinates x^i, where the position vector $\vec{x} = x^i\vec{e}_i$ describes the displacement from the origin. The fact that the basis vectors are constant and orthonormal quickly leads us to the conclusion that

$$\vec{e}_i = \vec{E}^i = \vec{E}_i, \tag{2.138}$$

meaning that there is no difference between the tangent vector basis and the dual basis. Thus, in Cartesian coordinates, there is no need to distinguish covariant and contravariant indices and we can write all indices up or down at our leisure. Naturally, there is an argument for keeping the indices where they would belong in a more general setting.

Even when keeping to Cartesian coordinates, we may change to a different Cartesian coordinate system. Selecting the new Cartesian coordinate system $x'^{i'}$, which has the basis vectors $\vec{e}\,'_{i'}$ and whose origin is displaced with respect to the origin of the x^i coordinates by a vector $\vec{A}$, we find that

$$\vec{x} = \vec{x}\,' + \vec{A} \quad\Longrightarrow\quad x'^{i'} = (x^i - A^i)\vec{e}\,'_{i'}\cdot\vec{e}_i = a^{i'}_i(x^i - A^i), \tag{2.139}$$

where $a^{i'}_i = \vec{e}\,'_{i'}\cdot\vec{e}_i$ are the transformation coefficients defined in connection to Eq. (1.11). As expected, we find that the more general tensor transformations using partial derivatives reduce to these transformation coefficients as

$$\frac{\partial x'^{i'}}{\partial x^i} = a^{i'}_i = a^i_{i'} = \frac{\partial x^i}{\partial x'^{i'}}. \tag{2.140}$$

Again, it becomes apparent that there is no difference between covariant and contravariant indices in Cartesian coordinates as they transform in the same fashion due to the $i' \leftrightarrow i$ symmetry of the transformation coefficients. With the basis being independent of the position, we may also have tensors that are defined without reference to a particular point in space. In fact, the very first example, Example 2.1 of this chapter, involved such a tensor, the moment of inertia, which is a property of an extended object rather than a single point, although it is expressed with respect to a point (usually the center of mass).

Example 2.24 The Kronecker delta δ^a_b as discussed earlier is generally a tensor. When restricted to Cartesian coordinate systems, we may exchange it for δ_{ij}, which we discussed already in Chapter 1. We have here been able to move the contravariant index down as there is no difference between covariant and contravariant indices in Cartesian coordinates. We also note that, due to the fact that $\vec{e}_i \cdot \vec{e}_j = \delta_{ij}$ and $\vec{E}_i = \vec{e}_i$ in Cartesian coordinates, the metric tensor in Cartesian coordinates becomes

$$g_{ij} = \vec{e}_i \cdot \vec{e}_j = \delta_{ij}. \tag{2.141}$$

In fact, an equivalent definition of transformations between Cartesian coordinate systems is affine transformations that preserve the metric tensor as δ_{ij}.

Naturally, since all basis vectors and components of the metric components are constant, the Christoffel symbols are all identically equal to zero in Cartesian coordinates.

Since the metric tensor for a Cartesian coordinate system is just the Kronecker delta δ_{ij}, it follows directly that the metric determinant is given by $g = 1$ in all such systems. At the same time, we are already aware that the metric determinant is a scalar density with weight two and therefore should transform from frame to frame along with a factor $\mathcal{J}^2$. There is only one way these two can be compatible, which is that any transition between Cartesian coordinate systems must have a Jacobian $\mathcal{J} = \pm 1$, where the positive sign holds for transitions between coordinate systems with the same handedness and the negative sign for transitions between systems with opposite handedness. This also follows from the fact that Cartesian coordinate transformations preserve the δ_{ij} form of the metric tensor, which imposes constraints on the transformation coefficients $a^{i'}_i$. From this insight follows that there is no distinction between tensor densities of different weights as long as we restrict ourselves to right-handed Cartesian coordinates. In particular, all tensor densities can be considered as tensors in right-handed Cartesian coordinates due to the tensor density transformation of Eq. (2.110) reducing to the normal tensor transformation when $\mathcal{J} = 1$, regardless of the weight w.

Example 2.25 Our prime example of a tensor density was the permutation symbol $\varepsilon_{a_1 \ldots a_N}$. When viewed in right-handed Cartesian coordinates, it can be taken as $\varepsilon_{i_1 \ldots i_N} = \varepsilon^{i_1 \ldots i_N} = \eta_{i_1 \ldots i_N}$. Again we note that the positioning of the indices does not matter in this case. The permutation symbol tensor densities, regardless of whether they are viewed as covariant or contravariant, are equivalent to each other and so is the totally anti-symmetric tensor $\eta_{i_1 \ldots i_N}$.

2.5 TENSOR INTEGRALS

Tensor integrals in general coordinates will not necessarily be well defined. This will be particularly true when we discuss curved spaces, where there is no unique way of relating vectors at different points in the base space to each other. In this section, we will therefore start by restricting ourselves to the integration of tensors in Cartesian coordinates and later examine which concepts we can carry with us to integrals in more general spaces.

2.5.1 Integration of tensors in Cartesian coordinates

The integration of vectors discussed in Chapter 1 can be readily extended to the case of tensors in Cartesian coordinates. As was the case for the integration of vectors, the volume, surface, and line elements can be parametrised and computed and the volume element will be an infinitesimal number, while the surface and line elements will be infinitesimal vector quantities. Since the Cartesian bases $e_{i_1 \ldots i_n}$ for any type of tensors are constant, they can be taken out of the integral and each component can be integrated as a separate function.

2.5.1.1 *Volume integration*

For volume integrals, we first note that the volume element takes on the same expression regardless of the coordinates as long as we use the Cartesian coordinates as integration parameters. In particular, we find that

$$dV = \vec{e}_1 \cdot (\vec{e}_2 \times \vec{e}_3)\, dx^1 dx^2 dx^3 = \varepsilon_{123} dx^1 dx^2 dx^3 = dx^1 dx^2 dx^3. \tag{2.142}$$

This also follows from the fact that $\mathcal{J} = 1$ for all Cartesian coordinate transformations and we will see the generalisation to arbitrary coordinates when we discuss more general integrations.

Since the volume element is an infinitesimal number, the volume integral of any tensor $T_{i_1 \ldots i_n}$ is a tensor $I_{i_1 \ldots i_n}$ of the same rank and is given by

$$I_{i_1 \ldots i_n} = \int_V T_{i_1 \ldots i_n} dV = \int_V T_{i_1 \ldots i_n} dx^1 dx^2 dx^3, \tag{2.143}$$

where V is the volume over which the integral is taken.

Example 2.26 The moment of inertia tensor of a solid object, which we have discussed earlier, may be expressed using a volume integral. The velocity $\vec{v}$ of the object at a point $\vec{x}$ is given by

$$\vec{v} = \vec{\omega} \times (\vec{x} - \vec{x}_0), \tag{2.144}$$

where $\vec{x}_0$ is the fixed point of the rotation. The mass within a small volume dV around this point is $dm = \rho\, dV$, where ρ is the mass density of the object. The angular momentum of this mass with respect to $\vec{x}_0$ is therefore given by $d\vec{L} = (\vec{x} - \vec{x}_0) \times dm\, \vec{v}$ and the total angular momentum of the solid can therefore also be written

$$L_i = \vec{e}_i \cdot \int_V \rho \vec{x} \times (\vec{\omega} \times \vec{x}) dV = \omega_j \int_V \rho (x_k x_k \delta_{ij} - x_i x_j) dV, \tag{2.145}$$

where we have set $\vec{x}_0 = 0$ for simplicity and V is the full extension of the solid. Identification of this expression with Eq. (2.2) shows that the moment of inertia tensor is given by the volume integral of the tensor $\rho(x_k x_k \delta_{ij} - x_i x_j)$

$$I_{ij} = \int_V \rho(x_k x_k \delta_{ij} - x_i x_j) dV. \tag{2.146}$$

In particular, we note that if the volume mass is purely along the rotational axis, i.e., $\vec{\omega} \propto \vec{x}$, then the angular momentum is zero as it should be.

2.5.1.2 *Surface integrals*

Since the surface element is an infinitesimal vector quantity, we can use it to either increase the rank of the tensor being integrated by one by performing an outer product or decrease it by one by contraction. There is also the possibility of using the scalar surface element, in which case the integral results in a tensor of the same type as the integrand, just as we saw for the volume integral. Naturally, which of these options should be used depends on the physical situation that we wish to describe. Just as for the integrals of vector quantities, the surface element will be given by Eq. (1.59).

Example 2.27 The stress tensor σ_{ij} relates a surface element $d\vec{S}$ to a force acting across the surface as described in Example 2.7. Integrating over the surface S of an object, we can find the total force acting on the object as

$$F_i = \oint_S df_i = \oint_S \sigma_{ij} dS_j. \tag{2.147}$$

It should be noted that this is the external force on the object resulting from contact forces at the surface. There is still the possibility of a force, such as gravity, acting directly on the constituents within the volume. For example, the gravitational force on an object of mass density ρ that takes up the volume V would be given by the volume integral

$$\vec{F}_g = \int_V \rho \vec{g}\, dV, \tag{2.148}$$

where $\vec{g}$ is the external gravitational field.

Example 2.28 Coming back to the moment of inertia tensor, which we saw can be written as a volume integral, some mass distributions will allow us to disregard one dimension of the distribution. In the case we started with, a disc of mass M, we neglected the thickness of the disc. This can be done as long as the thickness is much smaller than the radius R of the disc and the volume integral with the volume density ρ can be replaced by a surface integral with the surface density ρ_s

$$I_{ij} = \int_V \rho(\delta_{ij} x_k x_k - x_i x_j) dV \to \int_S \rho_s(\delta_{ij} x_k x_k - x_i x_j) dS. \tag{2.149}$$

In our case with the disc, we can compute the moment of inertia tensor about its center by the following consideration. We start by introducing a coordinate system such that the disc is in the x_1-x_2-plane. First of all, the term with $x_i x_j$ will be equal to zero whenever i or j is equal to three as $x_3 = 0$ everywhere on the disc. Furthermore, when $(i, j) = (1, 2)$ the integrand for the term $x_1 x_2$ is anti-symmetric with respect to $x_1 \to -x_1$ (and $x_2 \to -x_2$), while the integration domain is symmetric. Thus, the second term will only give a contribution when $i = j = 1$ or 2. Due to the symmetry of the disc, the value will be the same for both these cases and we find

$$\int_S \rho x_1^2 dS = \int_0^R r^3\, dr \int_0^{2\pi} \rho_s \cos^2(\varphi) d\varphi = \pi \rho_s \frac{R^4}{4}. \tag{2.150}$$

For the first term including the δ_{ij}, we find that

$$\int_S \delta_{ij} \rho_s x_k x_k dS = \delta_{ij} \rho_s \int_0^R r^3 dr \int_0^{2\pi} d\varphi = \pi \rho_s \delta_{ij} \frac{R^4}{2}. \tag{2.151}$$

We now take into account that the mass of the disc is

$$M = \int_S \rho_s dS = \pi R^2 \rho_s, \tag{2.152}$$

resulting in

$$I_{ij} = \frac{MR^2}{4} (\delta_{ij} + \delta_{i3}\delta_{j3}). \tag{2.153}$$

Thus, the non-zero components of the moment of inertia tensor in this coordinate system are $I_{11} = I_{22} = MR^2/4$ and $I_{33} = MR^2/2$. These are precisely the values quoted in the beginning of this chapter. Equivalently, including the tensor basis, this may be expressed as

$$I = \frac{MR^2}{4} (\delta + e_{33}), \tag{2.154}$$

where δ is the rank two Kronecker delta and $e_{33} = \vec{e}_3 \otimes \vec{e}_3$.

2.5.1.3 Line integrals

As was the case with the surface integral, the line element will generally come with a direction. Thus, also for a line integral, the resulting tensor may be of one order lower or higher than the tensor being integrated, depending on whether or not there is a contraction between the integrated tensor and the line element. We may also find situations when the direction of the line element is unimportant, resulting in a tensor of the same order as the integrand.

Example 2.29 The magnetic force on an infinitesimal part $d\vec{x}$ of a conductor carrying a current I is given by $d\vec{F} = I d\vec{x} \times \vec{B}$, where $\vec{B}$ is the external magnetic field. The total force on the conductor may therefore be written as a line integral

$$\vec{F} = I \int_\Gamma d\vec{x} \times \vec{B}, \tag{2.155}$$

where Γ is the curve in space occupied by the conductor. In terms of the magnetic field tensor $F_{ij} = \varepsilon_{ijk}B^k$ introduced earlier, the force can be rewritten as

$$F_i = I\int_\Gamma F_{ij}dx^j, \tag{2.156}$$

i.e., in terms of the line integral of F_{ij} contracted with the line element. Note that we have here used F_i and F_{ij} to denote different tensors, the first is the total force vector and the second the magnetic field tensor.

2.5.1.4 *Integral theorems*

As already mentioned, the integral theorems discussed in Section 1.5 may be generalised to the forms

$$\int_V \partial_i T_{j_1\ldots j_n}\,dV = \oint_S T_{j_1\ldots j_n}\,dS_i, \tag{2.157a}$$

$$\int_S \varepsilon_{ijk}\partial_k T_{\ell_1\ldots\ell_n}\,dS_j = \oint_\Gamma T_{\ell_1\ldots\ell_n}\,dx^i, \tag{2.157b}$$

where we have replaced the f of Eqs. (1.139) with the general tensor component $T_{j_1\ldots j_n}$ as already alluded to when we first discussed these theorems. Contractions of any of the indices of $T_{j_1\ldots j_n}$ with the free index i are also possible and the integral theorems will still hold since it does not matter whether the contraction is done before or after the integration. This may also be seen by writing the contraction in terms of the constant Kronecker delta, which may be moved out of the integral due to its components being constant, for example

$$\int_V \partial_i T_{ijk}dV = \delta_{i\ell}\int_V \partial_i T_{\ell jk}dV = \delta_{i\ell}\oint_S T_{\ell jk}dS_i = \oint_S T_{ijk}dS_i. \tag{2.158}$$

Just as the divergence and curl theorems, these generalised integral theorems are powerful tools that may be used in order to simplify several calculations that might otherwise be hard to perform.

Example 2.30 The surface force acting on an object can be found by taking the surface integral

$$F_i = \oint_S \sigma_{ij}dS_j \tag{2.159}$$

over its entire surface, where σ_{ij} is the stress tensor. By the generalisation of the divergence theorem, we find that

$$F_i = \int_V \partial_j\sigma_{ij}dV. \tag{2.160}$$

A special application of this formula is *Archimedes' principle*. For an object submerged in a fluid, the contact force from the fluid on the object will be the same as that which the fluid would exert on an equivalent volume of fluid that replaced the object, see Fig. 2.2. Within a stationary fluid of density ρ_0 in a homogeneous gravitational field $\vec{g}$, the stress tensor is given by $\sigma_{ij} = -p\delta_{ij}$, where $p = \rho_0\vec{g}\cdot\vec{x}$ is the pressure in the fluid at $\vec{x}$. It follows that

$$F_i = -\int_V \delta_{ij}\partial_j p\,dV = -\int_V \partial_i\rho_0 g_j x^j\,dV = -g_i\rho_0 V = -g_i M_V, \tag{2.161}$$

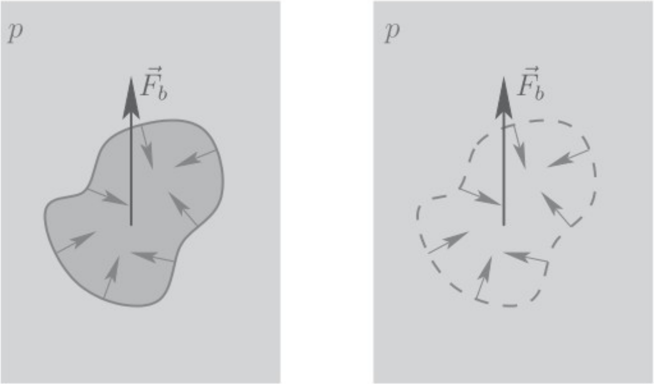

Figure 2.2 According to Archimedes' principle, the buoyant force $\vec{F}_b$ on an object immersed in a fluid with the pressure field p is equal to the force on the corresponding volume if the object was replaced by fluid. The buoyant force can be expressed as an integral over the object's surface using the stress tensor.

where $M_V = \rho_0 V$ is the mass of the displaced fluid. The force is therefore in the opposite direction of the gravitational field and equal in magnitude to the gravitational force on a mass M_V. Including the gravitational force, the total force on the object will therefore be given by

$$\vec{F}_{\text{total}} = \vec{g}(\rho - \rho_0)V, \tag{2.162}$$

where ρ is the density of the object itself. If the object is denser than the fluid, the net force is in the same direction as the gravitational field and this situation is referred to as the object having negative buoyancy. If the fluid is denser than the object, the total force is directed in the opposite direction from the gravitational field and the object has positive buoyancy. In the situation where $\rho = \rho_0$, the net force is zero and the buoyancy is neutral.

2.5.2 The volume element and general coordinates

When discussing volume integrals in general, we have so far only expressed the volume element in Cartesian or orthogonal coordinates, where it takes the form

$$dV = \prod_{a=1}^{N} h_a dx^a. \qquad \text{(no sum)} \tag{2.163}$$

This expression was derived from the volume spanned by the tangent vector basis $\vec{E}_a$ and the approach remains valid for a general coordinate system. Wanting to express the volume described by $y_0^a < y^a < y_0^a + dy^a$, the volume is spanned by the vectors $\vec{E}_a dy^a$ (no sum), see Fig. 2.3. In three dimensions, this results in

$$dV = \vec{E}_1 \cdot (\vec{E}_2 \times \vec{E}_3) dy^1 dy^2 dy^3. \tag{2.164}$$

Expressing this triple product in Cartesian coordinates, we find that

$$dV = \varepsilon_{ijk} \frac{\partial x^i}{\partial y^1} \frac{\partial x^j}{\partial y^2} \frac{\partial x^k}{\partial y^3} dy^1 dy^2 dy^3. \tag{2.165}$$

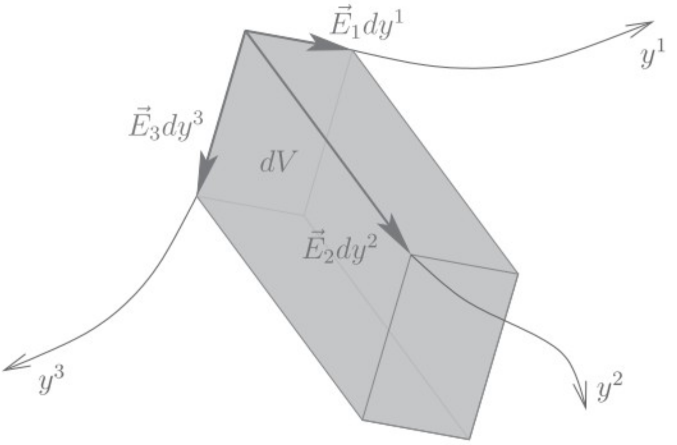

Figure 2.3 In a general coordinate system, the volume dV described by the coordinates $y_0^a < y^a < y_0^a + dy^a$ is spanned by the vectors $\vec{E}_a dy^a$ (no sum). The volume is therefore given by the triple product $dV = \vec{E}_1 \cdot (\vec{E}_2 \times \vec{E}_3) dy^1 dy^2 dy^3$. This is a good approximation as long as the dy^a are small and exact when they are infinitesimal.

The quantity multiplying the differentials dy^a now looks stunningly familiar as the 123 component of a completely anti-symmetric tensor with Cartesian components ε_{ijk}. Fortunately, we already know that this tensor is $\eta_{abc} = \sqrt{g}\,\varepsilon_{abc}$ and it directly follows that

$$dV = \sqrt{g}\,\varepsilon_{123} dy^1 dy^2 dy^3 = \sqrt{g}\,dy^1 dy^2 dy^3. \tag{2.166}$$

The generalisation of this argumentation to an N dimensional space is straightforward and we find that

$$dV = \sqrt{g} \prod_{k=1}^{N} dy^{a_k} \equiv \sqrt{g}\,d^N y. \tag{2.167}$$

This form of the volume element should not come as a surprise as we have already seen that the volume element expressed in a general orthogonal coordinate system is $dV = \mathcal{J} d^N y$, where $\mathcal{J}$ is the product of the scale factors, which, as noted earlier, is the square root of the metric determinant in such a coordinate system.

Despite our success in expressing the volume element, integration in a general coordinate system faces another obstacle that is not present in Cartesian coordinates. Unlike the Cartesian basis vectors, the tangent vector basis $\vec{E}_a$ and the dual basis $\vec{E}^a$ are not constant. This results in the complication that we cannot perform integrals of tensor quantities in general coordinates by just integrating the components one by one. For integrals of tensor quantities, we face the problem of which basis to use to express the result. Being an integral over a volume, surface, or curve, the resulting tensor quantity does not belong to a particular point in space, so there can be no preference for any particular basis. In an affine space, we may brush this aside and express the result in a Cartesian coordinate system, but in more general curved spaces, there will not exist a natural way of comparing, much less defining the sum of, tensors at different points in space. However, scalar quantities do not require a basis and integrals of quantities with all indices contracted will therefore continue to make sense even in general spaces.

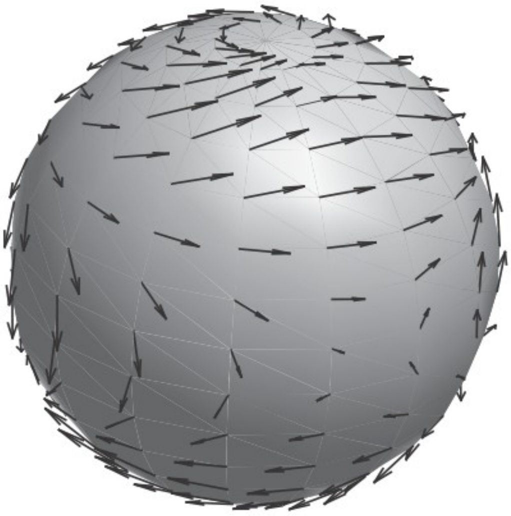

Figure 2.4 While the flow of a substance on a sphere may be defined as a vector at each point of the sphere, there is no meaningful definition of the vector integral of this flow. However, it is possible to define integrals on the sphere that describe, for example, the total flux into or out of a given region.

Example 2.31 Consider the concentration of a substance on the surface of a sphere. At each point on the sphere, there is a tangent vector J^a describing the flow of the substance, see Fig. 2.4, but the tangent vector spaces at different points are different. There is therefore no relevant way of integrating over the sphere to obtain the average flow of the substance as a vector in any of the tangent spaces of the sphere. Of course, there may be some notion of such an average flow if we are looking at the sphere as embedded in our three dimensional affine space, but with a description that is restricted to the sphere only, this is an impossibility. However, the flux integral

$$\Phi = \int_\Gamma J^a dS_a \tag{2.168}$$

of the vector field J^a over some curve Γ, where dS_a is orthogonal to the curve, is a well defined quantity that describes the amount of substance flowing across Γ per time. These issues will be discussed in more detail in Chapter 9.

2.6 TENSOR EXAMPLES

The last example of the preceding section gives us an appetiser of things to come when we will consider more general spaces. We postpone this discussion for later as the discussion will benefit from material that will be covered in the following chapters, in particular Chapter 8 on variational calculus will be of importance. Instead, we conclude this chapter by giving some more structured examples of the application of tensor analysis within different fields of physics. It should be stressed that these examples are only written for the purpose of

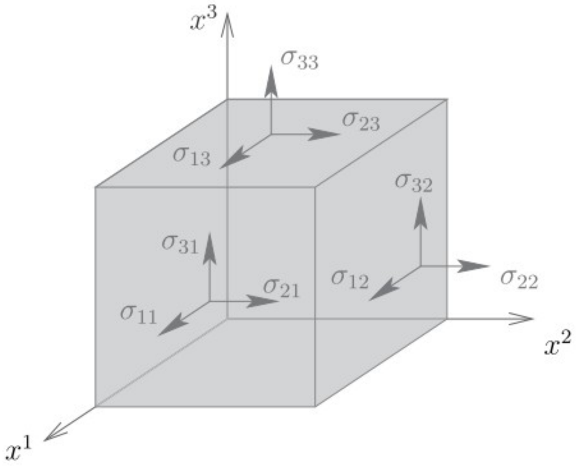

Figure 2.5 The nine components of the stress tensor represented as forces acting on the different faces of a cube. The stress σ_{ij} represents a force in the x^i direction on a surface with a normal $\vec{e}_j$.

discussing the application of tensor analysis in different fields and not as guides or learning material for the subject matters. Each subject is much broader than what can be presented here and will require dedicated texts to understand in full. However, it will provide us with some basics and a context in which we can apply the knowledge acquired throughout this chapter.

2.6.1 Solid mechanics

Solid mechanics is the study of solids and the forces that act within them. In the examples given in this section, we will restrict ourselves to static situations, where any object is in force (and torque) equilibrium. While rank two tensors are relatively common in many areas of physics, as they represent the most general linear relationship between two vectors, solid mechanics presents us with two of the most regularly encountered rank four tensors, the stiffness and compliance tensors.

2.6.1.1 *The stress tensor*

We are already familiar with one of the main actors of solid mechanics from our earlier examples. The *stress tensor* is a rank two tensor σ_{ij} that relates the directed surface element dS_i to the contact force dF_i acting on that surface element

$$dF_i = \sigma_{ij} dS_j. \tag{2.169}$$

For example, the component σ_{12} describes the force per unit area in the x^1 direction when the area element has a surface normal in the x^2 direction, see Fig. 2.5. For a solid in static equilibrium, we can find a set of differential equations that describe how the stress tensor depends on any volume forces, most commonly a gravitational force. We do this by considering an arbitrary volume V with a boundary surface S. Assuming that the body is subject to a volume force $f_i dV$, where f_i is a vector field, the total force on the volume is

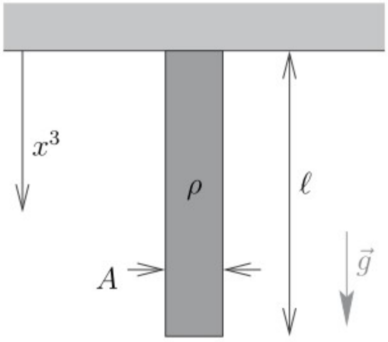

Figure 2.6 A rod of density ρ, cross sectional area A, and length ℓ hanging from the ceiling will be subject to internal stresses. The x^3 direction is taken to point in the same direction as the homogeneous gravitational field $\vec{g}$.

given by

$$F_i = \oint_S \sigma_{ij} dS_j + \int_V f_i dV, \tag{2.170}$$

where the first term represents the surface forces from the rest of the solid and the second term represents the volume force. Applying the generalised divergence theorem to this relation, we find that

$$F_i = \int_V (\partial_j \sigma_{ij} + f_i) dV = 0, \tag{2.171}$$

where we have used that in order for the solid to be in static equilibrium, its acceleration, and therefore the total force acting on it, must be equal to zero. Since the volume V was arbitrary, this relation must hold for any volume, which is true only if the integrand is identically equal to zero, i.e.,

$$\partial_j \sigma_{ij} = -f_i. \tag{2.172}$$

Given appropriate boundary conditions, this differential equation will allow us to solve for the stress tensor for an object subjected to a force density f_i.

Example 2.32 Consider a homogeneous rod of density ρ and square cross section of area A that is hanging from the ceiling as shown in Fig. 2.6. The volume force density acting on this rod due to gravity is given by $f_i = \rho g \delta_{i3}$, where the x^3 direction is defined to be in the same direction as the gravitational field. The resulting differential equation for the stress tensor is

$$\partial_j \sigma_{ij} = -\rho g \delta_{i3}. \tag{2.173}$$

With no forces acting perpendicular to the x^3 direction, the resulting differential equations for $i = 1, 2$ are solved by $\sigma_{1j} = \sigma_{2j} = 0$. Assuming no forces acting on the free surfaces of the rod, we also find $\sigma_{31} = \sigma_{32} = 0$ as well as the only non-zero component

$$\sigma_{33} = \rho g(\ell - x^3). \tag{2.174}$$

Note that this gives a force

$$\vec{F} = -\vec{e}_3 \rho g A \ell = -\vec{e}_3 M g, \tag{2.175}$$

where M is the mass of the rod, from the ceiling acting on the top of the rod. Not surprisingly, this is the exact force needed to cancel the gravitational force of the rod.

Force equilibrium is not sufficient for an object to be in static equilibrium, we also need to impose torque equilibrium in order not to induce rotations. Again looking at a volume V, the torque $\vec{\tau}$ relative to the origin is given by

$$\tau_i = \varepsilon_{ijk}\left(\oint_S x^j \sigma_{k\ell} dS_\ell + \int_V x^j f_k dV\right). \tag{2.176}$$

Note that, due to the force equilibrium that we have already imposed, torque equilibrium around the origin is equivalent to torque equilibrium about any other point. Just as for the force equilibrium, we can apply the generalised divergence theorem to the surface integral, resulting in

$$\begin{aligned}\tau_i &= \int_V \varepsilon_{ijk}(\partial_\ell x^j \sigma_{k\ell} + x^j f_k) dV = \int_V \varepsilon_{ijk}[\sigma_{kj} + x^j(\partial_\ell \sigma_{k\ell} + f_k)]dV \\ &= \int_V \varepsilon_{ijk}\sigma_{kj} dV,\end{aligned} \tag{2.177}$$

where we have applied the requirement of force equilibrium in the last step. Demanding torque equilibrium requires that $\vec{\tau} = 0$ and since this has to hold for any volume V, the integrand must be equal to zero. Multiplying by $\varepsilon_{i\ell m}$, we find that

$$\varepsilon_{i\ell m}\varepsilon_{ijk}\sigma_{jk} = 2\sigma_{[\ell m]} = 0, \tag{2.178}$$

meaning that the anti-symmetric part of the stress tensor σ_{ij} must vanish, i.e., the stress tensor is symmetric.

2.6.1.2 The strain tensor

We have so far only described a situation where we have been concerned with the internal forces inside a solid. If the solid is very stiff, the forces will not cause noticeable deformations of the solid. However, for some applications, it is necessary to also know how the material deforms based on the internal stresses. In order to handle this, we first need a good description of the deformations of the solid. We begin this endeavour by defining the *displacement field* $\vec{u}(\vec{x})$, which describes the displacement of a point in the solid that would be at position $\vec{x}$ if the solid was not strained. It follows that this point is located at

$$\vec{x}\,' = \vec{x} + \vec{u}(\vec{x}). \tag{2.179}$$

Although this field describes how each point of the solid has been displaced, a non-zero displacement field does not necessarily mean that the solid is strained. Possibilities for such situations include translations and rotations

$$x'^i = R_{ij}x^j + a^i \tag{2.180}$$

of the solid, where R_{ij} are the components of a rotation matrix and $\vec{a}$ is a constant vector. We thus need to relate the displacement field to the strain that is present in the solid.

In the following, we will assume that the solid is relatively stiff, meaning that the partial derivatives of the displacement field are much smaller than one $|\partial_i u_j| \ll 1$. In other words, the difference in the displacement between nearby points in the solid is much smaller than the distance between the points. We define the *linear strain* between two nearby points as

$$\epsilon = \frac{ds' - ds}{ds}, \tag{2.181}$$

where ds is the distance between the points in the unstrained solid and ds' the distance between the points after being displaced. Note that we have here used the symbol ϵ rather than ε for the strain in order to avoid confusion with the permutation symbol when introducing the strain tensor. For the two points $\vec{x}$ and $\vec{x} + \vec{n}\,ds$, where $\vec{n}$ is a unit vector describing the direction of the original spatial separation between the points, we find that the new displacement is given by

$$\vec{x}\,'(\vec{x} + \vec{n}\,ds) - \vec{x}\,'(\vec{x}) \simeq [\vec{n} + (\vec{n} \cdot \nabla)\vec{u}]ds. \tag{2.182}$$

Squaring this relation we find that, to linear order in u,

$$ds'^2 \simeq ds^2[1 + n_i n_j(\partial_j u_i + \partial_i u_j)] \tag{2.183a}$$

and taking the square root of this expression and expanding in the small derivatives gives us

$$ds' \simeq ds\left[1 + n_i n_j \frac{1}{2}(\partial_j u_i + \partial_i u_j)\right]. \tag{2.183b}$$

It therefore follows that the linear strain is given by

$$\epsilon = n_i n_j \frac{1}{2}(\partial_j u_i + \partial_i u_j) = n_i n_j \epsilon_{ij}, \tag{2.184}$$

where we have defined the symmetric *strain tensor*

$$\epsilon_{ij} = \frac{1}{2}(\partial_j u_i + \partial_i u_j). \tag{2.185}$$

The strain tensor can be used to describe the deformation of the solid in many different manners, but we will leave most of this for dedicated texts on solid mechanics and only provide the following example.

Example 2.33 The *volumetric strain* of a small element of a solid with unstrained volume dV can be quantified as

$$\delta = \frac{dV' - dV}{dV}, \tag{2.186}$$

where dV' is the volume of the element when the solid is strained. Taking an original volume spanned by the coordinate basis vectors $d\vec{x}_i = \vec{e}_i ds_i$ (no sum), we find that

$$d\vec{x}\,'_1 = (\vec{e}_1 + \partial_1 \vec{u})ds_1, \tag{2.187}$$

with the equivalent expressions for $d\vec{x}\,'_2$ and $d\vec{x}\,'_3$. The volume dV' is therefore given by

$$dV' = d\vec{x}\,'_1 \cdot (d\vec{x}\,'_2 \times d\vec{x}\,'_3) \simeq (1 + \partial_i u_i)ds_1 ds_2 ds_3 = (1 + \epsilon_{ii})dV. \tag{2.188}$$

Thus, the volumetric strain is given by the trace ϵ_{ii} of the strain tensor.

With the above example in mind, we note that it is always possible to rewrite the strain tensor as

$$\epsilon_{ij} = \frac{1}{3}\theta\delta_{ij} + \underbrace{\left(\epsilon_{ij} - \frac{1}{3}\theta\delta_{ij}\right)}_{\equiv\kappa_{ij}}, \tag{2.189}$$

where θ is an arbitrary scalar field. With the choice of θ equal to the volumetric strain ϵ_{kk}, the tensor κ_{ij} becomes traceless and is known as the *shear strain tensor* (or *deviatoric strain tensor*).

2.6.1.3 *The stiffness and compliance tensors*

For elastic materials, the internal stresses are linearly related to the strains in the material. For our purposes, we will not consider more complicated situations with large strains and inelastic materials and the most general way of linearly relating two rank two tensors is by a rank four tensor. We define this rank four tensor in the relation between the stress and strain tensors to be the *stiffness tensor* $c_{ijk\ell}$. The corresponding relation, *Hooke's law*, is given by

$$\sigma_{ij} = c_{ijk\ell}\epsilon_{k\ell} \tag{2.190}$$

and the symmetry of the stress tensor implies that the stiffness tensor must be symmetric in the first two indices $c_{ijk\ell} = c_{jik\ell} = c_{\{ij\}k\ell}$. In addition, the fact that the strain tensor is symmetric also implies that any anti-symmetric part with respect to the last two indices will be irrelevant for the relation and we might as well take $c_{ijk\ell} = c_{ij\ell k} = c_{ij\{k\ell\}}$. A general rank four tensor would have $3^4 = 81$ independent components. However, the symmetries of the stiffness tensor brings this number down to $6^2 = 36$.

Example 2.34 If a material is well described only by the deformations in one direction and the deformation only depends on that direction, it can be regarded within a one-dimensional setting with a single coordinate x. As a result, the stress and displacement only have one component and can be written as σ and ε, respectively. Hooke's law now takes the form

$$\sigma = c\varepsilon, \tag{2.191}$$

where c is the single component c_{1111} of the stiffness tensor.

By the assumption of linearity, the stiffness tensor itself is not dependent on the actual strains or stresses in the material, only on the properties of the material itself. Depending on the structure of the material, further simplifications may be performed to reduce the number of independent components. The most constraining case is obtained if we assume that the material is isotropic, meaning that the stiffness tensor must have the same components in all frames. We already know that the rank two Kronecker delta tensor is isotropic and thus any outer product of Kronecker deltas will also be an isotropic rank four tensor. The most general linear combination $C_{ijk\ell}$ of such products is

$$C_{ijk\ell} = c_1\delta_{ij}\delta_{k\ell} + c_2\delta_{ik}\delta_{j\ell} + c_3\delta_{i\ell}\delta_{jk}, \tag{2.192}$$

which has three independent parameters. However, only the first of these terms has the symmetry required from the stiffness tensor and the last two terms display this symmetry only if $c_2 = c_3$. It is possible to show that this is the only isotropic tensor of rank four with the required symmetries and we can therefore write the stiffness tensor of an isotropic material on the form

$$c_{ijk\ell} = \lambda\delta_{ij}\delta_{k\ell} + \mu(\delta_{ik}\delta_{j\ell} + \delta_{i\ell}\delta_{jk}). \tag{2.193}$$

The parameters λ and μ are material constants and we note that the stress is now related to the strain according to

$$\sigma_{ij} = \lambda\delta_{ij}\delta_{k\ell}\varepsilon_{k\ell} + \mu(\varepsilon_{ij} + \varepsilon_{ji}) = \lambda\varepsilon_{kk}\delta_{ij} + 2\mu\varepsilon_{ij}. \tag{2.194}$$

Decomposing the strain tensor into volumetric and shear strains, we find that

$$\sigma_{ij} = \left(\lambda + \frac{2\mu}{3}\right)\varepsilon_{kk}\delta_{ij} + 2\mu\kappa_{ij} \equiv K\varepsilon_{kk}\delta_{ij} + 2G\kappa_{ij}. \tag{2.195}$$

In this last expression we have introduced the *bulk modulus* K and the *shear modulus* G. These are both material constants and can be found tabulated in standard reference texts.

The relation in Eq. (2.190) can also be inverted. We can do this by finding a tensor $s_{ijk\ell}$ such that

$$\epsilon_{ij} = s_{ijk\ell}\sigma_{k\ell}. \tag{2.196}$$

This tensor is known as the *compliance tensor*, which tells us how easy it is to deform the material, with larger components indicating larger deformation for the same stress. By the same argumentation as for the stiffness tensor, the symmetries of the stress and strain tensors imply the very same symmetries for the compliance tensor. The usual form of writing the compliance tensor for an isotropic material is

$$s_{ijk\ell} = \frac{1}{E}\left[\frac{1+\nu}{2}(\delta_{ik}\delta_{j\ell} + \delta_{i\ell}\delta_{jk}) - \nu\delta_{ij}\delta_{k\ell}\right] \tag{2.197a}$$

implying that

$$\epsilon_{ij} = \frac{1}{E}\left[(1+\nu)\sigma_{ij} - \nu\sigma_{kk}\delta_{ij}\right]. \tag{2.197b}$$

The material constants involved here are *Young's modulus* E and *Poisson's ratio* ν. Being the inverse relation of that given by the stiffness tensor, these constants are related to the bulk and shear moduli and are also found in standard references. Relating E and ν to K and G is left as Problem 2.41.

2.6.2 Electromagnetism

Electromagnetism is the theory describing the interactions of electric and magnetic fields with matter based upon charges and currents. For the simplest ideas in the theory, it is sufficient to have a description based on vector analysis using the electric field $\vec{E}$ and magnetic field $\vec{B}$. In free space, these fields satisfy *Maxwell's equations*

$$\nabla \cdot \vec{E} = \frac{\rho}{\varepsilon_0}, \tag{2.198a}$$

$$\nabla \cdot \vec{B} = 0, \tag{2.198b}$$

$$\nabla \times \vec{E} + \frac{\partial \vec{B}}{\partial t} = 0, \tag{2.198c}$$

$$\nabla \times \vec{B} - \frac{1}{c^2}\frac{\partial \vec{E}}{\partial t} = \mu_0\vec{J}, \tag{2.198d}$$

Chapter 1

Coordinate Systems and Vectors

Coordinates and vectors—in one form or another—are two of the most fundamental concepts in any discussion of mathematics as applied to physical problems. So, it is beneficial to start our study with these two concepts. Both vectors and coordinates have generalizations that cover a wide variety of physical situations including not only ordinary three-dimensional space with its ordinary vectors, but also the four-dimensional spacetime of relativity with its so-called *four vectors*, and even the infinite-dimensional spaces used in quantum physics with their vectors of infinite components. Our aim in this chapter is to review the *ordinary space* and how it is used to describe physical phenomena. To facilitate this discussion, we first give an outline of some of the properties of vectors.

1.1 Vectors in a Plane and in Space

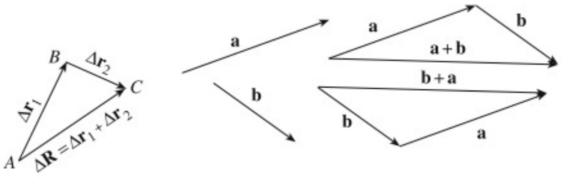
We start with the most common definition of a vector as a directed line segment without regard to where the vector is located. In other words, a vector is a directed line segment whose only important attributes are its direction and its length. As long as we do not change these two attributes, the vector is not affected. Thus, we are allowed to move a vector parallel to itself without changing the vector. Examples of vectors[1] are position $\mathbf{r}$, displacement $\Delta\mathbf{r}$, velocity $\mathbf{v}$, momentum $\mathbf{p}$, electric field $\mathbf{E}$, and magnetic field $\mathbf{B}$. The vector that has no length is called the **zero vector** and is denoted by $\mathbf{0}$.

general properties of vectors

Vectors would be useless unless we could perform some kind of operation on them. The most basic operation is changing the length of a vector. This is accomplished by multiplying the vector by a real positive number. For example, $3.2\mathbf{r}$ is a vector in the same direction as $\mathbf{r}$ but 3.2 times longer. We

---

[1] Vectors will be denoted by Roman letters printed in boldface type.



(a) (b)

Figure 1.1: Illustration of the commutative law of addition of vectors.

operations on vectors

can flip the direction of a vector by multiplying it by -1. That is, $(-1)\times\mathbf{r} = -\mathbf{r}$ is a vector having the same length as $\mathbf{r}$ but pointing in the opposite direction. We can combine these two operations and think of multiplying a vector by any real (positive or negative) number. The result is another vector *lying along the same line* as the original vector. Thus, $-0.732\mathbf{r}$ is a vector that is 0.732 times as long as $\mathbf{r}$ and points in the opposite direction. The zero *vector* is obtained every time one multiplies any vector by the *number* zero.

Another operation is the addition of two vectors. This operation, with which we assume the reader to have some familiarity, is inspired by the obvious addition law for displacements. In Figure 1.1(a), a displacement, $\Delta\mathbf{r}_1$ from A to B is added to the displacement $\Delta\mathbf{r}_2$ from B to C to give $\Delta\mathbf{R}$ their resultant, or their sum, i.e., the displacement from A to C: $\Delta\mathbf{r}_1+\Delta\mathbf{r}_2=\Delta\mathbf{R}$. Figure 1.1(b) shows that addition of vectors is commutative: $\mathbf{a}+\mathbf{b}=\mathbf{b}+\mathbf{a}$. It is also associative, $\mathbf{a}+(\mathbf{b}+\mathbf{c})=(\mathbf{a}+\mathbf{b})+\mathbf{c}$, i.e., the order in which you add vectors is irrelevant. It is clear that $\mathbf{a}+\mathbf{0}=\mathbf{0}+\mathbf{a}=\mathbf{a}$ for any vector $\mathbf{a}$.

Example 1.1.1. The parametric equation of a line through two given points can be obtained in vector form by noting that any point in space defines a vector whose components are the coordinates of the given point.[2] If the components of the points P and Q in Figure 1.2 are, respectively, (p_x, p_y, p_z) and (q_x, q_y, q_z), then we can define vectors $\mathbf{p}$ and $\mathbf{q}$ with those components. An arbitrary point X with components (x, y, z) will lie on the line PQ if and only if the vector $\mathbf{x}=(x,y,z)$ has its tip on that line. This will happen if and only if the vector joining P and X, namely $\mathbf{x}-\mathbf{p}$, is proportional to the vector joining P and Q, namely $\mathbf{q}-\mathbf{p}$. Thus, for some real number t, we must have

vector form of the parametric equation of a line

$$\mathbf{x}-\mathbf{p}=t(\mathbf{q}-\mathbf{p}) \qquad \text{or} \qquad \mathbf{x}=t(\mathbf{q}-\mathbf{p})+\mathbf{p}.$$

This is the vector form of the equation of a line. We can write it in component form by noting that the equality of vectors implies the equality of corresponding components. Thus,

$$\begin{aligned} x &= (q_x - p_x)t + p_x, \\ y &= (q_y - p_y)t + p_y, \\ z &= (q_z - p_z)t + p_z, \end{aligned}$$

which is the usual parametric equation for a line. ■

---

[2] We shall discuss components and coordinates in greater detail later in this chapter. For now, the knowledge gained in calculus is sufficient for our discussion.

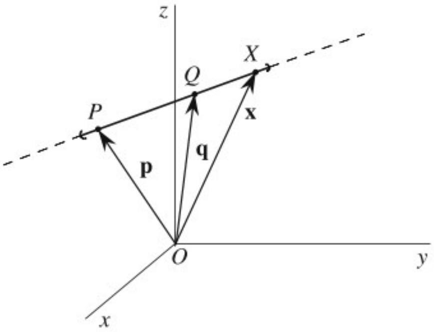


Figure 1.2: The parametric equation of a line in space can be obtained easily using vectors.

There are some special vectors that are extremely useful in describing physical quantities. These are the **unit vectors**. If one divides a vector by its length, one gets a unit vector in the direction of the original vector. Unit vectors are generally denoted by the symbol $\hat{\mathbf{e}}$ with a subscript which designates its direction. Thus, if we divided the vector $\mathbf{a}$ by its length $|\mathbf{a}|$ we get the unit vector $\hat{\mathbf{e}}_a$ in the direction of $\mathbf{a}$. Turning this definition around, we have

use of unit vectors

Box 1.1.1. *If we know the magnitude* $|\mathbf{a}|$ *of a vector quantity as well as its direction* $\hat{\mathbf{e}}_a$*, we can construct the vector:* $\mathbf{a} = |\mathbf{a}|\hat{\mathbf{e}}_a$.

This construction will be used often in the sequel.

The most commonly used unit vectors are those in the direction of coordinate axes. Thus $\hat{\mathbf{e}}_x$, $\hat{\mathbf{e}}_y$, and $\hat{\mathbf{e}}_z$ are the unit vectors pointing in the positive directions of the x-, y-, and z-axes, respectively.[3] We shall introduce unit vectors in other coordinate systems when we discuss those coordinate systems later in this chapter.

unit vectors along the x-, y-, and z-axes

1.1.1 Dot Product

The reader is no doubt familiar with the concept of **dot product** whereby two vectors are "multiplied" and the result is a number. The dot product of $\mathbf{a}$ and $\mathbf{b}$ is defined by

$$\mathbf{a} \cdot \mathbf{b} \equiv |\mathbf{a}|\,|\mathbf{b}|\cos\theta, \tag{1.1}$$

dot product defined

where $|\mathbf{a}|$ is the length of $\mathbf{a}$, $|\mathbf{b}|$ is the length of $\mathbf{b}$, and θ is the angle between the two vectors. This definition is motivated by many physical situations.

---

[3] These unit vectors are usually denoted by **i**, **j**, and **k**, a notation that can be confusing when other non-Cartesian coordinates are used. We shall not use this notation, but adhere to the more suggestive notation introduced above.

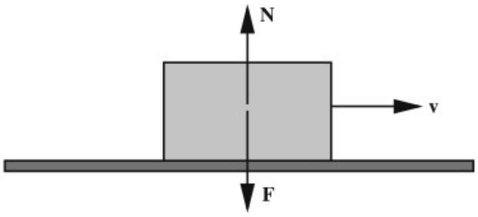

Figure 1.3: No work is done by a force orthogonal to displacement. If such a work were not zero, it would have to be positive or negative; but no consistent rule exists to assign a sign to the work.

The prime example is work which is defined as the scalar product of force and displacement. The presence of $\cos\theta$ ensures the requirement that the work done by a force perpendicular to the displacement is zero. If this requirement were not met, we would have the precarious situation of Figure 1.3 in which the two vertical forces add up to zero but the total work done by them is not zero! This is because it would be impossible to assign a "sign" to the work done by forces being displaced perpendicular to themselves, and make the rule of such an assignment in such a way that the work of **F** in the figure cancels that of **N**. (The reader is urged to try to come up with a rule—e.g., assigning a positive sign to the work if the velocity points to the right of the observer and a negative sign if it points to the observer's left—and see that it will not work, no matter how elaborate it may be!) The only logical definition of work is that which includes a $\cos\theta$ factor.

properties of dot product

The dot product is clearly commutative, $\mathbf{a}\cdot\mathbf{b} = \mathbf{b}\cdot\mathbf{a}$. Moreover, it distributes over vector addition

$$(\mathbf{a}+\mathbf{b})\cdot\mathbf{c} = \mathbf{a}\cdot\mathbf{c} + \mathbf{b}\cdot\mathbf{c}.$$

To see this, note that Equation (1.1) can be interpreted as the product of the length of **a** with the projection of **b** along **a**. Now Figure 1.4 demonstrates[4] that the projection of $\mathbf{a}+\mathbf{b}$ along **c** is the sum of the projections of **a** and **b** along **c** (see Problem 1.2 for details). The third property of the inner product is that $\mathbf{a}\cdot\mathbf{a}$ is always a *positive* number unless **a** is the zero vector in which case $\mathbf{a}\cdot\mathbf{a} = 0$. In mathematics, the collection of these three properties—commutativity, positivity, and distribution over addition—*defines* a dot (or inner) product on a vector space.

properties defining the dot (inner) product

The definition of the dot product leads directly to $\mathbf{a}\cdot\mathbf{a} = |\mathbf{a}|^2$ or

$$|\mathbf{a}| = \sqrt{\mathbf{a}\cdot\mathbf{a}}, \tag{1.2}$$

which is useful in calculating the length of sums or differences of vectors.

---

[4] Figure 1.4 appears to prove the distributive property only for vectors lying in the same plane. However, the argument will be valid even if the three vectors are not coplanar. Instead of dropping perpendicular *lines* from the tips of **a** and **b**, one drops perpendicular *planes*.

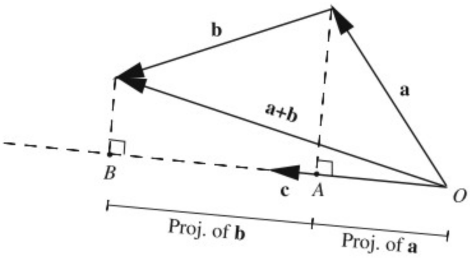

Figure 1.4: The distributive property of the dot product is clearly demonstrated if we interpret the dot product as the length of one vector times the projection of the other vector on the first.

One can use the distributive property of the dot product to show that if (a_x, a_y, a_z) and (b_x, b_y, b_z) represent the components of $\mathbf{a}$ and $\mathbf{b}$ along the axes x, y, and z, then

dot product in terms of components

$$\mathbf{a} \cdot \mathbf{b} = a_x b_x + a_y b_y + a_z b_z. \tag{1.3}$$

From the definition of the dot product, we can draw an important conclusion. If we divide both sides of $\mathbf{a} \cdot \mathbf{b} = |\mathbf{a}|\,|\mathbf{b}| \cos\theta$ by $|\mathbf{a}|$, we get

$$\frac{\mathbf{a} \cdot \mathbf{b}}{|\mathbf{a}|} = |\mathbf{b}| \cos\theta \quad \text{or} \quad \left(\frac{\mathbf{a}}{|\mathbf{a}|}\right) \cdot \mathbf{b} = |\mathbf{b}| \cos\theta \;\Rightarrow\; \hat{\mathbf{e}}_a \cdot \mathbf{b} = |\mathbf{b}| \cos\theta.$$

a useful relation to be used frequently in the sequel

Noting that $|\mathbf{b}| \cos\theta$ is simply the projection of $\mathbf{b}$ along $\mathbf{a}$, we conclude

> **Box 1.1.2.** *To find the perpendicular projection of a vector* **b** *along another vector* **a**, *take the dot product of* **b** *with* $\hat{\mathbf{e}}_a$, *the unit vector along* **a**.

Sometimes "component" is used for perpendicular projection. This is not entirely correct. For any set of three *mutually perpendicular* unit vectors in space, Box 1.1.2 can be used to find the *components* of a vector along the three unit vectors. Only if the unit vectors are mutually perpendicular do components and projections coincide.

1.1.2 Vector or Cross Product

Given two space vectors, $\mathbf{a}$ and $\mathbf{b}$, we can find a third *space* vector $\mathbf{c}$, called the **cross product** of $\mathbf{a}$ and $\mathbf{b}$, and denoted by $\mathbf{c} = \mathbf{a} \times \mathbf{b}$. The magnitude of $\mathbf{c}$ is defined by $|\mathbf{c}| = |\mathbf{a}|\,|\mathbf{b}| \sin\theta$ where θ is the angle between $\mathbf{a}$ and $\mathbf{b}$. The direction of $\mathbf{c}$ is given by the **right-hand rule**: If $\mathbf{a}$ is turned to $\mathbf{b}$ (note the order in which $\mathbf{a}$ and $\mathbf{b}$ appear here) through the angle between $\mathbf{a}$ and $\mathbf{b}$,

cross product of two space vectors

right-hand rule explained

a (right-handed) screw that is perpendicular to **a** and **b** will advance in the direction of $\mathbf{a}\times\mathbf{b}$. This definition implies that

$$\mathbf{a}\times\mathbf{b} = -\mathbf{b}\times\mathbf{a}.$$

cross product is antisymmetric

This property is described by saying that the cross product is **antisymmetric**. The definition also implies that

$$\mathbf{a}\cdot(\mathbf{a}\times\mathbf{b}) = \mathbf{b}\cdot(\mathbf{a}\times\mathbf{b}) = 0.$$

That is, $\mathbf{a}\times\mathbf{b}$ is perpendicular to both **a** and **b**.[5]

The vector product has the following properties:

$$\begin{aligned}
&\mathbf{a}\times(\alpha\mathbf{b}) = (\alpha\mathbf{a})\times\mathbf{b} = \alpha(\mathbf{a}\times\mathbf{b}), \qquad && \mathbf{a}\times\mathbf{b} = -\mathbf{b}\times\mathbf{a},\\
&\mathbf{a}\times(\mathbf{b}+\mathbf{c}) = \mathbf{a}\times\mathbf{b}+\mathbf{a}\times\mathbf{c}, && \mathbf{a}\times\mathbf{a} = 0.
\end{aligned} \tag{1.4}$$

cross product in terms of components

Using these properties, we can write the vector product of two vectors in terms of their components. We are interested in a more general result valid in other coordinate systems as well. So, rather than using x, y, and z as subscripts for unit vectors, we use the numbers 1, 2, and 3. In that case, our results can also be used for spherical and cylindrical coordinates which we shall discuss shortly.

$$\begin{aligned}
\mathbf{a}\times\mathbf{b} &= (\alpha_1\hat{\mathbf{e}}_1+\alpha_2\hat{\mathbf{e}}_2+\alpha_3\hat{\mathbf{e}}_3)\times(\beta_1\hat{\mathbf{e}}_1+\beta_2\hat{\mathbf{e}}_2+\beta_3\hat{\mathbf{e}}_3)\\
&= \alpha_1\beta_1\hat{\mathbf{e}}_1\times\hat{\mathbf{e}}_1+\alpha_1\beta_2\hat{\mathbf{e}}_1\times\hat{\mathbf{e}}_2+\alpha_1\beta_3\hat{\mathbf{e}}_1\times\hat{\mathbf{e}}_3\\
&\quad +\alpha_2\beta_1\hat{\mathbf{e}}_2\times\hat{\mathbf{e}}_1+\alpha_2\beta_2\hat{\mathbf{e}}_2\times\hat{\mathbf{e}}_2+\alpha_2\beta_3\hat{\mathbf{e}}_2\times\hat{\mathbf{e}}_3\\
&\quad +\alpha_3\beta_1\hat{\mathbf{e}}_3\times\hat{\mathbf{e}}_1+\alpha_3\beta_2\hat{\mathbf{e}}_3\times\hat{\mathbf{e}}_2+\alpha_3\beta_3\hat{\mathbf{e}}_3\times\hat{\mathbf{e}}_3.
\end{aligned}$$

But, by the last property of Equation (1.4), we have

$$\hat{\mathbf{e}}_1\times\hat{\mathbf{e}}_1 = \hat{\mathbf{e}}_2\times\hat{\mathbf{e}}_2 = \hat{\mathbf{e}}_3\times\hat{\mathbf{e}}_3 = 0.$$

right-handed set of unit vectors

Also, if we assume that $\hat{\mathbf{e}}_1$, $\hat{\mathbf{e}}_2$, and $\hat{\mathbf{e}}_3$ form a so-called **right-handed set**, i.e., if

$$\begin{aligned}
\hat{\mathbf{e}}_1\times\hat{\mathbf{e}}_2 &= -\hat{\mathbf{e}}_2\times\hat{\mathbf{e}}_1 = \hat{\mathbf{e}}_3,\\
\hat{\mathbf{e}}_1\times\hat{\mathbf{e}}_3 &= -\hat{\mathbf{e}}_3\times\hat{\mathbf{e}}_1 = -\hat{\mathbf{e}}_2,\\
\hat{\mathbf{e}}_2\times\hat{\mathbf{e}}_3 &= -\hat{\mathbf{e}}_3\times\hat{\mathbf{e}}_2 = \hat{\mathbf{e}}_1,
\end{aligned} \tag{1.5}$$

then we obtain

$$\mathbf{a}\times\mathbf{b} = (\alpha_2\beta_3-\alpha_3\beta_2)\hat{\mathbf{e}}_1+(\alpha_3\beta_1-\alpha_1\beta_3)\hat{\mathbf{e}}_2+(\alpha_1\beta_2-\alpha_2\beta_1)\hat{\mathbf{e}}_3$$

---

[5] This fact makes it clear why $\mathbf{a}\times\mathbf{b}$ is not defined in the plane. Although it is possible to define $\mathbf{a}\times\mathbf{b}$ for vectors **a** and **b** lying in a plane, $\mathbf{a}\times\mathbf{b}$ *will not lie in that plane* (it will be perpendicular to that plane). For the vector product, **a** and **b** (although lying in a plane) must be considered as space vectors.

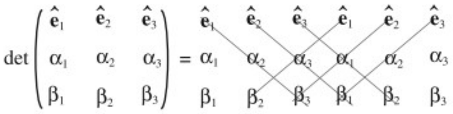

Figure 1.5: A 3×3 determinant is obtained by writing the entries twice as shown, multiplying all terms on each slanted line and adding the results. The lines from upper left to lower right bear a positive sign, and those from upper right to lower left a negative sign.

which can be nicely written in a determinant form[6]

cross product in terms of the determinant of components

$$\mathbf{a} \times \mathbf{b} = \det \begin{pmatrix} \hat{\mathbf{e}}_1 & \hat{\mathbf{e}}_2 & \hat{\mathbf{e}}_3 \\ \alpha_1 & \alpha_2 & \alpha_3 \\ \beta_1 & \beta_2 & \beta_3 \end{pmatrix}. \tag{1.6}$$

Figure 1.5 explains the rule for "expanding" a determinant.

Example 1.1.2. From the definition of the vector product and Figure 1.6(a), we note that

area of a parallelogram in terms of cross product of its two sides

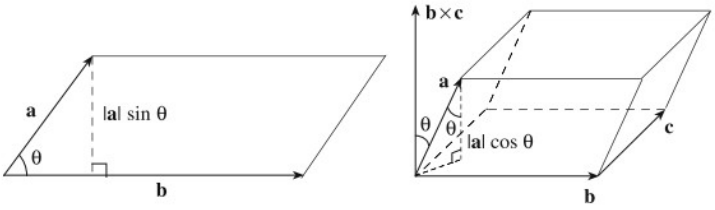
$$|\mathbf{a} \times \mathbf{b}| = \text{area of the parallelogram defined by } \mathbf{a} \text{ and } \mathbf{b}.$$

So we can use Equation (1.6) to find the area of a parallelogram defined by two vectors directly in terms of their components. For instance, the area defined by $\mathbf{a} = (1, 1, -2)$ and $\mathbf{b} = (2, 0, 3)$ can be found by calculating their vector product

$$\mathbf{a} \times \mathbf{b} = \det \begin{pmatrix} \hat{\mathbf{e}}_1 & \hat{\mathbf{e}}_2 & \hat{\mathbf{e}}_3 \\ 1 & 1 & -2 \\ 2 & 0 & 3 \end{pmatrix} = 3\hat{\mathbf{e}}_1 - 7\hat{\mathbf{e}}_2 - 2\hat{\mathbf{e}}_3,$$

and then computing its length

$$|\mathbf{a} \times \mathbf{b}| = \sqrt{3^2 + (-7)^2 + (-2)^2} = \sqrt{62}. \qquad \blacksquare$$



(a) (b)

Figure 1.6: (a) The area of a parallelogram is the absolute value of the cross product of the two vectors describing its sides. (b) The volume of a parallelepiped can be obtained by mixing the dot and the cross products.

---

[6] No knowledge of determinants is necessary at this point. The reader may consider (1.6) to be a mnemonic device useful for remembering the components of $\mathbf{a} \times \mathbf{b}$.

Example 1.1.3. The volume of a parallelepiped defined by three non-coplanar vectors, **a**, **b**, and **c**, is given by $|\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c})|$. This can be seen from Figure 1.6(b), where it is clear that

volume of a parallelepiped as a combination of dot and cross products

$$\text{volume} = (\text{area of base})(\text{altitude}) = |\mathbf{b} \times \mathbf{c}|(|\mathbf{a}|\cos\theta) = |(\mathbf{b} \times \mathbf{c}) \cdot \mathbf{a}|.$$

The absolute value is taken to ensure the positivity of the area. In terms of components we have

$$\begin{aligned}\text{volume} &= |(\mathbf{b} \times \mathbf{c})_1\alpha_1 + (\mathbf{b} \times \mathbf{c})_2\alpha_2 + (\mathbf{b} \times \mathbf{c})_3\alpha_3| \\ &= |(\beta_2\gamma_3 - \beta_3\gamma_2)\alpha_1 + (\beta_3\gamma_1 - \beta_1\gamma_3)\alpha_2 + (\beta_1\gamma_2 - \beta_2\gamma_1)\alpha_3|,\end{aligned}$$

volume of a parallelepiped as the determinant of the components of its side vectors

which can be written in determinant form as

$$\text{volume} = |\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c})| = \left|\det\begin{pmatrix}\alpha_1 & \alpha_2 & \alpha_3 \\ \beta_1 & \beta_2 & \beta_3 \\ \gamma_1 & \gamma_2 & \gamma_3\end{pmatrix}\right|.$$

Note how we have put the absolute value sign around the determinant of the matrix, so that the area comes out positive. ■

Historical Notes

The concept of vectors as directed line segments that could represent velocities, forces, or accelerations has a very long history. Aristotle knew that the effect of two forces acting on an object could be described by a single force using what is now called *the parallelogram law.* However, the real development of the concept took an unexpected turn in the nineteenth century.

With the advent of *complex numbers* and the realization by Gauss, Wessel, and especially Argand, that they could be represented by points in a plane, mathematicians discovered that complex numbers could be used to study vectors in a plane. A complex number is represented by a pair[7] of real numbers—called the real and imaginary parts of the complex number—which could be considered as the two components of a planar vector.

This connection between vectors in a plane and complex numbers was well established by 1830. Vectors are, however, useful only if they are treated as objects in *space.* After all, velocities, forces, and accelerations are mostly three-dimensional objects. So, the two-dimensional complex numbers had to be generalized to three dimensions. This meant inventing ways of adding, subtracting, multiplying, and dividing objects such as (x, y, z).

William R. Hamilton 1805–1865

The invention of a spatial analogue of the planar complex numbers is due to **William R. Hamilton**. Next to Newton, Hamilton is the greatest of all English mathematicians, and like Newton he was even greater as a physicist than as a mathematician. At the age of five Hamilton could read Latin, Greek, and Hebrew. At eight he added Italian and French; at ten he could read Arabic and Sanskrit, and at fourteen, Persian. A contact with a lightning calculator inspired him to study mathematics. In 1822 at the age of seventeen and a year before he entered Trinity College in Dublin, he prepared a paper on caustics which was read before the Royal Irish Academy in 1824 but not published. Hamilton was advised to rework and expand it. In 1827 he submitted to the Academy a revision which initiated the science of geometrical optics and introduced new techniques in analytical mechanics.

---

[7] See Chapter 18.

In 1827, while still an undergraduate, he was appointed Professor of Astronomy at Trinity College in which capacity he had to manage the astronomical observations and teach science. He did not do much of the former, but he was a fine lecturer.

Hamilton had very good intuition, and knew how to use analogy to reason from the known to the unknown. Although he lacked great flashes of insight, he worked very hard and very long on special problems to see what generalizations they would lead to. He was patient and systematic in working on specific problems and was willing to go through detailed and laborious calculations to check or prove a point.

After mastering and clarifying the concept of complex numbers and their relation to planar vectors (see Problem 18.11 for the connection between complex multiplication on the one hand, and dot and cross products on the other), Hamilton was able to think more clearly about the three-dimensional generalization. His efforts led unfortunately to frustration because the vectors (a) required four components, and (b) defied commutativity! Both features were revolutionary and set the standard for algebra. He called these new numbers **quaternions**.

In retrospect, one can see that the new three-dimensional complex numbers *had* to contain four components. Each "number," when acting on a vector, rotates the latter about an axis and stretches (or contracts) it. Two angles are required to specify the axis of rotation, one angle to specify the amount of rotation, and a fourth number to specify the amount of stretch (or contraction).

Hamilton announced the invention of quaternions in 1843 at a meeting of the Royal Irish Academy, and spent the rest of his life developing the subject.

1.2 Coordinate Systems

Coordinates are "functions" that specify **points** of a space. The smallest number of these functions necessary to specify a point is called the **dimension** of that space. For instance, a point of a plane is specified by two numbers, and as the point moves in the plane the two numbers change, i.e., the coordinates are functions of the position of the point. If we designate the point as P, we may write the coordinate functions of P as $(f(P), g(P))$.[8] Each pair of such functions is called a **coordinate system**.

coordinate systems as functions.

There are two coordinate systems used for a plane, **Cartesian**, denoted by $(x(P), y(P))$, and **polar**, denoted by $(r(P), \theta(P))$. As shown in Figure 1.7,

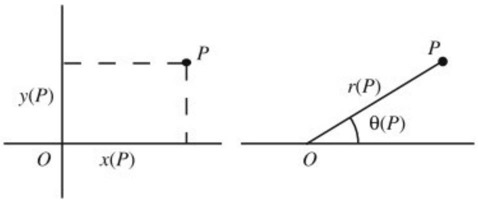


Figure 1.7: Cartesian and polar coordinates of a point P in two dimensions.

---

[8] Think of f (or g) as a rule by which a unique number is assigned to each point P.

the "function" x is defined as giving the distance from P to the vertical axis, while θ is the function which gives the angle that the line OP makes with a given fiducial (usually horizontal) line. The origin O and the fiducial line are completely arbitrary. Similarly, the functions r and y give distances from the origin and to the horizontal axis, respectively.

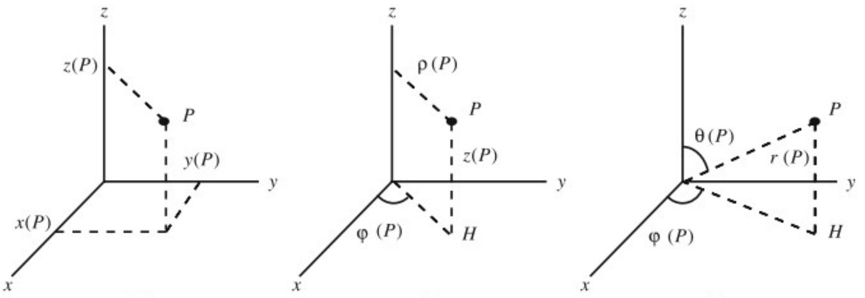
Box 1.2.1. *In practice, one drops the argument P and writes (x, y) and (r, θ).*

the three common coordinate systems: Cartesian, cylindrical and spherical

We can generalize the above concepts to three dimensions. There are three coordinate functions now. So for a point P in space we write

$$(f(P), g(P), h(P)),$$

where f, g, and h are functions on the three-dimensional space. There are three widely used coordinate systems, **Cartesian** $(x(P), y(P), z(P))$, **cylindrical** $(\rho(P), \varphi(P), z(P))$, and **spherical** $(r(P), \theta(P), \varphi(P))$. $\varphi(P)$ is called the **azimuth** or the **azimuthal angle** of P, while $\theta(P)$ is called its **polar angle**. To find the spherical coordinates of P, one chooses an arbitrary point as the origin O and an arbitrary line through O called the **polar axis**. One measures $\overline{OP}$ and calls it $r(P)$; $\theta(P)$ is the angle between $\overline{OP}$ and the polar axis. To find the third coordinate, we construct the plane through O and perpendicular to the polar axis, drop a projection from P to the plane meeting the latter at H, draw an arbitrary fiducial line through O in this plane, and measure the angle between this line and $\overline{OH}$. This angle is $\varphi(P)$. Cartesian and cylindrical coordinate systems can be described similarly. The three coordinate systems are shown in Figure 1.8. As indicated in the figure, the polar axis is usually taken to be the z-axis, and the fiducial line from which $\varphi(P)$ is measured is chosen to be the x-axis. Although there are other coordinate systems, the three mentioned above are by far the most widely used.



(a) (b) (c)

Figure 1.8: (a) Cartesian, (b) cylindrical, and (c) spherical coordinates of a point P in three dimensions.

Which one of the three systems of coordinates to use in a given physical problem is dictated mainly by the geometry of that problem. As a rule, spherical coordinates are best suited for spheres and spherically symmetric problems. Spherical symmetry describes situations in which quantities of interest are functions only of the distance from a fixed point and not on the orientation of that distance. Similarly, cylindrical coordinates ease calculations when cylinders or cylindrical symmetries are involved. Finally, Cartesian coordinates are used in rectangular geometries.

limitations of non-Cartesian coordinates

Of the three coordinate systems, Cartesian is the most complete in the following sense: *A point in space can have only* one triplet *as its coordinates.* This property is not shared by the other two systems. For example, a point P located on the z-axis of a cylindrical coordinate system does not have a well-defined $\varphi(P)$. In practice, such imperfections are not of dire consequence and we shall ignore them.

transformation from spherical to cylindrical coordinates

Once we have three coordinate systems to work with, we need to know how to translate from one to another. First we give the transformation rule from spherical to cylindrical. It is clear from Figure 1.9 that

$$\rho = r\sin\theta, \quad \varphi_{\text{cyl}} = \varphi_{\text{sph}}, \quad z = r\cos\theta. \tag{1.7}$$

Thus, given (r, θ, φ) of a point P, we can obtain (ρ, φ, z) of the same point by substituting in the RHS.

transformation from cylindrical to Cartesian coordinates

Next we give the transformation rule from cylindrical to Cartesian. Again Figure 1.9 gives the result:

$$x = \rho\cos\varphi, \quad y = \rho\sin\varphi, \quad z_{\text{car}} = z_{\text{cyl}}. \tag{1.8}$$

transformation from spherical to Cartesian coordinates

We can combine (1.7) and (1.8) to connect Cartesian and spherical coordinates:

$$x = r\sin\theta\cos\varphi, \quad y = r\sin\theta\sin\varphi, \quad z = r\cos\theta. \tag{1.9}$$

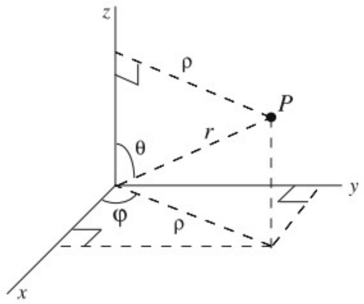


Figure 1.9: The relation between the cylindrical and spherical coordinates of a point P can be obtained using this diagram.

Box 1.2.2. *Equations (1.7)–(1.9) are extremely important and worth being committed to memory. The reader is advised to study Figure 1.9 carefully and learn to reproduce (1.7)–(1.9) from the figure!*

The transformations given are in their standard form. We can turn them around and give the inverse transformations. For instance, squaring the first and third equations of (1.7) and adding gives $\rho^2 + z^2 = r^2$ or $r = \sqrt{\rho^2 + z^2}$. Similarly, dividing the first and third equation yields $\tan\theta = \rho/z$, which implies that $\theta = \tan^{-1}(\rho/z)$, or equivalently,

$$\frac{z}{r} = \cos\theta \;\Rightarrow\; \theta = \cos^{-1}\left(\frac{z}{r}\right) = \cos^{-1}\left(\frac{z}{\sqrt{\rho^2 + z^2}}\right).$$

transformation from cylindrical to spherical coordinates

Thus, the inverse of (1.7) is

$$r = \sqrt{\rho^2 + z^2}, \quad \theta = \tan^{-1}\left(\frac{\rho}{z}\right) = \cos^{-1}\left(\frac{z}{\sqrt{\rho^2 + z^2}}\right), \quad \varphi_{\text{sph}} = \varphi_{\text{cyl}}. \tag{1.10}$$

Similarly, the inverse of (1.8) is

$$\begin{aligned} \rho &= \sqrt{x^2 + y^2}, \\ \varphi &= \tan^{-1}\left(\frac{y}{x}\right) = \cos^{-1}\left(\frac{x}{\sqrt{x^2 + y^2}}\right) = \sin^{-1}\left(\frac{y}{\sqrt{x^2 + y^2}}\right), \\ z_{\text{cyl}} &= z_{\text{car}}, \end{aligned} \tag{1.11}$$

transformation from Cartesian to spherical coordinates

and that of (1.9) is

$$\begin{aligned} r &= \sqrt{x^2 + y^2 + z^2}, \\ \theta &= \tan^{-1}\left(\frac{\sqrt{x^2 + y^2}}{z}\right) = \cos^{-1}\left(\frac{z}{\sqrt{x^2 + y^2 + z^2}}\right) \\ &= \sin^{-1}\left(\frac{\sqrt{x^2 + y^2}}{\sqrt{x^2 + y^2 + z^2}}\right), \\ \varphi &= \tan^{-1}\left(\frac{y}{x}\right) = \cos^{-1}\left(\frac{x}{\sqrt{x^2 + y^2}}\right) = \sin^{-1}\left(\frac{y}{\sqrt{x^2 + y^2}}\right). \end{aligned} \tag{1.12}$$

An important question concerns the *range* of these quantities. In other words: *In what range should we allow these quantities to vary in order to cover the whole space?* For Cartesian coordinates all three variables vary between $-\infty$ and $+\infty$. Thus,

range of coordinate variables

$$-\infty < x < +\infty, \quad -\infty < y < +\infty, \quad -\infty < z < +\infty.$$

The ranges of cylindrical coordinates are

$$0 \le \rho < \infty, \quad 0 \le \varphi \le 2\pi, \quad -\infty < z < \infty.$$

Note that ρ, being a distance, cannot have negative values.[9] Similarly, the ranges of spherical coordinates are

$$0 \leq r < \infty, \quad 0 \leq \theta \leq \pi, \quad 0 \leq \varphi \leq 2\pi.$$

Again, r is never negative for similar reasons as above. Also note that the range of θ excludes values larger than π. This is because the range of φ takes care of points where θ "appears" to have been increased by π.

Historical Notes

One of the greatest achievements in the development of mathematics since Euclid was the introduction of coordinates. Two men take credit for this development: Fermat and Descartes. These two great French mathematicians were interested in the unification of geometry and algebra, which resulted in the creation of a most fruitful branch of mathematics now called **analytic geometry**. Fermat and Descartes who were heavily involved in physics, were keenly aware of both the need for quantitative methods and the capacity of algebra to deliver that method.

Pierre de Fermat
1601–1665

Fermat's interest in the unification of geometry and algebra arose because of his involvement in optics. His interest in the attainment of maxima and minima—thus his contribution to calculus—stemmed from the investigation of the passage of light rays through media of different indices of refraction, which resulted in *Fermat's principle* in optics and the law of refraction. With the introduction of coordinates, Fermat was able to quantify the study of optics and set a trend to which all physicists of posterity would adhere. It is safe to say that without analytic geometry the progress of science, and in particular physics, would have been next to impossible.

Born into a family of tradespeople, **Pierre de Fermat** was trained as a lawyer and made his living in this profession becoming a councillor of the parliament of the city of Toulouse. Although mathematics was but a hobby for him and he could devote only spare time to it, he made great contributions to number theory, to calculus, and, together with Pascal, initiated work on probability theory.

The coordinate system introduced by Fermat was not a convenient one. For one thing, the coordinate axes were not at right angles to one another. Furthermore, the use of negative coordinates was not considered. Nevertheless, he was able to translate geometric curves into algebraic equations.

René Descartes was a great philosopher, a founder of modern biology, and a superb physicist and mathematician. His interest in mathematics stemmed from his desire to understand nature. He wrote:

> ...I have resolved to quit only abstract geometry, that is to say, the consideration of questions which *serve only to exercise the mind*, and this, in order to study another kind of geometry, which has for its object the explanation of the phenomena of nature.

René Descartes
1596–1650

His father, a relatively wealthy lawyer, sent him to a Jesuit school at the age of eight where, due to his delicate health, he was allowed to spend the mornings in bed, during which time he worked. He followed this habit during his entire life. At twenty he graduated from the University of Poitier as a lawyer and went to Paris where he studied mathematics with a Jesuit priest. After one year he decided to join the army of Prince Maurice of Orange in 1617. During the next nine years he vacillated between various armies while studying mathematics.

---

[9] In some calculus books ρ is allowed to have negative values to account for points on the opposite side of the origin. However, in physics literature ρ is assumed to be positive.To go to "the other side" of the origin along ρ, we change φ by π, keeping ρ positive at all times.

He eventually returned to Paris, where he devoted his efforts to the study of optical instruments motivated by the newly discovered power of the telescope. In 1628 he moved to Holland to a quieter and freer intellectual environment. There he lived for the next twenty years and wrote his famous works. In 1649 Queen Christina of Sweden persuaded Descartes to go to Stockholm as her private tutor. However the Queen had an uncompromising desire to draw curves and tangents at 5 a.m., causing Descartes to break the lifelong habit of getting up at 11 o'clock! After only a few months in the cold northern climate, walking to the palace for the 5 o'clock appointment with the queen, he died of pneumonia in 1650.

Descartes described his algebraic approach to geometry in his monumental work *La Géométrie*. It is in this work that he solves geometrical problems using algebra by introducing coordinates. These coordinates, as in Fermat's case, were not lengths along perpendicular axes. Nevertheless they paved the way for the later generations of scientists such as Newton to build on Descartes' and Fermat's ideas and improve on them.

Newton uses polar coordinates for the first time

Throughout the seventeenth century, mathematicians used one axis with the y values drawn at an oblique or right angle onto that axis. Newton, however, in a book called *The Method of Fluxions and Infinite Series* written in 1671, and translated much later into English in 1736, describes a coordinate system in which points are located in reference to a fixed point and a fixed line through that point. This was the first introduction of essentially the *polar coordinates* we use today.

1.3 Vectors in Different Coordinate Systems

Many physical situations require the study of vectors in different coordinate systems. For example, the study of the solar system is best done in spherical coordinates because of the nature of the gravitational force. Similarly calculation of electromagnetic fields in a cylindrical cavity will be easier if we use cylindrical coordinates. This requires not only writing functions in terms of these coordinate variables, but also expressing vectors in terms of unit vectors suitable for these coordinate systems. It turns out that, for the three coordinate systems described above, the most natural construction of such vectors renders them mutually perpendicular.

orthonormal basis

Any set of three (two) mutually perpendicular unit vectors in space (in the plane) is called an **orthonormal basis**.[10] Basis vectors have the property that any vector can be written in terms of them.

Let us start with the plane in which the coordinate system could be Cartesian or polar. In general, we construct an orthonormal basis *at a point* and note that

---

[10] The word "orthonormal" comes from *orthogonal* meaning "perpendicular," and *normal* meaning "of unit length."

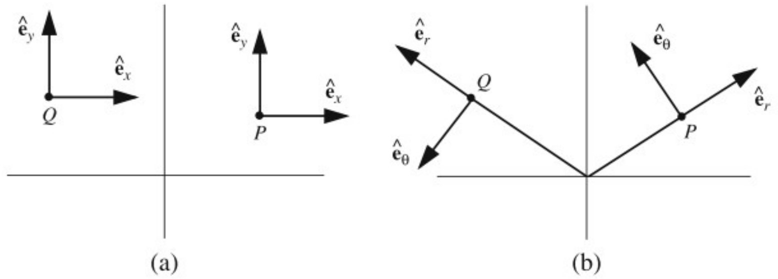

Figure 1.10: The unit vectors in (a) Cartesian coordinates and (b) polar coordinates. The unit vectors at P and Q are the same for Cartesian coordinates, but different in polar coordinates.

Box 1.3.1. *The orthonormal basis, generally speaking, depends on the point at which it is constructed.*

The vectors of a basis are constructed as follows. To find the unit vector corresponding to a coordinate at a point P, hold the other coordinate fixed and *increase* the coordinate in question. The initial direction of motion of P is the direction of the unit vector sought. Thus, we obtain the Cartesian unit vectors at point P of Figure 1.10(a): $\hat{\mathbf{e}}_x$ is obtained by holding y fixed and letting x vary in the increasing direction; and $\hat{\mathbf{e}}_y$ is obtained by holding x fixed at P and letting y increase. In each case, the unit vectors show the initial direction of the motion of P. It should be clear that one obtains the same set of unit vectors regardless of the location of P. However, the reader should take note that this is true only for coordinates that are defined in terms of axes whose directions are fixed, such as Cartesian coordinates.

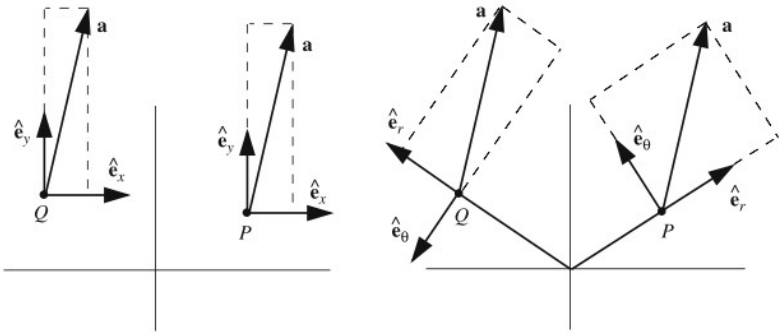
general rule for constructing a basis at a point

If we use polar coordinates for P, then holding θ fixed at P gives the direction of $\hat{\mathbf{e}}_r$ as shown in Figure 1.10(b), because for fixed θ, that is the direction of increase for r. Similarly, if r is fixed at P, the initial direction of motion of P when θ is increased is that of $\hat{\mathbf{e}}_\theta$ shown in the figure. If we choose another point such as Q shown in the figure, then a new set of unit vectors will be obtained which are different form those of P. This is because polar coordinates are not defined in terms of any fixed axes.

Since $\{\hat{\mathbf{e}}_x, \hat{\mathbf{e}}_y\}$ and $\{\hat{\mathbf{e}}_r, \hat{\mathbf{e}}_\theta\}$ form a basis in the plane, any vector $\mathbf{a}$ in the plane can be expressed in terms of either basis as shown in Figure 1.11. Thus, we can write

$$\mathbf{a} = a_{xP}\hat{\mathbf{e}}_{xP} + a_{yP}\hat{\mathbf{e}}_{yP} = a_{rP}\hat{\mathbf{e}}_{rP} + a_{\theta P}\hat{\mathbf{e}}_{\theta P} = a_{rQ}\hat{\mathbf{e}}_{rQ} + a_{\theta Q}\hat{\mathbf{e}}_{\theta Q}, \qquad (1.13)$$

where the coordinates are subscripted to emphasize their dependence on the points at which the unit vectors are erected. In the case of Cartesian coordinates, this, of course, is not necessary because the unit vectors happen to be independent of the point. In the case of polar coordinates, although this



(a) (b)

Figure 1.11: (a) The vector **a** has the same components along unit vectors at P and Q in Cartesian coordinates. (b) The vector **a** has different components along unit vectors at different points for a polar coordinate system.

dependence exists, we normally do not write the points as subscripts, being aware of this dependence every time we use polar coordinates.

angle brackets denote vector components

So far we have used parentheses to designate the (components of) a vector. Since, parentheses—as a universal notation—are used for coordinates of points, we shall write components of a vector in angle brackets. So Equation (1.13) can also be written as

$$\mathbf{a} = \langle a_x, a_y \rangle_P = \langle a_r, a_\theta \rangle_P = \langle a_r, a_\theta \rangle_Q,$$

where again the subscript indicating the point at which the unit vectors are defined is normally deleted. However, we need to keep in mind that although $\langle a_x, a_y \rangle$ is independent of the point in question, $\langle a_r, a_\theta \rangle$ is very much point-dependent. Caution should be exercised when using this notation as to the location of the unit vectors.

The unit vectors in the coordinate systems of space are defined the same way. We follow the rule given before:

Box 1.3.2. (***Rule for Finding Coordinate Unit Vectors***). *To find the unit vector corresponding to a coordinate at a point P, hold the other coordinates fixed and* increase *the coordinate in question. The initial direction of motion of P is the direction of the unit vector sought.*

It should be clear that the Cartesian basis $\{\hat{\mathbf{e}}_x, \hat{\mathbf{e}}_y, \hat{\mathbf{e}}_z\}$ is the same for all points, and usually they are drawn at the origin along the three axes. An arbitrary vector **a** can be written as

$$\mathbf{a} = a_x\hat{\mathbf{e}}_x + a_y\hat{\mathbf{e}}_y + a_z\hat{\mathbf{e}}_z \qquad \text{or} \qquad \mathbf{a} = \langle a_x, a_y, a_z \rangle, \tag{1.14}$$

where we used angle brackets to denote *components* of the vector, reserving the parentheses for *coordinates* of points in space.

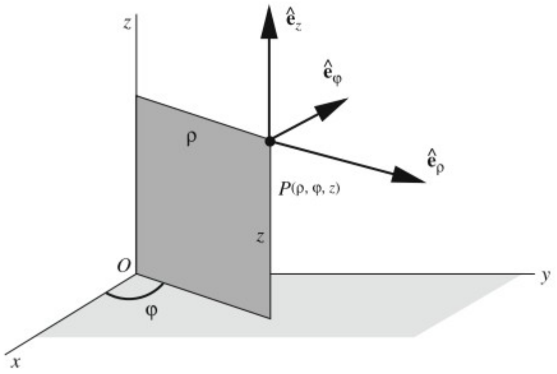


Figure 1.12: Unit vectors of cylindrical coordinates.

The unit vectors at a point P in the other coordinate systems are obtained similarly. In cylindrical coordinates, $\hat{\mathbf{e}}_\rho$ lies along and points in the direction of increasing ρ at P; $\hat{\mathbf{e}}_\varphi$ is perpendicular to the plane formed by P and the z-axis and points in the direction of increasing φ; $\hat{\mathbf{e}}_z$ points in the direction of positive z (see Figure 1.12). We note that only $\hat{\mathbf{e}}_z$ is independent of the point at which the unit vectors are defined because z is a fixed axis in cylindrical coordinates. Given any vector $\mathbf{a}$, we can write it as

$$\mathbf{a} = a_\rho \hat{\mathbf{e}}_\rho + a_\varphi \hat{\mathbf{e}}_\varphi + a_z \hat{\mathbf{e}}_z \qquad \text{or} \qquad \mathbf{a} = \langle a_\rho, a_\varphi, a_z \rangle. \tag{1.15}$$

radial direction

The unit vectors in spherical coordinates are defined similarly: $\hat{\mathbf{e}}_r$ is taken along r and points in the direction of increasing r; this direction is called **radial**; $\hat{\mathbf{e}}_\theta$ is taken to lie in the plane formed by P and the z-axis, is perpendicular to r, and points in the direction of increasing θ; $\hat{\mathbf{e}}_\varphi$ is as in the cylindrical case (Figure 1.13). An arbitrary vector in space can be expressed in terms of the spherical unit vectors at P:

$$\mathbf{a} = a_r \hat{\mathbf{e}}_r + a_\theta \hat{\mathbf{e}}_\theta + a_\varphi \hat{\mathbf{e}}_\varphi \qquad \text{or} \qquad \mathbf{a} = \langle a_r, a_\theta, a_\varphi \rangle. \tag{1.16}$$

It should be emphasized that

Box 1.3.3. *The cylindrical and spherical unit vectors* $\hat{\mathbf{e}}_\rho$, $\hat{\mathbf{e}}_r$, $\hat{\mathbf{e}}_\theta$, *and* $\hat{\mathbf{e}}_\varphi$ *are dependent on the position of* P.

position vector

Once an origin O is designated, every point P in space will define a vector, called a **position vector** and denoted by $\mathbf{r}$. This is simply the vector drawn from O to P. In Cartesian coordinates this vector has *components* $\langle x, y, z \rangle$, thus one can write

$$\mathbf{r} = x\hat{\mathbf{e}}_x + y\hat{\mathbf{e}}_y + z\hat{\mathbf{e}}_z. \tag{1.17}$$

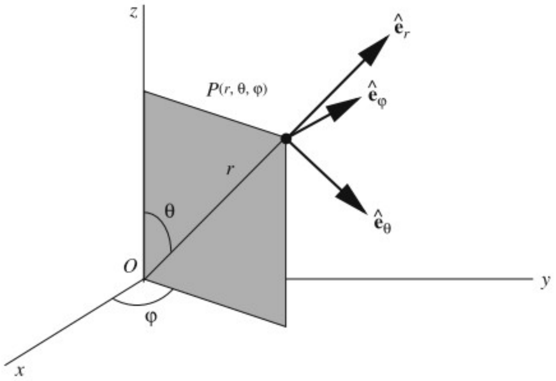

Figure 1.13: Unit vectors of spherical coordinates. Note that the intersection of the shaded plane with the xy-plane is a line along the cylindrical coordinate ρ.

difference between coordinates and components explained

But (x, y, z) are also the *coordinates* of the point P. This can be a source of confusion when other coordinate systems are used. For example, in spherical coordinates, the *components* of the vector $\mathbf{r}$ at P are $\langle r, 0, 0\rangle$ because $\mathbf{r}$ has only a component along $\hat{\mathbf{e}}_r$ and none along $\hat{\mathbf{e}}_\theta$ or $\hat{\mathbf{e}}_\varphi$. One writes[11]

$$\mathbf{r} = r\hat{\mathbf{e}}_r. \tag{1.18}$$

However, the *coordinates* of P are still (r, θ, φ)! Similarly, the coordinates of P are (ρ, φ, z) in a cylindrical system, while

$$\mathbf{r} = \rho\,\hat{\mathbf{e}}_\rho + z\hat{\mathbf{e}}_z, \tag{1.19}$$

because $\mathbf{r}$ lies in the ρz-plane and has no component along $\hat{\mathbf{e}}_\varphi$. Therefore,

Box 1.3.4. *Make a clear distinction between the **components** of the vector* $\mathbf{r}$ *and the **coordinates** of the point* P.

A common symptom of confusing components with coordinates is as follows. Point P_1 has position vector $\mathbf{r}_1$ with spherical components $\langle r_1, 0, 0\rangle$ at P_1. The position vector of a second point P_2 is $\mathbf{r}_2$ with spherical components $\langle r_2, 0, 0\rangle$ at P_2. It is easy to fall into the trap of thinking that $\mathbf{r}_1 - \mathbf{r}_2$ has spherical components $\langle r_1 - r_2, 0, 0\rangle$! This is, of course, not true, because the spherical unit vectors at P_1 are completely different from those at P_2, and, therefore, contrary to the Cartesian case, we cannot simply subtract components.

---

[11] We should really label everything with P. But, as usual, we assume this labeling to be implied.

One of the great advantages of vectors is their ability to express results independent of any specific coordinate systems. Physical laws are always coordinate-independent. For example, when we write $\mathbf{F} = m\mathbf{a}$ both $\mathbf{F}$ and $\mathbf{a}$ could be expressed in terms of Cartesian, spherical, cylindrical, or any other convenient coordinate system. This independence allows us the freedom to choose the coordinate systems most convenient for the problem at hand. For example, it is extremely difficult to solve the planetary motions in Cartesian coordinates, while the use of spherical coordinates facilitates the solution of the problem tremendously.

Physical laws ought to be coordinate independent!

Example 1.3.1. We can express the *coordinates* of the **center of mass** (CM) of a collection of particles in terms of their position vectors.[12] Thus, if $\overline{\mathbf{r}}$ denotes the position vector of the CM of the collection of N mass points, $m_1, m_2, \ldots, m_N$ with respective position vectors $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N$ relative to an origin O, then[13]

center of mass

$$\overline{\mathbf{r}} = \frac{m_1\mathbf{r}_1 + m_2\mathbf{r}_2 + \cdots + m_N\mathbf{r}_N}{m_1 + m_2 + \cdots + m_N} = \frac{\sum_{k=1}^{N} m_k\mathbf{r}_k}{M}, \tag{1.20}$$

where $M = \sum_{k=1}^{N} m_k$ is the total mass of the system. One can also think of Equation (1.20) as a *vector* equation. To find the component equations in a coordinate system, one needs to pick a *fixed* point (say the origin), a set of unit vectors at that point (usually the unit vectors along the axes of some coordinate system), and substitute the *components* of $\mathbf{r}_k$ along those unit vectors to find the components of $\overline{\mathbf{r}}$ along the unit vectors. ■

1.3.1 Fields and Potentials

The distributive property of the dot product and the fact that the unit vectors of the bases in all coordinate systems are mutually perpendicular can be used to derive the following:

dot product in terms of components in the three coordinate systems

$$\begin{aligned}
\mathbf{a} \cdot \mathbf{b} &= a_x b_x + a_y b_y + a_z b_z \quad \text{(Cartesian)},\\
\mathbf{a} \cdot \mathbf{b} &= a_\rho b_\rho + a_\varphi b_\varphi + a_z b_z \quad \text{(cylindrical)},\\
\mathbf{a} \cdot \mathbf{b} &= a_r b_r + a_\theta b_\theta + a_\varphi b_\varphi \quad \text{(spherical)}.
\end{aligned} \tag{1.21}$$

The first of these equations is the same as (1.3).

It is important to keep in mind that the components are to be expressed in the same set of unit vectors. This typically means setting up mutually perpendicular unit vectors (an orthonormal basis) *at a single point* and resolving all vectors along those unit vectors.

The dot product, in various forms and guises, has many applications in physics. As pointed out earlier, it was introduced in the definition of work, but soon spread to many other concepts of physics. One of the simplest—and most important—applications is its use in writing the laws of physics in a coordinate-independent way.

---

[12] This implies that the equation is most useful only when Cartesian coordinates are used, because only for these coordinates do the components of the position vector of a point coincide with the coordinates of that point.

[13] We assume that the reader is familiar with the symbol $\sum$ simply as a summation symbol. We shall discuss its properties and ways of manipulating it in Chapter 9.

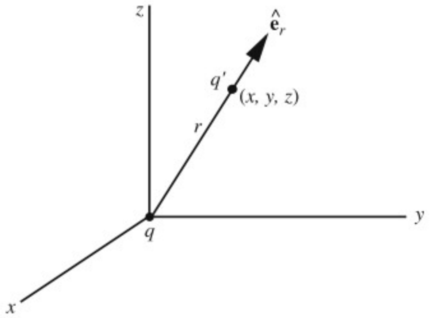

Figure 1.14: The diagram illustrating the electrical force when one charge is at the origin.

Example 1.3.2. A point charge q is situated at the origin. A second charge q' is located at (x, y, z) as shown in Figure 1.14. We want to express the electric force on q' in Cartesian, spherical, and cylindrical coordinate systems.

Coulomb's law

We know that the electric force, as given by **Coulomb's law**, lies along the line joining the two charges and is either attractive or repulsive according to the signs of q and q'. All of this information can be summarized in the formula

$$\mathbf{F}_{q'} = \frac{k_e q q'}{r^2}\hat{\mathbf{e}}_r \tag{1.22}$$

where $k_e = 1/(4\pi\epsilon_0) \approx 9 \times 10^9$ in SI units. Note that if q and q' are unlike, $qq' < 0$ and $\mathbf{F}_{q'}$ is opposite to $\hat{\mathbf{e}}_r$, i.e., it is *attractive*. On the other hand, if q and q' are of the same sign, $qq' > 0$ and $\mathbf{F}_{q'}$ is in the same direction as $\hat{\mathbf{e}}_r$, i.e., *repulsive*.

Equation (1.22) expresses $\mathbf{F}_{q'}$ in spherical coordinates. Thus, its components in terms of unit vectors at q' are $\langle k_e qq'/r^2, 0, 0\rangle$. To get the components in the other coordinate systems, we rewrite (1.22). Noting that $\hat{\mathbf{e}}_r = \mathbf{r}/r$, we write

$$\mathbf{F}_{q'} = \frac{k_e q q'}{r^2}\frac{\mathbf{r}}{r} = \frac{k_e q q'}{r^3}\mathbf{r}. \tag{1.23}$$

For Cartesian coordinates we use (1.12) to obtain $r^3 = (x^2+y^2+z^2)^{3/2}$. Substituting this and (1.17) in (1.23) yields

$$\mathbf{F}_{q'} = \frac{k_e q q'}{(x^2+y^2+z^2)^{3/2}}(x\hat{\mathbf{e}}_x + y\hat{\mathbf{e}}_y + z\hat{\mathbf{e}}_z).$$

Therefore, the components of $\mathbf{F}_{q'}$ in Cartesian coordinates are

$$\left\langle \frac{k_e q q' x}{(x^2+y^2+z^2)^{3/2}}, \frac{k_e q q' y}{(x^2+y^2+z^2)^{3/2}}, \frac{k_e q q' z}{(x^2+y^2+z^2)^{3/2}} \right\rangle.$$

Finally, using (1.10) and (1.19) in (1.23), we obtain

$$\mathbf{F}_{q'} = \frac{k_e q q'}{(\rho^2+z^2)^{3/2}}(\rho\,\hat{\mathbf{e}}_\rho + z\hat{\mathbf{e}}_z).$$

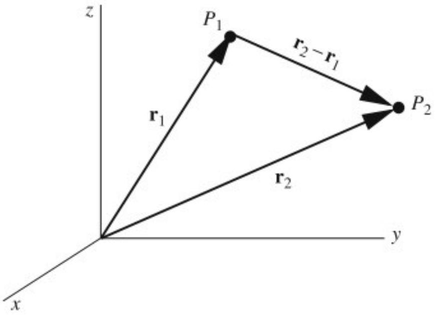

Figure 1.15: The displacement vector between P_1 and P_2 is the difference between their position vectors.

Thus the components of $\mathbf{F}_{q'}$ along the cylindrical unit vectors constructed at the location of q' are

$$\left\langle \frac{k_e q q' \rho}{(\rho^2 + z^2)^{3/2}}, 0, \frac{k_e q q' z}{(\rho^2 + z^2)^{3/2}} \right\rangle . \qquad \blacksquare$$

Since $\mathbf{r}$ gives the position of a point in space, one can use it to write the distance between two points P_1 and P_2 with position vectors $\mathbf{r}_1$ and $\mathbf{r}_2$. Figure 1.15 shows that $\mathbf{r}_2 - \mathbf{r}_1$ is the displacement vector from P_1 to P_2. The importance of this vector stems from the fact that many physical quantities are functions of distances between point particles, and $\mathbf{r}_2 - \mathbf{r}_1$ is a concise way of expressing this distance. The following example illustrates this.

Historical Notes

During the second half of the eighteenth century many physicists were engaged in a quantitative study of electricity and magnetism. **Charles Augustin de Coulomb**, who developed the so-called *torsion balance* for measuring weak forces, is credited with the discovery of the law governing the force between electrical charges.

Charles Coulomb
1736–1806

Coulomb was an army engineer in the West Indies. After spending nine years there, due to his poor health, he returned to France about the same time that the French Revolution began, at which time he retired to the country to do scientific research.

Beside his experiments on electricity, Coulomb worked on applied mechanics, structural analysis, the fracture of beams and columns, the thrust of arches, and the thrust of the soil.

Henry Cavendish
1731–1810

At about the same time that Coulomb discovered the law of electricity, there lived in England a very reclusive character named **Henry Cavendish**. He was born into the nobility, had no close friends, was afraid of women, and disinterested in music or arts of any kind. His life revolved around experiments in physics and chemistry that he carried out in a private laboratory located in his large mansion.

During his long life he published only a handful of relatively unimportant papers. But after his death about one million pounds sterling were found in his bank account and twenty bundles of notes in his laboratory. These notes remained in the possession of his relatives for a long time, but when they were published one hundred years later, it became clear that Henry Cavendish was one of the greatest experimental physicists ever. He discovered all the laws of electric and magnetic interactions at the same time as Coulomb, and his work in chemistry matches that of Lavoisier. Furthermore, he used a torsion balance to measure the universal gravitational constant for the first time, and as a result was able to arrive at the exact mass of the Earth.

Example 1.3.3. COULOMB'S LAW FOR TWO ARBITRARY CHARGES
Suppose there are point charges q_1 at P_1 and q_2 at P_2. Let us write the force exerted on q_2 by q_1. The magnitude of the force is

$$F_{21} = \frac{k_e q_1 q_2}{d^2},$$

where $d = \overline{P_1 P_2}$ is the distance between the two charges. We use d because the usual notation r has special meaning for us: it is one of the coordinates in spherical systems. If we multiply this magnitude by the unit vector describing the direction of the force, we obtain the full force vector (see Box 1.1.1). But, assuming repulsion for the moment, this unit vector is

$$\frac{\mathbf{r}_2 - \mathbf{r}_1}{|\mathbf{r}_2 - \mathbf{r}_1|} \equiv \hat{\mathbf{e}}_{21}.$$

Also, since $d = |\mathbf{r}_2 - \mathbf{r}_1|$, we have

$$\mathbf{F}_{21} = \frac{k_e q_1 q_2}{d^2}\hat{\mathbf{e}}_{21} = \frac{k_e q_1 q_2}{|\mathbf{r}_2 - \mathbf{r}_1|^2}\frac{\mathbf{r}_2 - \mathbf{r}_1}{|\mathbf{r}_2 - \mathbf{r}_1|}$$

Coulomb's law when charges are arbitrarily located

or

$$\mathbf{F}_{21} = \frac{k_e q_1 q_2}{|\mathbf{r}_2 - \mathbf{r}_1|^3}(\mathbf{r}_2 - \mathbf{r}_1). \tag{1.24}$$

Although we assumed repulsion, we see that (1.24) includes attraction as well. Indeed, if $q_1 q_2 < 0$, $\mathbf{F}_{21}$ is opposite to $\mathbf{r}_2 - \mathbf{r}_1$, i.e., $\mathbf{F}_{21}$ is directed from P_2 to P_1. Since $\mathbf{F}_{21}$ is the force *on* q_2 by q_1, this is an *attraction*. We also note that Newton's third law is included in (1.24):

$$\mathbf{F}_{12} = \frac{k_e q_2 q_1}{|\mathbf{r}_1 - \mathbf{r}_2|^3}(\mathbf{r}_1 - \mathbf{r}_2) = -\mathbf{F}_{21}$$

because $\mathbf{r}_2 - \mathbf{r}_1 = -(\mathbf{r}_1 - \mathbf{r}_2)$ and $|\mathbf{r}_2 - \mathbf{r}_1| = |\mathbf{r}_1 - \mathbf{r}_2|$.

vector form of gravitational force

We can also write the gravitational force immediately

$$\mathbf{F}_{21} = -\frac{G m_1 m_2}{|\mathbf{r}_2 - \mathbf{r}_1|^3}(\mathbf{r}_2 - \mathbf{r}_1), \tag{1.25}$$

where m_1 and m_2 are point masses and the minus sign is introduced to ensure attraction. ■

Now that we have expressions for electric and gravitational forces, we can obtain the electric field of a point charge and the gravitational field of a point mass. First recall that the **electric field** at a point P is defined to be the force on a test charge q located at P divided by q. Thus if we have a charge q_1, at P_1 with position vector $\mathbf{r}_1$ and we are interested in its fields at P with position vector $\mathbf{r}$, we introduce a charge q at $\mathbf{r}$ and calculate the force on q from Equation (1.24):

$$\mathbf{F}_q = \frac{k_e q_1 q}{|\mathbf{r} - \mathbf{r}_1|^3}(\mathbf{r} - \mathbf{r}_1).$$

electric field of a point charge

Dividing by q gives

$$\mathbf{E}_1 = \frac{k_e q_1}{|\mathbf{r} - \mathbf{r}_1|^3}(\mathbf{r} - \mathbf{r}_1), \tag{1.26}$$

where we have given the field the same index as the charge producing it.

The calculation of the gravitational field follows similarly. The result is

$$\mathbf{g}_1 = -\frac{Gm_1}{|\mathbf{r} - \mathbf{r}_1|^3}(\mathbf{r} - \mathbf{r}_1). \tag{1.27}$$

field point and source point

In (1.26) and (1.27), P is called the **field point** and P_1 the **source point**. Note that in both expressions, the field position vector comes first.

superposition principle explained

If there are several point charges (or masses) producing an electric (gravitational) field, we simply add the contributions from each source. The principle behind this procedure is called the **superposition principle**. It is a principle that "seems" intuitively obvious, but upon further reflection its validity becomes surprising. Suppose a charge q_1 produces a field $\mathbf{E}_1$ around itself. Now we introduce a second charge q_2 which, far away and isolated from any other charges, produced a field $\mathbf{E}_2$ around itself. It is not at all obvious that once we move these charges together, the individual fields should not change. After all, this is not what happens to human beings! We act completely differently when we are alone than when we are in the company of others. The presence of others drastically changes our individual behaviors. Nevertheless, charges and masses, unfettered by any social chains, retain their individuality and produce fields as if no other charges were present.

It is important to keep in mind that the superposition principle applies only to point sources. For example, a charged conducting sphere will not produce the same field when another charge is introduced nearby, because the presence of the new charge alters the charge distribution of the sphere and indeed does change the sphere's field. However each individual point charge (electron) on the sphere, whatever location on the sphere it happens to end up in, will retain its individual electric field.[14]

Going back to the electric field, we can write

$$\mathbf{E} = \mathbf{E}_1 + \mathbf{E}_2 + \cdots + \mathbf{E}_n$$

for n point charges $q_1, q_2, \ldots, q_n$ (see Figure 1.16). Substituting from (1.26), with appropriate indices, we obtain

$$\mathbf{E} = \frac{k_e q_1}{|\mathbf{r} - \mathbf{r}_1|^3}(\mathbf{r} - \mathbf{r}_1) + \frac{k_e q_2}{|\mathbf{r} - \mathbf{r}_2|^3}(\mathbf{r} - \mathbf{r}_2) + \cdots + \frac{k_e q_n}{|\mathbf{r} - \mathbf{r}_n|^3}(\mathbf{r} - \mathbf{r}_n)$$

or, using the summation symbol, we obtain

---

[14] The superposition principle, which in the case of electrostatics and gravity is needed to calculate the fields of large sources consisting of many point sources, becomes a vital pillar upon which quantum theory is built and by which many of the strange phenomena of quantum physics are explained.

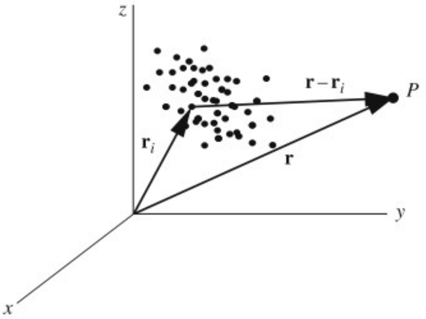

Figure 1.16: The electrostatic field of N point charges is the sum of the electric fields of the individual charges.

Box 1.3.5. *The electric field of n point charges $q_1, q_2, \ldots, q_n$, located at position vectors $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_n$ is $\mathbf{E} = \sum_{i=1}^{n} \frac{k_e q_i}{|\mathbf{r}-\mathbf{r}_i|^3}(\mathbf{r}-\mathbf{r}_i)$, and the analogous expression for the gravitational field of n point masses $m_1, m_2, \ldots, m_n$ is $\mathbf{g} = -\sum_{i=1}^{n} \frac{G m_i}{|\mathbf{r}-\mathbf{r}_i|^3}(\mathbf{r}-\mathbf{r}_i)$.*

Historical Notes

The concept of force has a fascinating history which started in the works of Galileo around the beginning of the seventeenth century, mathematically formulated and precisely defined by Sir Isaac Newton in the second half of the seventeenth century, revised and redefined in the form of **fields** by Michael Faraday and James Maxwell in the mid nineteenth century, and finally brought to its modern quantum field theoretical form by Dirac, Heisenberg, Feynman, Schwinger, and others by the mid twentieth century.

notion of field elaborated

Newton, in his theory of gravity, thought of gravitational force as "action-at-a-distance," an agent which affects something that is "there" because of the influence of something that is "here." This kind of interpretation of force had both philosophical and physical drawbacks. It is hard to accept a ghostlike influence on a distant object. Is there an agent that "carries" this influence? What is this agent, if any? Does the influence travel infinitely fast? If we remove the Sun from the Solar System would the Earth and other planets "feel" the absence of the Sun immediately?

These questions, plus others, prompted physicists to come up with the idea of a field. According to this interpretation, the Sun, by its mere presence, creates around itself an invisible three dimensional "sheet" such that, if any object is placed in this sheet, it feels the gravitational force. The reason that planets feel the force of gravity of the Sun is because they happen to be located in the gravitational field of the Sun. The reason that an apple falls to the Earth is because it is in the gravitational field of the Earth and not due to some kind of action-at-a-distance ghost.

Therefore, according to this concept, the force acts on an object *here*, because there exists a field right *here*. And force becomes a local concept. The field concept removes the difficulties associated with action-at-a-distance. The "agent" that transmits the influence from the source to the object, is the field. If the Sun is stolen from the solar system, the Earth will not feel the absence of the Sun immediately. It will receive the information of such cosmic burglary after a certain time-lapse corresponding to the time required for the disturbance to travel from the Sun to the Earth. We can liken such a disturbance (disappearance of the Sun) to a disturbance in the smooth water of a quiet pond (by dropping a stone into it). Clearly, the disturbance travels from the source (where the stone was dropped) to any other point with a finite speed, the speed of the water waves.

The concept of a field was actually introduced first in the context of electricity and magnetism by Michael Faraday as a means of "visualizing" electromagnetic effects to replace certain mathematical ideas for which he had little talent. However, in the hands of James Maxwell, fields were molded into a physical entity having an existence of their own in the form of electromagnetic waves to be produced in 1887 by Hertz and used in 1901 by Marconi in the development of radio.

potential

A concept related to that of fields is **potential** which is closely tied to the work done by the fields on a charge (in the case of electrostatics) or a mass (in the case of gravity). It can be shown[15] that the gravitational potential $\Phi(\mathbf{r})$ at $\mathbf{r}$, of n point masses, is given by

$$\Phi(\mathbf{r}) = -\sum_{i=1}^{n} \frac{Gm_i}{|\mathbf{r} - \mathbf{r}_i|} \tag{1.28}$$

and that of n point charges by

$$\Phi(\mathbf{r}) = \sum_{i=1}^{n} \frac{k_e q_i}{|\mathbf{r} - \mathbf{r}_i|}. \tag{1.29}$$

Note that in both cases, the potential goes to zero as $\mathbf{r}$ goes to infinity. This has to do with the choice of the location of the zero of potential, which we have chosen to be the point at infinity in Equations (1.28) and (1.29).

Example 1.3.4. The electric charges q_1, q_2, q_3, and q_4 are located at Cartesian $(a, 0, 0)$, $(0, a, 0)$, $(-a, 0, 0)$, and $(0, -a, 0)$, respectively. We want to find the electric field and the electrostatic potential at an arbitrary point on the z-axis. We note that

$$\mathbf{r}_1 = a\hat{\mathbf{e}}_x, \quad \mathbf{r}_2 = a\hat{\mathbf{e}}_y, \quad \mathbf{r}_3 = -a\hat{\mathbf{e}}_x, \quad \mathbf{r}_4 = -a\hat{\mathbf{e}}_y, \quad \mathbf{r} = z\hat{\mathbf{e}}_z,$$

so that

$$\begin{aligned} \mathbf{r} - \mathbf{r}_1 &= -a\hat{\mathbf{e}}_x + z\hat{\mathbf{e}}_z, & \mathbf{r} - \mathbf{r}_2 &= -a\hat{\mathbf{e}}_y + z\hat{\mathbf{e}}_z, \\ \mathbf{r} - \mathbf{r}_3 &= a\hat{\mathbf{e}}_x + z\hat{\mathbf{e}}_z, & \mathbf{r} - \mathbf{r}_4 &= a\hat{\mathbf{e}}_y + z\hat{\mathbf{e}}_z, \end{aligned}$$

---

[15] See Chapter 14 for details.

and $|\mathbf{r}-\mathbf{r}_i|^3 = (a^2+z^2)^{3/2}$ for all i. The electric field can now be calculated using Box 1.3.5:

$$\begin{aligned}\mathbf{E} &= \frac{k_e q_1}{(a^2+z^2)^{3/2}}(-a\hat{\mathbf{e}}_x + z\hat{\mathbf{e}}_z) + \frac{k_e q_2}{(a^2+z^2)^{3/2}}(-a\hat{\mathbf{e}}_y + z\hat{\mathbf{e}}_z) \\ &+ \frac{k_e q_3}{(a^2+z^2)^{3/2}}(a\hat{\mathbf{e}}_x + z\hat{\mathbf{e}}_z) + \frac{k_e q_4}{(a^2+z^2)^{3/2}}(a\hat{\mathbf{e}}_y + z\hat{\mathbf{e}}_z) \\ &= \frac{k_e}{(a^2+z^2)^{3/2}}\left[(-aq_1+aq_3)\hat{\mathbf{e}}_x + (-aq_2+aq_4)\hat{\mathbf{e}}_y + (q_1+q_2+q_3+q_4)z\hat{\mathbf{e}}_z\right].\end{aligned}$$

It is interesting to note that if the sum of all charges is zero, the z-component of the electric field vanishes at all points on the z-axis. Furthermore, if, in addition, $q_1 = q_3$ and $q_2 = q_4$, there will be no electric field at any point on the z-axis.

The potential is obtained similarly:

$$\begin{aligned}\Phi &= \frac{k_e q_1}{(a^2+z^2)^{1/2}} + \frac{k_e q_2}{(a^2+z^2)^{1/2}} + \frac{k_e q_3}{(a^2+z^2)^{1/2}} + \frac{k_e q_4}{(a^2+z^2)^{1/2}} \\ &= \frac{k_e(q_1+q_2+q_3+q_4)}{\sqrt{a^2+z^2}}.\end{aligned}$$

So, the potential is zero at all points of the z-axis, as long as the total charge is zero. ■

1.3.2 Cross Product

The unit vectors in the three coordinate systems are not only mutually perpendicular, but in the order in which they are given, they also form a right-handed set [see Equation (1.5)]. Therefore, we can use Equation (1.6) and write

$$\mathbf{a}\times\mathbf{b} = \underbrace{\det\begin{pmatrix}\hat{\mathbf{e}}_x & \hat{\mathbf{e}}_y & \hat{\mathbf{e}}_z \\ a_x & a_y & a_z \\ b_x & b_y & b_z\end{pmatrix}}_{\text{in Cartesian CS}} = \underbrace{\det\begin{pmatrix}\hat{\mathbf{e}}_\rho & \hat{\mathbf{e}}_\varphi & \hat{\mathbf{e}}_z \\ a_\rho & a_\varphi & a_z \\ b_\rho & b_\varphi & b_z\end{pmatrix}}_{\text{in cylindrical CS}} = \underbrace{\det\begin{pmatrix}\hat{\mathbf{e}}_r & \hat{\mathbf{e}}_\theta & \hat{\mathbf{e}}_\varphi \\ a_r & a_\theta & a_\varphi \\ b_r & b_\theta & b_\varphi\end{pmatrix}}_{\text{in spherical CS}} \tag{1.30}$$

Two important prototypes of the concept of cross product are **angular momentum** and **torque**. A particle moving with instantaneous linear momentum $\mathbf{p}$ relative to an origin O has *instantaneous* angular momentum $\mathbf{L} = \mathbf{r}\times\mathbf{p}$ if its instantaneous position vector with respect to O is $\mathbf{r}$. In Figure 1.17 we have shown $\mathbf{r}$, $\mathbf{p}$, and $\mathbf{r}\times\mathbf{p}$. Similarly, if the instantaneous force on the above particle is $\mathbf{F}$, then the instantaneous torque acting on it is $\mathbf{T} = \mathbf{r}\times\mathbf{F}$.

angular momentum and torque as examples of cross products

If there are more than one particle we simply add the contribution of individual particles. Thus, the total angular momentum $\mathbf{L}$ of N particles and the total torque $\mathbf{T}$ acting on them are

$$\mathbf{L} = \sum_{k=1}^{N}\mathbf{r}_k\times\mathbf{p}_k \qquad \text{and} \qquad \mathbf{T} = \sum_{k=1}^{N}\mathbf{r}_k\times\mathbf{F}_k, \tag{1.31}$$

where $\mathbf{r}_k$ is the position of the kth particle, $\mathbf{p}_k$ its instantaneous momentum, and $\mathbf{F}_k$ the instantaneous force acting on it.

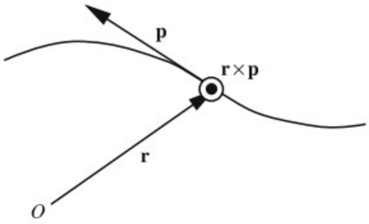

Figure 1.17: Angular momentum of a moving particle with respect to the origin O. The circle with a dot in its middle represents a vector pointing out of the page. It is assumed that $\mathbf{r}$ and $\mathbf{p}$ lie in the page.

Example 1.3.5. In this example, we show that the torque on a collection of three particles is caused by *external* forces only. The torques due to the internal forces add up to zero. The generalization to an arbitrary number of particles will be done in Example 9.2.1 when we learn how to manipulate summation symbols.

For $N = 3$, the second formula in Equation (1.31) reduces to

$$\mathbf{T} = \mathbf{r}_1 \times \mathbf{F}_1 + \mathbf{r}_2 \times \mathbf{F}_2 + \mathbf{r}_3 \times \mathbf{F}_3.$$

Each force can be divided into an external part and an internal part, the latter being the force caused by the presence of the other particles. So, we have

$$\begin{aligned}
\mathbf{F}_1 &= \mathbf{F}_1^{(\text{ext})} + \mathbf{F}_{12} + \mathbf{F}_{13}, \\
\mathbf{F}_2 &= \mathbf{F}_2^{(\text{ext})} + \mathbf{F}_{21} + \mathbf{F}_{23}, \\
\mathbf{F}_3 &= \mathbf{F}_3^{(\text{ext})} + \mathbf{F}_{31} + \mathbf{F}_{32},
\end{aligned}$$

where $\mathbf{F}_{12}$ is the force on particle 1 exerted by particle 2, etc. Substituting in the above expression for the torque, we get

$$\begin{aligned}
\mathbf{T} &= \mathbf{r}_1 \times \mathbf{F}_1^{(\text{ext})} + \mathbf{r}_2 \times \mathbf{F}_2^{(\text{ext})} + \mathbf{r}_3 \times \mathbf{F}_3^{(\text{ext})} \\
&\quad + \mathbf{r}_1 \times \mathbf{F}_{12} + \mathbf{r}_1 \times \mathbf{F}_{13} + \mathbf{r}_2 \times \mathbf{F}_{21} + \mathbf{r}_2 \times \mathbf{F}_{23} + \mathbf{r}_3 \times \mathbf{F}_{31} + \mathbf{r}_3 \times \mathbf{F}_{32} \\
&= \mathbf{T}^{(\text{ext})} + (\mathbf{r}_1 - \mathbf{r}_2) \times \mathbf{F}_{12} + (\mathbf{r}_1 - \mathbf{r}_3) \times \mathbf{F}_{13} + (\mathbf{r}_2 - \mathbf{r}_3) \times \mathbf{F}_{23},
\end{aligned}$$

where we used the third law of motion: $\mathbf{F}_{12} = -\mathbf{F}_{21}$, etc. Now we note that the internal force between two particles, 1 and 2 say, is along the line joining them, i.e., along $\mathbf{r}_1 - \mathbf{r}_2$. It follows that all the cross products in the last line of the equation above vanish and we get $\mathbf{T} = \mathbf{T}^{(\text{ext})}$. ■

We have already seen that multiplying *a vector by a number* gives another vector. A physical example of this is electric force which is obtained by multiplying electric field by electric charge. In fact we divided the electric force by charge to get the electric field. Historically, it was the law of the force which was discovered first and *then* the concept of electric field was defined. We have also seen that one can get a new vector by cross-multiplying *two vectors*. The rule of this kind of multiplication is, however, more complicated. It turns out

from electric field to electric force

8H <

that the magnetic force is related to the magnetic field via such a cross multiplication. What is worse is that the magnetic field is also related to its source (electric charges *in motion*) via such a product. Little wonder that magnetic phenomena are mathematically so much more complicated than their electric counterparts. That is why in the study of magnetism, one first introduces the concept of magnetic field and how it is related to the motion of charges producing it, and *then* the force of this field on moving charges.

magnetic field of a moving charge or Biot–Savart law

Example 1.3.6. A charge q, located instantaneously at the origin, is moving with velocity $\mathbf{v}$ relative to P [see Figure 1.18(a)]. Assuming that $|\mathbf{v}|$ is much smaller than the speed of light, the *instantaneous* magnetic field at P due to q is given by $\mathbf{B} = \frac{k_m q\,\mathbf{v} \times \hat{\mathbf{e}}_r}{r^2}$, or, using $\hat{\mathbf{e}}_r = \mathbf{r}/r$, by $\mathbf{B} = \frac{k_m q\,\mathbf{v} \times \mathbf{r}}{r^3}$. This is a simple version of a more general formula known as the **Biot–Savart law**. In the above relations, k_m is the analog of k_e in the electric case.

If we are interested in the magnetic field when q is located at a point other than the origin, we replace $\mathbf{r}$ with the vector from the instantaneous location of the moving charge to P. This is shown in Figure 1.18(b), where the vector from q_1 to P is to replace $\mathbf{r}$ in the above equation. More specifically, we have

$$\mathbf{B}_1 = \frac{k_m q_1 \mathbf{v}_1 \times (\mathbf{r} - \mathbf{r}_1)}{|\mathbf{r} - \mathbf{r}_1|^3}. \tag{1.32}$$

If there are N charges, the total magnetic field will be

$$\mathbf{B} = \sum_{k=1}^{N} \frac{k_m q_k \mathbf{v}_k \times (\mathbf{r} - \mathbf{r}_k)}{|\mathbf{r} - \mathbf{r}_k|^3}, \tag{1.33}$$

where we have used the superposition principle. ■

magnetic force on a moving charge.

When a charge q moves with velocity $\mathbf{v}$ in a magnetic field $\mathbf{B}$, it experiences a force given by

$$\mathbf{F} = q\mathbf{v} \times \mathbf{B}. \tag{1.34}$$

It is instructive to write the magnetic force exerted by a charge q_1 moving with velocity $\mathbf{v}_1$ on a second charge q_2 moving with velocity $\mathbf{v}_2$. We leave this as an exercise for the reader.

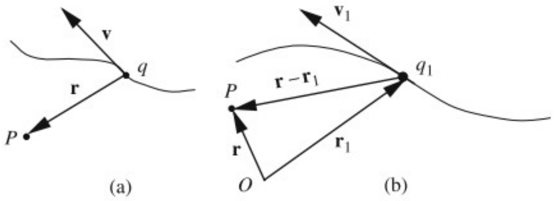

Figure 1.18: The (instantaneous) magnetic field at P of a moving point charge (a) when P is at the origin, and (b) when P is different from the origin. The field points out of the page for the configuration shown.

Example 1.3.7. A charge q moves with constant speed v (assumed to be small compared to the speed of light) on a straight line. We want to calculate the magnetic field produced by the charge at a point P located at a distance ρ from the line as a function of time. Cylindrical coordinates are most suitable for this problem because of the existence of a natural axis. Choose the path of the charge to be the z-axis. Also assume that P lies in the xy-plane, and that q was at the origin at $t = 0$. Then $\mathbf{v} = v\hat{\mathbf{e}}_z$, $\mathbf{r} = \rho\hat{\mathbf{e}}_\rho$, $\mathbf{r}_1 = vt\hat{\mathbf{e}}_z$, $\mathbf{r} - \mathbf{r}_1 = \rho\hat{\mathbf{e}}_\rho - vt\hat{\mathbf{e}}_z$. So

$$|\mathbf{r} - \mathbf{r}_1| = \sqrt{(\rho\hat{\mathbf{e}}_\rho - vt\hat{\mathbf{e}}_z) \cdot (\rho\hat{\mathbf{e}}_\rho - vt\hat{\mathbf{e}}_z)} = \sqrt{\rho^2 + v^2t^2}$$

and $\mathbf{v} \times (\mathbf{r} - \mathbf{r}_1) = v\hat{\mathbf{e}}_z \times (\rho\hat{\mathbf{e}}_\rho - vt\hat{\mathbf{e}}_z) = \rho v\hat{\mathbf{e}}_\varphi$. Therefore, the magnetic field is

$$\mathbf{B} = \frac{k_m q\mathbf{v} \times (\mathbf{r} - \mathbf{r}_1)}{|\mathbf{r} - \mathbf{r}_1|^3} = \frac{k_m q\rho v}{(\rho^2 + v^2t^2)^{3/2}}\hat{\mathbf{e}}_\varphi.$$

Readers familiar with the relation between magnetic fields and currents in long wires will note that the magnetic field above obeys the right-hand rule. ■

1.4 Relations Among Unit Vectors

We have seen that, depending on the nature of problems encountered in physics, one coordinate system may be more useful than others. We have also seen that the *coordinates* can be transformed back and forth using functional relations that connect them. Since many physical quantities are vectors, transformation and expression of components in bases of various coordinate systems also become important. The key to this transformation is writing one set of unit vectors in terms of others. In the derivation of these relations, we shall make heavy use of Box 1.1.2.

First we write the cylindrical unit vectors in terms of Cartesian unit vectors. Since $\{\hat{\mathbf{e}}_x, \hat{\mathbf{e}}_y, \hat{\mathbf{e}}_z\}$ form a basis, any vector can be written in terms of them. In particular, $\hat{\mathbf{e}}_\rho$ can be expressed as

$$\hat{\mathbf{e}}_\rho = a_1\hat{\mathbf{e}}_x + b_1\hat{\mathbf{e}}_y + c_1\hat{\mathbf{e}}_z \tag{1.35}$$

with a_1, b_1, and c_1 to be determined. Next we recall that

Box 1.4.1. *The dot product of two unit vectors is the cosine of the angle between them.*

Furthermore, Figure 1.12 shows that the angle between $\hat{\mathbf{e}}_\rho$ and $\hat{\mathbf{e}}_x$ is φ, and that between $\hat{\mathbf{e}}_\rho$ and $\hat{\mathbf{e}}_y$ is $\pi/2 - \varphi$. So, by dotting both sides of Equation (1.35) by $\hat{\mathbf{e}}_x$, $\hat{\mathbf{e}}_y$, and $\hat{\mathbf{e}}_z$ in succession, we obtain

$$\underbrace{\hat{\mathbf{e}}_x \cdot \hat{\mathbf{e}}_\rho}_{=\cos\varphi} = a_1 + 0 + 0 = a_1 \;\Rightarrow\; a_1 = \cos\varphi,$$

$$\underbrace{\hat{\mathbf{e}}_y \cdot \hat{\mathbf{e}}_\rho}_{=\sin\varphi} = 0 + b_1 + 0 = b_1 \;\Rightarrow\; b_1 = \sin\varphi,$$

$$\underbrace{\hat{\mathbf{e}}_z \cdot \hat{\mathbf{e}}_\rho}_{=0} = 0 + 0 + c_1 = c_1 \;\Rightarrow\; c_1 = 0.$$

Therefore,

$$\hat{\mathbf{e}}_\rho = \hat{\mathbf{e}}_x \cos\varphi + \hat{\mathbf{e}}_y \sin\varphi.$$

With the first and third cylindrical unit vectors $\hat{\mathbf{e}}_\rho$ and $\hat{\mathbf{e}}_z$ at our disposal,[16] we can determine the second, using Equation (1.5):

$$\hat{\mathbf{e}}_\varphi = \hat{\mathbf{e}}_z \times \hat{\mathbf{e}}_\rho = \det\begin{pmatrix} \hat{\mathbf{e}}_x & \hat{\mathbf{e}}_y & \hat{\mathbf{e}}_z \\ 0 & 0 & 1 \\ \cos\varphi & \sin\varphi & 0 \end{pmatrix} = -\hat{\mathbf{e}}_x \sin\varphi + \hat{\mathbf{e}}_y \cos\varphi.$$

Thus,

cylindrical unit vectors in terms of Cartesian unit vectors

$$\begin{aligned} \hat{\mathbf{e}}_\rho &= \hat{\mathbf{e}}_x \cos\varphi + \hat{\mathbf{e}}_y \sin\varphi, \\ \hat{\mathbf{e}}_\varphi &= -\hat{\mathbf{e}}_x \sin\varphi + \hat{\mathbf{e}}_y \cos\varphi, \\ \hat{\mathbf{e}}_z &= \hat{\mathbf{e}}_z. \end{aligned} \tag{1.36}$$

This equation can easily be inverted to find the Cartesian unit vectors in terms of the cylindrical unit vectors. For example, the coefficients in

$$\hat{\mathbf{e}}_x = a_2\hat{\mathbf{e}}_\rho + b_2\hat{\mathbf{e}}_\varphi + c_2\hat{\mathbf{e}}_z$$

can be obtained by dotting both sides of it with $\hat{\mathbf{e}}_\rho$, $\hat{\mathbf{e}}_\varphi$, and $\hat{\mathbf{e}}_z$, respectively,

$$\begin{aligned} \hat{\mathbf{e}}_\rho \cdot \hat{\mathbf{e}}_x &= a_2 + 0 + 0 \;\Rightarrow\; \cos\varphi = a_2, \\ \hat{\mathbf{e}}_\varphi \cdot \hat{\mathbf{e}}_x &= 0 + b_2 + 0 \;\Rightarrow\; -\sin\varphi = b_2, \\ \hat{\mathbf{e}}_z \cdot \hat{\mathbf{e}}_x &= 0 + 0 + c_2 \;\Rightarrow\; 0 = c_2, \end{aligned}$$

where we have used $\hat{\mathbf{e}}_\rho \cdot \hat{\mathbf{e}}_x = \cos\varphi$, and $\hat{\mathbf{e}}_\varphi \cdot \hat{\mathbf{e}}_x = -\sin\varphi$—obtained by dotting the first and second equations of (1.36) with $\hat{\mathbf{e}}_x$—as well as $\hat{\mathbf{e}}_z \cdot \hat{\mathbf{e}}_x = 0$. Similarly, one can obtain $\hat{\mathbf{e}}_y$ in terms of the cylindrical unit vectors. The entire result is

Cartesian unit vectors in terms of cylindrical unit vectors

$$\begin{aligned} \hat{\mathbf{e}}_x &= \hat{\mathbf{e}}_\rho \cos\varphi - \hat{\mathbf{e}}_\varphi \sin\varphi \\ \hat{\mathbf{e}}_y &= \hat{\mathbf{e}}_\rho \sin\varphi + \hat{\mathbf{e}}_\varphi \cos\varphi \\ \hat{\mathbf{e}}_z &= \hat{\mathbf{e}}_z \end{aligned} \tag{1.37}$$

Now we express the spherical unit vectors in terms of the cylindrical ones. This is easily done for $\hat{\mathbf{e}}_r$, because it has only $\hat{\mathbf{e}}_\rho$ and $\hat{\mathbf{e}}_z$ components (why?). Thus, with

$$\hat{\mathbf{e}}_r = a_3\hat{\mathbf{e}}_\rho + b_3\hat{\mathbf{e}}_z,$$

we obtain

$$\begin{aligned} \hat{\mathbf{e}}_\rho \cdot \hat{\mathbf{e}}_r &= a_3 + 0 \;\Rightarrow\; a_3 = \sin\theta, \\ \hat{\mathbf{e}}_z \cdot \hat{\mathbf{e}}_r &= 0 + b_3 \;\Rightarrow\; b_3 = \cos\theta, \end{aligned}$$

---

[16] Remember that $\hat{\mathbf{e}}_z$ is a unit vector in both coordinate systems. So, one can say that the *cylindrical* $\hat{\mathbf{e}}_z$ has components $\langle 0, 0, 1\rangle$ in the *Cartesian* basis $\{\hat{\mathbf{e}}_x, \hat{\mathbf{e}}_y, \hat{\mathbf{e}}_z\}$.

where in the last step of each line, we used the fact that the angle between $\hat{\mathbf{e}}_r$ and $\hat{\mathbf{e}}_z$ is θ and that between $\hat{\mathbf{e}}_r$ and $\hat{\mathbf{e}}_\rho$ is $\pi/2-\theta$ (see Figure 1.13). With a_3 and b_3 so determined, we can write

$$\hat{\mathbf{e}}_r = \hat{\mathbf{e}}_\rho \sin\theta + \hat{\mathbf{e}}_z \cos\theta.$$

Having two spherical unit vectors $\hat{\mathbf{e}}_r$ and $\hat{\mathbf{e}}_\varphi$ at our disposal,[17] we can determine the third one, using (1.5) and (1.30):

$$\hat{\mathbf{e}}_\theta = \hat{\mathbf{e}}_\varphi \times \hat{\mathbf{e}}_r = \det\begin{pmatrix} \hat{\mathbf{e}}_\rho & \hat{\mathbf{e}}_\varphi & \hat{\mathbf{e}}_z \\ 0 & 1 & 0 \\ \sin\theta & 0 & \cos\theta \end{pmatrix} = \hat{\mathbf{e}}_\rho \cos\theta - \hat{\mathbf{e}}_z \sin\theta.$$

Thus,

$$\begin{aligned} \hat{\mathbf{e}}_r &= \hat{\mathbf{e}}_\rho \sin\theta + \hat{\mathbf{e}}_z \cos\theta, \\ \hat{\mathbf{e}}_\theta &= \hat{\mathbf{e}}_\rho \cos\theta - \hat{\mathbf{e}}_z \sin\theta, \\ \hat{\mathbf{e}}_\varphi &= \hat{\mathbf{e}}_\varphi. \end{aligned} \tag{1.38}$$

spherical unit vectors in terms of cylindrical unit vectors

The inverse relations can be obtained as before. We leave the details of the calculation as an exercise for the reader.

Combining Equations (1.36) and (1.38), we can express spherical unit vectors in terms of the Cartesian unit vectors:

spherical unit vectors in terms of Cartesian unit vectors

$$\begin{aligned} \hat{\mathbf{e}}_r &= \hat{\mathbf{e}}_x \sin\theta\cos\varphi + \hat{\mathbf{e}}_y \sin\theta\sin\varphi + \hat{\mathbf{e}}_z \cos\theta, \\ \hat{\mathbf{e}}_\theta &= \hat{\mathbf{e}}_x \cos\theta\cos\varphi + \hat{\mathbf{e}}_y \cos\theta\sin\varphi - \hat{\mathbf{e}}_z \sin\theta, \\ \hat{\mathbf{e}}_\varphi &= -\hat{\mathbf{e}}_x \sin\varphi + \hat{\mathbf{e}}_y \cos\varphi. \end{aligned} \tag{1.39}$$

Equations (1.39) and (1.36) are very useful when calculating vector quantities in spherical and cylindrical coordinates as we shall see in many examples to follow. These equations also allow us to express a unit vector in one of the three coordinate systems in terms of the unit vectors of any other coordinate system.

Example 1.4.1. P_1 and P_2 have Cartesian coordinates $(1,1,1)$ and $(-1,2,-1)$, respectively. A vector $\mathbf{a}$ has spherical components $\langle 0,2,0\rangle$ at P_1. We want to find the spherical components of $\mathbf{a}$ at P_2. These are given by $\mathbf{a}\cdot\hat{\mathbf{e}}_{r_2}$, $\mathbf{a}\cdot\hat{\mathbf{e}}_{\theta_2}$, and $\mathbf{a}\cdot\hat{\mathbf{e}}_{\varphi_2}$. In order to calculate these dot products, it is most convenient to express all vectors in Cartesian form. So, using Equation (1.39), we have

$$\mathbf{a} = 2\hat{\mathbf{e}}_{\theta_1} = 2\left(\hat{\mathbf{e}}_x \cos\theta_1\cos\varphi_1 + \hat{\mathbf{e}}_y \cos\theta_1\sin\varphi_1 - \hat{\mathbf{e}}_z \sin\theta_1\right),$$

where (r_1,θ_1,φ_1) are coordinates of P_1. We can calculate these from the Cartesian coordinates of P_1:

$$r_1 = \sqrt{1^2+1^2+1^2} = \sqrt{3}, \quad \cos\theta_1 = \frac{z_1}{r_1} = \frac{1}{\sqrt{3}}, \quad \tan\varphi_1 = \frac{y_1}{x_1} = 1 \;\Rightarrow\; \varphi_1 = \frac{\pi}{4}.$$

---

[17] Recall that $\hat{\mathbf{e}}_\varphi$ is both a cylindrical and a spherical unit vector.

Therefore,

$$\mathbf{a} = 2\left(\hat{\mathbf{e}}_x \frac{1}{\sqrt{3}}\frac{1}{\sqrt{2}} + \hat{\mathbf{e}}_y \frac{1}{\sqrt{3}}\frac{1}{\sqrt{2}} - \hat{\mathbf{e}}_z \sqrt{\frac{2}{3}}\right) = \frac{2}{\sqrt{6}}\hat{\mathbf{e}}_x + \frac{2}{\sqrt{6}}\hat{\mathbf{e}}_y - \frac{4}{\sqrt{6}}\hat{\mathbf{e}}_z.$$

Now we need to express $\hat{\mathbf{e}}_{r_2}$, $\hat{\mathbf{e}}_{\theta_2}$, and $\hat{\mathbf{e}}_{\varphi_2}$ in terms of Cartesian unit vectors. Once again we use Equation (1.39) for which we need the spherical coordinates of P_2:

$$r_2 = \sqrt{(-1)^2 + 2^2 + (-1)^2} = \sqrt{6}, \quad \cos\theta_2 = \frac{z_2}{r_2} = -\frac{1}{\sqrt{6}}, \quad \tan\varphi_2 = \frac{y_2}{x_2} = -2.$$

Similarly, Equations (1.11) and (1.12) yield

$$\sin\theta_2 = +\sqrt{\frac{5}{6}}, \qquad \cos\varphi_2 = -\frac{1}{\sqrt{5}}, \qquad \sin\varphi_2 = +\frac{2}{\sqrt{5}}.$$

Then

$$\begin{aligned}
\hat{\mathbf{e}}_{r_2} &= \hat{\mathbf{e}}_x \sin\theta_2\cos\varphi_2 + \hat{\mathbf{e}}_y \sin\theta_2 \sin\varphi_2 + \hat{\mathbf{e}}_z \cos\theta_2 \\
&= \hat{\mathbf{e}}_x \sqrt{\frac{5}{6}}\left(-\frac{1}{\sqrt{5}}\right) + \hat{\mathbf{e}}_y \sqrt{\frac{5}{6}}\frac{2}{\sqrt{5}} - \hat{\mathbf{e}}_z \frac{1}{\sqrt{6}} \\
&= -\frac{1}{\sqrt{6}}\hat{\mathbf{e}}_x + \frac{2}{\sqrt{6}}\hat{\mathbf{e}}_y - \frac{1}{\sqrt{6}}\hat{\mathbf{e}}_z, \\
\hat{\mathbf{e}}_{\theta_2} &= \hat{\mathbf{e}}_x \cos\theta_2\cos\varphi_2 + \hat{\mathbf{e}}_y \cos\theta_2 \sin\varphi_2 - \hat{\mathbf{e}}_z \sin\theta_2 \\
&= \hat{\mathbf{e}}_x\left(-\frac{1}{\sqrt{6}}\right)\left(-\frac{1}{\sqrt{5}}\right) + \hat{\mathbf{e}}_y\left(-\frac{1}{\sqrt{6}}\right)\frac{2}{\sqrt{5}} - \hat{\mathbf{e}}_z\sqrt{\frac{5}{6}} \\
&= \frac{1}{\sqrt{30}}\hat{\mathbf{e}}_x - \frac{2}{\sqrt{30}}\hat{\mathbf{e}}_y - \frac{5}{\sqrt{30}}\hat{\mathbf{e}}_z, \\
\hat{\mathbf{e}}_{\varphi_2} &= -\hat{\mathbf{e}}_x \sin\varphi_2 + \hat{\mathbf{e}}_y \cos\varphi_2 = -\frac{2}{\sqrt{5}}\hat{\mathbf{e}}_x - \frac{1}{\sqrt{5}}\hat{\mathbf{e}}_y.
\end{aligned}$$

We can now take the dot products required for the components:

$$\begin{aligned}
r \text{ comp} = \mathbf{a}\cdot\hat{\mathbf{e}}_{r_2} &= \left(\frac{2}{\sqrt{6}}\hat{\mathbf{e}}_x + \frac{2}{\sqrt{6}}\hat{\mathbf{e}}_y - \frac{4}{\sqrt{6}}\hat{\mathbf{e}}_z\right)\cdot\left(-\frac{1}{\sqrt{6}}\hat{\mathbf{e}}_x + \frac{2}{\sqrt{6}}\hat{\mathbf{e}}_y - \frac{1}{\sqrt{6}}\hat{\mathbf{e}}_z\right) \\
&= -\frac{2}{6} + \frac{4}{6} + \frac{4}{6} = 1,
\end{aligned}$$

$$\begin{aligned}
\theta \text{ comp} = \mathbf{a}\cdot\hat{\mathbf{e}}_{\theta_2} &= \left(\frac{2}{\sqrt{6}}\hat{\mathbf{e}}_x + \frac{2}{\sqrt{6}}\hat{\mathbf{e}}_y - \frac{4}{\sqrt{6}}\hat{\mathbf{e}}_z\right)\cdot\left(\frac{1}{\sqrt{30}}\hat{\mathbf{e}}_x - \frac{2}{\sqrt{30}}\hat{\mathbf{e}}_y - \frac{5}{\sqrt{30}}\hat{\mathbf{e}}_z\right) \\
&= \frac{2}{6\sqrt{5}} - \frac{4}{6\sqrt{5}} + \frac{20}{6\sqrt{5}} = \frac{3}{\sqrt{5}}, \\
\varphi \text{ comp} = \mathbf{a}\cdot\hat{\mathbf{e}}_{\varphi_2} &= \left(\frac{2}{\sqrt{6}}\hat{\mathbf{e}}_x + \frac{2}{\sqrt{6}}\hat{\mathbf{e}}_y - \frac{4}{\sqrt{6}}\hat{\mathbf{e}}_z\right)\cdot\left(-\frac{2}{\sqrt{5}}\hat{\mathbf{e}}_x - \frac{1}{\sqrt{5}}\hat{\mathbf{e}}_y\right) \\
&= -\frac{4}{\sqrt{30}} - \frac{2}{\sqrt{30}} = -\frac{6}{\sqrt{30}} = -\sqrt{\frac{6}{5}}.
\end{aligned}$$

It now follows that

$$\mathbf{a} = \hat{\mathbf{e}}_{r_2} + \frac{3}{\sqrt{5}}\hat{\mathbf{e}}_{\theta_2} - \sqrt{\frac{6}{5}}\hat{\mathbf{e}}_{\varphi_2}.$$

As a check, we note that

$$|\mathbf{a}| = \sqrt{1^2 + \left(\frac{3}{\sqrt{5}}\right)^2 + \left(-\sqrt{\frac{6}{5}}\right)^2} = \sqrt{\frac{5+9+6}{5}} = \sqrt{4} = 2,$$

which agrees with the length of $\mathbf{a}$. ■

Example 1.4.2. Points P_1 and P_2 have spherical coordinates $(r_1, \theta_1, \varphi_1)$ and $(r_2, \theta_2, \varphi_2)$, respectively. We want to find: (a) the angle between their position vectors $\mathbf{r}_1$ and $\mathbf{r}_2$ in terms of their coordinates; (b) the spherical components of $\mathbf{r}_2$ at P_1; and (c) the spherical components of $\mathbf{r}_1$ at P_2. Once again, we shall express all vectors in terms of Cartesian unit vectors when evaluating dot products.

(a) The cosine of the angle—call it γ_{12}—between the position vectors is simply $\hat{\mathbf{e}}_{r_1} \cdot \hat{\mathbf{e}}_{r_2}$. We can readily find this by using Equation (1.39):

$$\begin{aligned}
\cos\gamma_{12} = \hat{\mathbf{e}}_{r_1} \cdot \hat{\mathbf{e}}_{r_2} &= (\hat{\mathbf{e}}_x \sin\theta_1 \cos\varphi_1 + \hat{\mathbf{e}}_y \sin\theta_1 \sin\varphi_1 + \hat{\mathbf{e}}_z \cos\theta_1) \\
&\quad \cdot (\hat{\mathbf{e}}_x \sin\theta_2 \cos\varphi_2 + \hat{\mathbf{e}}_y \sin\theta_2 \sin\varphi_2 + \hat{\mathbf{e}}_z \cos\theta_2) \\
&= \sin\theta_1 \cos\varphi_1 \sin\theta_2 \cos\varphi_2 + \sin\theta_1 \sin\varphi_1 \sin\theta_2 \sin\varphi_2 + \cos\theta_1 \cos\theta_2 \\
&= \sin\theta_1 \sin\theta_2 (\cos\varphi_1 \cos\varphi_2 + \sin\varphi_1 \sin\varphi_2) + \cos\theta_1 \cos\theta_2 \\
&= \sin\theta_1 \sin\theta_2 \cos(\varphi_1 - \varphi_2) + \cos\theta_1 \cos\theta_2.
\end{aligned}$$

(b) To find the spherical components of $\mathbf{r}_2$ at P_1, we need to take the dot product of $\mathbf{r}_2$ with the spherical unit vectors at P_1:

$$\begin{aligned}
r \text{ comp} &= \mathbf{r}_2 \cdot \hat{\mathbf{e}}_{r_1} = r_2 \hat{\mathbf{e}}_{r_2} \cdot \hat{\mathbf{e}}_{r_1} \\
&= r_2 \left[\sin\theta_1 \sin\theta_2 \cos(\varphi_1 - \varphi_2) + \cos\theta_1 \cos\theta_2\right], \\
\theta \text{ comp} &= \mathbf{r}_2 \cdot \hat{\mathbf{e}}_{\theta_1} = r_2 \hat{\mathbf{e}}_{r_2} \cdot \hat{\mathbf{e}}_{\theta_1} \\
&= r_2 \left(\hat{\mathbf{e}}_x \sin\theta_2 \cos\varphi_2 + \hat{\mathbf{e}}_y \sin\theta_2 \sin\varphi_2 + \hat{\mathbf{e}}_z \cos\theta_2\right) \\
&\quad \cdot \left(\hat{\mathbf{e}}_x \cos\theta_1 \cos\varphi_1 + \hat{\mathbf{e}}_y \cos\theta_1 \sin\varphi_1 - \hat{\mathbf{e}}_z \sin\theta_1\right) \\
&= r_2 (\sin\theta_2 \cos\varphi_2 \cos\theta_1 \cos\varphi_1 + \sin\theta_2 \sin\varphi_2 \cos\theta_1 \sin\varphi_1 - \cos\theta_2 \sin\theta_1) \\
&= r_2 [\sin\theta_2 \cos\theta_1 \cos(\varphi_1 - \varphi_2) - \cos\theta_2 \sin\theta_1], \\
\varphi \text{ comp} &= \mathbf{r}_2 \cdot \hat{\mathbf{e}}_{\varphi_1} = r_2 \hat{\mathbf{e}}_{r_2} \cdot \hat{\mathbf{e}}_{\varphi_1} \\
&= r_2 \left(\hat{\mathbf{e}}_x \sin\theta_2 \cos\varphi_2 + \hat{\mathbf{e}}_y \sin\theta_2 \sin\varphi_2 + \hat{\mathbf{e}}_z \cos\theta_2\right) \cdot \left(-\hat{\mathbf{e}}_x \sin\varphi_1 + \hat{\mathbf{e}}_y \cos\varphi_1\right) \\
&= r_2 \left(-\sin\theta_2 \cos\varphi_2 \sin\varphi_1 + \sin\theta_2 \sin\varphi_2 \cos\varphi_1\right) = r_2 \sin\theta_2 \sin(\varphi_2 - \varphi_1).
\end{aligned}$$

(c) The spherical components of $\mathbf{r}_1$ at P_2 can be found similarly. In fact, switching the indices "1" and "2" in the expressions of part (b) gives the desired formulas. ■

Example 1.4.3. To illustrate further the conversion of vectors from one coordinate system to another, consider a charge q that is located at the *cylindrical* coordinates $(a, \pi/3, -a)$. We want to find the *spherical* components of the electrostatic field $\mathbf{E}$ of this charge at a point P with *Cartesian* coordinates (a, a, a).

The most straightforward way of doing this is to convert all coordinates to Cartesian, find the field, and then take the dot products with appropriate unit vectors. The Cartesian coordinates of the charge are

$$\begin{aligned}
x_q &= \rho_q \cos\varphi_q = a \cos\left(\frac{\pi}{3}\right) = \tfrac{1}{2}a, \\
y_q &= \rho_q \sin\varphi_q = a \sin\left(\frac{\pi}{3}\right) = \frac{\sqrt{3}a}{2} = 0.866a, \\
z_q &= -a.
\end{aligned}$$

Thus,

$$\mathbf{r}-\mathbf{r}_q=(a-\tfrac{1}{2}a)\hat{\mathbf{e}}_x+(a-0.866a)\hat{\mathbf{e}}_y+(a-(-a))\hat{\mathbf{e}}_z=0.5a\hat{\mathbf{e}}_x+0.134a\hat{\mathbf{e}}_y+2a\hat{\mathbf{e}}_z$$

and

$$|\mathbf{r}-\mathbf{r}_q|=\sqrt{(0.5a)^2+(0.134a)^2+(2a)^2}=2.066a,$$

and the electric field at P can be written in terms of Cartesian unit vectors at P:

$$\begin{aligned}\mathbf{E}&=\frac{k_eq}{|\mathbf{r}-\mathbf{r}_q|^3}(\mathbf{r}-\mathbf{r}_q)=k_eq\frac{0.5a\hat{\mathbf{e}}_x+0.134a\hat{\mathbf{e}}_y+2a\hat{\mathbf{e}}_z}{(2.066a)^3}\\&=k_eq\frac{0.5\hat{\mathbf{e}}_x+0.134\hat{\mathbf{e}}_y+2\hat{\mathbf{e}}_z}{8.818a^2}=\frac{k_eq}{a^2}(0.0567\hat{\mathbf{e}}_x+0.0152\hat{\mathbf{e}}_y+0.2268\hat{\mathbf{e}}_z).\end{aligned}$$

To find the *spherical* components of the field at P, we first express the spherical unit vectors at P in terms of Cartesian unit vectors. For this, we need the spherical coordinates of P:

$$\begin{aligned}r&=\sqrt{a^2+a^2+a^2}=\sqrt{3}\,a=1.732a,\\\cos\theta&=\frac{z}{r}=\frac{a}{\sqrt{3}\,a}=\frac{1}{\sqrt{3}}=0.577\ \Rightarrow\ \theta=0.955,\\\tan\varphi&=\frac{y}{x}=\frac{a}{a}=1\ \Rightarrow\ \varphi=\frac{\pi}{4}=0.785.\end{aligned}$$

It now follows that

$$\begin{aligned}\hat{\mathbf{e}}_r&=\hat{\mathbf{e}}_x\sin\theta\cos\varphi+\hat{\mathbf{e}}_y\sin\theta\sin\varphi+\hat{\mathbf{e}}_z\cos\theta=0.577\hat{\mathbf{e}}_x+0.577\hat{\mathbf{e}}_y+0.577\hat{\mathbf{e}}_z,\\\hat{\mathbf{e}}_\theta&=\hat{\mathbf{e}}_x\cos\theta\cos\varphi+\hat{\mathbf{e}}_y\cos\theta\sin\varphi-\hat{\mathbf{e}}_z\sin\theta=0.408\hat{\mathbf{e}}_x+0.408\hat{\mathbf{e}}_y-0.816\hat{\mathbf{e}}_z,\\\hat{\mathbf{e}}_\varphi&=-\hat{\mathbf{e}}_x\sin\varphi+\hat{\mathbf{e}}_y\cos\varphi=-0.707\hat{\mathbf{e}}_x+0.707\hat{\mathbf{e}}_y.\end{aligned}$$

Now we take the dot product of $\mathbf{E}$ with these unit vectors to find its spherical components at P. The reader may first easily check that

$$\begin{aligned}&\hat{\mathbf{e}}_r\cdot\hat{\mathbf{e}}_x=0.577, &&\hat{\mathbf{e}}_r\cdot\hat{\mathbf{e}}_y=0.577, &&\hat{\mathbf{e}}_r\cdot\hat{\mathbf{e}}_z=0.577,\\&\hat{\mathbf{e}}_\theta\cdot\hat{\mathbf{e}}_x=0.408, &&\hat{\mathbf{e}}_\theta\cdot\hat{\mathbf{e}}_y=0.408, &&\hat{\mathbf{e}}_\theta\cdot\hat{\mathbf{e}}_z=-0.816,\\&\hat{\mathbf{e}}_\varphi\cdot\hat{\mathbf{e}}_x=-0.707, &&\hat{\mathbf{e}}_\varphi\cdot\hat{\mathbf{e}}_y=0.707, &&\hat{\mathbf{e}}_\varphi\cdot\hat{\mathbf{e}}_z=0.\end{aligned}$$

We can now finally calculate the field components:

$$\begin{aligned}E_r&=\mathbf{E}\cdot\hat{\mathbf{e}}_r=\frac{k_eq}{a^2}(0.0567\hat{\mathbf{e}}_r\cdot\hat{\mathbf{e}}_x+0.0152\hat{\mathbf{e}}_r\cdot\hat{\mathbf{e}}_y+0.2268\hat{\mathbf{e}}_r\cdot\hat{\mathbf{e}}_z)\\&=\frac{k_eq}{a^2}(0.0567\times0.577+0.0152\times0.577+0.2268\times0.577)=0.1724\frac{k_eq}{a^2},\\E_\theta&=\mathbf{E}\cdot\hat{\mathbf{e}}_\theta=\frac{k_eq}{a^2}(0.0567\hat{\mathbf{e}}_\theta\cdot\hat{\mathbf{e}}_x+0.0152\hat{\mathbf{e}}_\theta\cdot\hat{\mathbf{e}}_y+0.2268\hat{\mathbf{e}}_\theta\cdot\hat{\mathbf{e}}_z)\\&=\frac{k_eq}{a^2}(0.0567\times0.408+0.0152\times0.408-0.2268\times0.816)=-0.1558\frac{k_eq}{a^2},\\E_\varphi&=\mathbf{E}\cdot\hat{\mathbf{e}}_\varphi=\frac{k_eq}{a^2}(0.0567\hat{\mathbf{e}}_\varphi\cdot\hat{\mathbf{e}}_x+0.0152\hat{\mathbf{e}}_\varphi\cdot\hat{\mathbf{e}}_y+0.2268\hat{\mathbf{e}}_\varphi\cdot\hat{\mathbf{e}}_z)\\&=\frac{k_eq}{a^2}(-0.0567\times0.707+0.0152\times0.707)=-0.0294\frac{k_eq}{a^2}.\end{aligned}$$

The choice of Cartesian coordinates was the most straightforward one, but one can choose any other coordinate system to calculate the field and find the components in any other set of unit vectors. The reader is urged to try the other choices. ■

3

Complex numbers and hyperbolic functions

This chapter is concerned with the representation and manipulation of complex numbers. Complex numbers pervade this book, underscoring their wide application in the mathematics of the physical sciences. The application of complex numbers to the description of physical systems is left until later chapters and only the basic tools are presented here.

3.1 The need for complex numbers

Although complex numbers occur in many branches of mathematics, they arise most directly out of solving polynomial equations. We examine a specific quadratic equation as an example.

Consider the quadratic equation

$$z^2 - 4z + 5 = 0. \tag{3.1}$$

Equation (3.1) has two solutions, z_1 and z_2, such that

$$(z - z_1)(z - z_2) = 0. \tag{3.2}$$

Using the familiar formula for the roots of a quadratic equation, (1.4), the solutions z_1 and z_2, written in brief as $z_{1,2}$, are

$$\begin{aligned} z_{1,2} &= \frac{4 \pm \sqrt{(-4)^2 - 4(1 \times 5)}}{2} \\ &= 2 \pm \frac{\sqrt{-4}}{2}. \end{aligned} \tag{3.3}$$

Both solutions contain the square root of a negative number. However, it is not true to say that there are no solutions to the quadratic equation. The *fundamental theorem of algebra* states that a quadratic equation will always have two solutions and these are in fact given by (3.3). The second term on the RHS of (3.3) is called an *imaginary* term since it contains the square root of a negative number;

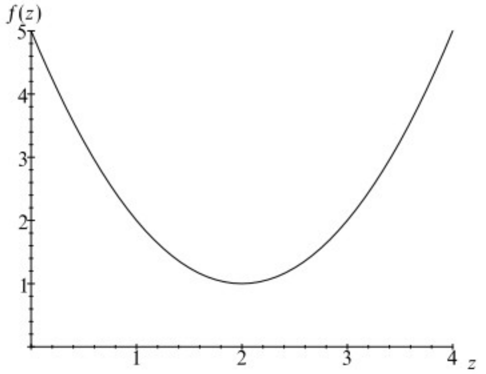

Figure 3.1 The function $f(z) = z^2 - 4z + 5$.

the first term is called a *real* term. The full solution is the sum of a real term and an imaginary term and is called a *complex number*. A plot of the function $f(z) = z^2 - 4z + 5$ is shown in figure 3.1. It will be seen that the plot does not intersect the z-axis, corresponding to the fact that the equation $f(z) = 0$ has no purely real solutions.

The choice of the symbol z for the quadratic variable was not arbitrary; the conventional representation of a complex number is z, where z is the sum of a real part x and i times an imaginary part y, i.e.

$$z = x + iy,$$

where i is used to denote the square root of -1. The real part x and the imaginary part y are usually denoted by $\operatorname{Re} z$ and $\operatorname{Im} z$ respectively. We note at this point that some physical scientists, engineers in particular, use j instead of i. However, for consistency, we will use i throughout this book.

In our particular example, $\sqrt{-4} = 2\sqrt{-1} = 2i$, and hence the two solutions of (3.1) are

$$z_{1,2} = 2 \pm \frac{2i}{2} = 2 \pm i.$$

Thus, here $x = 2$ and $y = \pm 1$.

For compactness a complex number is sometimes written in the form

$$z = (x, y),$$

where the components of z may be thought of as coordinates in an xy-plot. Such a plot is called an *Argand diagram* and is a common representation of complex numbers; an example is shown in figure 3.2.

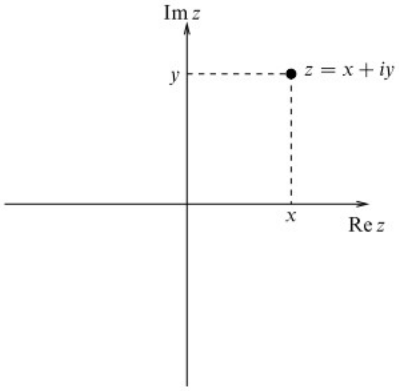

Figure 3.2 The Argand diagram.

Our particular example of a quadratic equation may be generalised readily to polynomials whose highest power (degree) is greater than 2, e.g. cubic equations (degree 3), quartic equations (degree 4) and so on. For a general polynomial $f(z)$, of degree n, the fundamental theorem of algebra states that the equation $f(z) = 0$ will have exactly n solutions. We will examine cases of higher-degree equations in subsection 3.4.3.

The remainder of this chapter deals with: the algebra and manipulation of complex numbers; their polar representation, which has advantages in many circumstances; complex exponentials and logarithms; the use of complex numbers in finding the roots of polynomial equations; and hyperbolic functions.

3.2 Manipulation of complex numbers

This section considers basic complex number manipulation. Some analogy may be drawn with vector manipulation (see chapter 7) but this section stands alone as an introduction.

3.2.1 Addition and subtraction

The addition of two complex numbers, z_1 and z_2, in general gives another complex number. The real components and the imaginary components are added separately and in a like manner to the familiar addition of real numbers:

$$z_1 + z_2 = (x_1 + iy_1) + (x_2 + iy_2) = (x_1 + x_2) + i(y_1 + y_2),$$

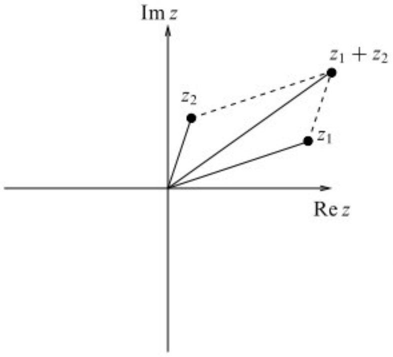

Figure 3.3 The addition of two complex numbers.

or in component notation

$$z_1 + z_2 = (x_1, y_1) + (x_2, y_2) = (x_1 + x_2, y_1 + y_2).$$

The Argand representation of the addition of two complex numbers is shown in figure 3.3.

By straightforward application of the commutativity and associativity of the real and imaginary parts separately, we can show that the addition of complex numbers is itself commutative and associative, i.e.

$$z_1 + z_2 = z_2 + z_1,$$
$$z_1 + (z_2 + z_3) = (z_1 + z_2) + z_3.$$

Thus it is immaterial in what order complex numbers are added.

►*Sum the complex numbers* $1 + 2i$, $3 - 4i$, $-2 + i$.

Summing the real terms we obtain

$$1 + 3 - 2 = 2,$$

and summing the imaginary terms we obtain

$$2i - 4i + i = -i.$$

Hence

$$(1 + 2i) + (3 - 4i) + (-2 + i) = 2 - i. \blacktriangleleft$$

The subtraction of complex numbers is very similar to their addition. As in the case of real numbers, if two identical complex numbers are subtracted then the result is zero.

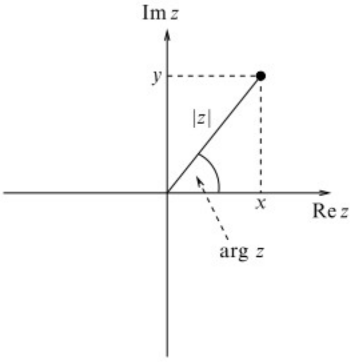

Figure 3.4 The modulus and argument of a complex number.

3.2.2 Modulus and argument

The modulus of the complex number z is denoted by $|z|$ and is defined as

$$|z| = \sqrt{x^2 + y^2}. \tag{3.4}$$

Hence the modulus of the complex number is the distance of the corresponding point from the origin in the Argand diagram, as may be seen in figure 3.4.

The argument of the complex number z is denoted by $\arg z$ and is defined as

$$\arg z = \tan^{-1}\left(\frac{y}{x}\right). \tag{3.5}$$

It can be seen that $\arg z$ is the angle that the line joining the origin to z on the Argand diagram makes with the positive x-axis. The anticlockwise direction is taken to be positive by convention. The angle $\arg z$ is shown in figure 3.4. Account must be taken of the signs of x and y individually in determining in which quadrant $\arg z$ lies. Thus, for example, if x and y are both negative then $\arg z$ lies in the range $-\pi < \arg z < -\pi/2$ rather than in the first quadrant ($0 < \arg z < \pi/2$), though both cases give the same value for the ratio of y to x.

►*Find the modulus and the argument of the complex number $z = 2 - 3i$.*

Using (3.4), the modulus is given by

$$|z| = \sqrt{2^2 + (-3)^2} = \sqrt{13}.$$

Using (3.5), the argument is given by

$$\arg z = \tan^{-1}\left(-\tfrac{3}{2}\right).$$

The two angles whose tangents equal -1.5 are -0.9828 rad and 2.1588 rad. Since $x = 2$ and $y = -3$, z clearly lies in the fourth quadrant; therefore $\arg z = -0.9828$ is the appropriate answer. ◄

3.2.3 Multiplication

Complex numbers may be multiplied together and in general give a complex number as the result. The product of two complex numbers z_1 and z_2 is found by multiplying them out in full and remembering that $i^2 = -1$, i.e.

$$\begin{aligned} z_1 z_2 &= (x_1 + iy_1)(x_2 + iy_2) \\ &= x_1 x_2 + i x_1 y_2 + i y_1 x_2 + i^2 y_1 y_2 \\ &= (x_1 x_2 - y_1 y_2) + i(x_1 y_2 + y_1 x_2). \end{aligned} \tag{3.6}$$

►*Multiply the complex numbers* $z_1 = 3 + 2i$ *and* $z_2 = -1 - 4i$.

By direct multiplication we find

$$\begin{aligned} z_1 z_2 &= (3 + 2i)(-1 - 4i) \\ &= -3 - 2i - 12i - 8i^2 \\ &= 5 - 14i. \blacktriangleleft \end{aligned} \tag{3.7}$$

The multiplication of complex numbers is both commutative and associative, i.e.

$$z_1 z_2 = z_2 z_1, \tag{3.8}$$

$$(z_1 z_2) z_3 = z_1 (z_2 z_3). \tag{3.9}$$

The product of two complex numbers also has the simple properties

$$|z_1 z_2| = |z_1||z_2|, \tag{3.10}$$

$$\arg(z_1 z_2) = \arg z_1 + \arg z_2. \tag{3.11}$$

These relations are derived in subsection 3.3.1.

►*Verify that (3.10) holds for the product of* $z_1 = 3 + 2i$ *and* $z_2 = -1 - 4i$.

From (3.7)

$$|z_1 z_2| = |5 - 14i| = \sqrt{5^2 + (-14)^2} = \sqrt{221}.$$

We also find

$$\begin{aligned} |z_1| &= \sqrt{3^2 + 2^2} = \sqrt{13}, \\ |z_2| &= \sqrt{(-1)^2 + (-4)^2} = \sqrt{17}, \end{aligned}$$

and hence

$$|z_1||z_2| = \sqrt{13}\sqrt{17} = \sqrt{221} = |z_1 z_2|. \blacktriangleleft$$

We now examine the effect on a complex number z of multiplying it by ± 1 and $\pm i$. These four multipliers have modulus unity and we can see immediately from (3.10) that multiplying z by another complex number of unit modulus gives a product with the same modulus as z. We can also see from (3.11) that if we

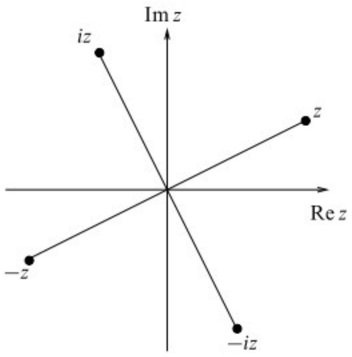

Figure 3.5 Multiplication of a complex number by ± 1 and $\pm i$.

multiply z by a complex number then the argument of the product is the sum of the argument of z and the argument of the multiplier. Hence multiplying z by unity (which has argument zero) leaves z unchanged in both modulus and argument, i.e. z is completely unaltered by the operation. Multiplying by -1 (which has argument π) leads to rotation, through an angle π, of the line joining the origin to z in the Argand diagram. Similarly, multiplication by i or $-i$ leads to corresponding rotations of $\pi/2$ or $-\pi/2$ respectively. This geometrical interpretation of multiplication is shown in figure 3.5.

►*Using the geometrical interpretation of multiplication by i, find the product* $i(1-i)$.

The complex number $1-i$ has argument $-\pi/4$ and modulus $\sqrt{2}$. Thus, using (3.10) and (3.11), its product with i has argument $+\pi/4$ and unchanged modulus $\sqrt{2}$. The complex number with modulus $\sqrt{2}$ and argument $+\pi/4$ is $1+i$ and so

$$i(1-i) = 1+i,$$

as is easily verified by direct multiplication. ◄

The division of two complex numbers is similar to their multiplication but requires the notion of the complex conjugate (see the following subsection) and so discussion is postponed until subsection 3.2.5.

3.2.4 Complex conjugate

If z has the convenient form $x+iy$ then the complex conjugate, denoted by z^*, may be found simply by changing the sign of the imaginary part, i.e. if $z = x+iy$ then $z^* = x - iy$. More generally, we may define the complex conjugate of z as the (complex) number having the same magnitude as z that when multiplied by z leaves a real result, i.e. there is no imaginary component in the product.

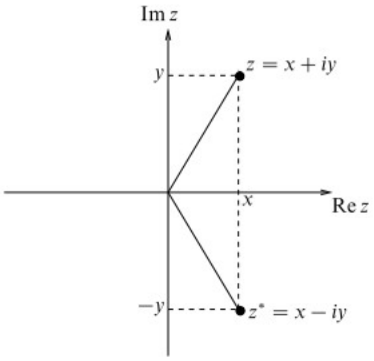

Figure 3.6 The complex conjugate as a mirror image in the real axis.

In the case where z can be written in the form $x + iy$ it is easily verified, by direct multiplication of the components, that the product zz^* gives a real result:

$$zz^* = (x + iy)(x - iy) = x^2 - ixy + ixy - i^2y^2 = x^2 + y^2 = |z|^2.$$

Complex conjugation corresponds to a reflection of z in the real axis of the Argand diagram, as may be seen in figure 3.6.

►*Find the complex conjugate of* $z = a + 2i + 3ib$.

The complex number is written in the standard form

$$z = a + i(2 + 3b);$$

then, replacing i by $-i$, we obtain

$$z^* = a - i(2 + 3b). ◄$$

In some cases, however, it may not be simple to rearrange the expression for z into the standard form $x + iy$. Nevertheless, given two complex numbers, z_1 and z_2, it is straightforward to show that the complex conjugate of their sum (or difference) is equal to the sum (or difference) of their complex conjugates, i.e. $(z_1 \pm z_2)^* = z_1^* \pm z_2^*$. Similarly, it may be shown that the complex conjugate of the product (or quotient) of z_1 and z_2 is equal to the product (or quotient) of their complex conjugates, i.e. $(z_1z_2)^* = z_1^*z_2^*$ and $(z_1/z_2)^* = z_1^*/z_2^*$.

Using these results, it can be deduced that, no matter how complicated the expression, its complex conjugate may *always* be found by replacing every i by $-i$. To apply this rule, however, we must always ensure that all complex parts are first written out in full, so that no i's are hidden.

►*Find the complex conjugate of the complex number $z = w^{(3y+2ix)}$, where $w = x + 5i$.*

Although we do not discuss complex powers until section 3.5, the simple rule given above still enables us to find the complex conjugate of z.

In this case w itself contains real and imaginary components and so must be written out in full, i.e.

$$z = w^{3y+2ix} = (x + 5i)^{3y+2ix}.$$

Now we can replace each i by $-i$ to obtain

$$z^* = (x - 5i)^{(3y-2ix)}.$$

It can be shown that the product zz^* is real, as required. ◄

The following properties of the complex conjugate are easily proved and others may be derived from them. If $z = x + iy$ then

$$(z^*)^* = z, \tag{3.12}$$

$$z + z^* = 2\,\mathrm{Re}\,z = 2x, \tag{3.13}$$

$$z - z^* = 2i\,\mathrm{Im}\,z = 2iy, \tag{3.14}$$

$$\frac{z}{z^*} = \left(\frac{x^2 - y^2}{x^2 + y^2}\right) + i\left(\frac{2xy}{x^2 + y^2}\right). \tag{3.15}$$

The derivation of this last relation relies on the results of the following subsection.

3.2.5 Division

The division of two complex numbers z_1 and z_2 bears some similarity to their multiplication. Writing the quotient in component form we obtain

$$\frac{z_1}{z_2} = \frac{x_1 + iy_1}{x_2 + iy_2}. \tag{3.16}$$

In order to separate the real and imaginary components of the quotient, we multiply both numerator and denominator by the complex conjugate of the denominator. By definition, this process will leave the denominator as a real quantity. Equation (3.16) gives

$$\begin{aligned}\frac{z_1}{z_2} &= \frac{(x_1 + iy_1)(x_2 - iy_2)}{(x_2 + iy_2)(x_2 - iy_2)} = \frac{(x_1x_2 + y_1y_2) + i(x_2y_1 - x_1y_2)}{x_2^2 + y_2^2}\\ &= \frac{x_1x_2 + y_1y_2}{x_2^2 + y_2^2} + i\frac{x_2y_1 - x_1y_2}{x_2^2 + y_2^2}.\end{aligned}$$

Hence we have separated the quotient into real and imaginary components, as required.

In the special case where $z_2 = z_1^*$, so that $x_2 = x_1$ and $y_2 = -y_1$, the general result reduces to (3.15).

►*Express z in the form $x + iy$, when*

$$z = \frac{3 - 2i}{-1 + 4i}.$$

Multiplying numerator and denominator by the complex conjugate of the denominator we obtain

$$\begin{aligned} z &= \frac{(3-2i)(-1-4i)}{(-1+4i)(-1-4i)} = \frac{-11-10i}{17} \\ &= -\frac{11}{17} - \frac{10}{17}i. \blacktriangleleft \end{aligned}$$

In analogy to (3.10) and (3.11), which describe the multiplication of two complex numbers, the following relations apply to division:

$$\left|\frac{z_1}{z_2}\right| = \frac{|z_1|}{|z_2|}, \tag{3.17}$$

$$\arg\left(\frac{z_1}{z_2}\right) = \arg z_1 - \arg z_2. \tag{3.18}$$

The proof of these relations is left until subsection 3.3.1.

3.3 Polar representation of complex numbers

Although considering a complex number as the sum of a real and an imaginary part is often useful, sometimes the *polar representation* proves easier to manipulate. This makes use of the complex exponential function, which is defined by

$$e^z = \exp z \equiv 1 + z + \frac{z^2}{2!} + \frac{z^3}{3!} + \cdots. \tag{3.19}$$

Strictly speaking it is the function $\exp z$ that is defined by (3.19). The number e is the value of $\exp(1)$, i.e. it is just a number. However, it may be shown that e^z and $\exp z$ are equivalent when z is real and rational and mathematicians then *define* their equivalence for irrational and complex z. For the purposes of this book we will not concern ourselves further with this mathematical nicety but, rather, assume that (3.19) is valid for all z. We also note that, using (3.19), by multiplying together the appropriate series we may show that (see chapter 24)

$$e^{z_1} e^{z_2} = e^{z_1 + z_2}, \tag{3.20}$$

which is analogous to the familiar result for exponentials of real numbers.

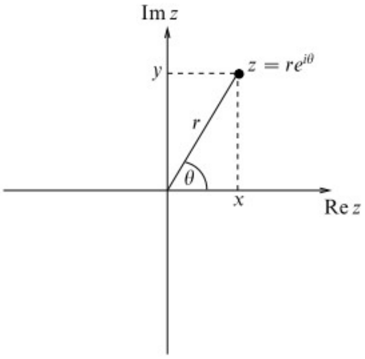

Figure 3.7 The polar representation of a complex number.

From (3.19), it immediately follows that for $z = i\theta$, θ real,

$$e^{i\theta} = 1 + i\theta - \frac{\theta^2}{2!} - \frac{i\theta^3}{3!} + \cdots \tag{3.21}$$

$$= 1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \cdots + i\left(\theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \cdots\right) \tag{3.22}$$

and hence that

$$e^{i\theta} = \cos\theta + i\sin\theta, \tag{3.23}$$

where the last equality follows from the series expansions of the sine and cosine functions (see subsection 4.6.3). This last relationship is called *Euler's equation.* It also follows from (3.23) that

$$e^{in\theta} = \cos n\theta + i\sin n\theta$$

for all n. From Euler's equation (3.23) and figure 3.7 we deduce that

$$\begin{aligned} re^{i\theta} &= r(\cos\theta + i\sin\theta) \\ &= x + iy. \end{aligned}$$

Thus a complex number may be represented in the polar form

$$z = re^{i\theta}. \tag{3.24}$$

Referring again to figure 3.7, we can identify r with $|z|$ and θ with $\arg z$. The simplicity of the representation of the modulus and argument is one of the main reasons for using the polar representation. The angle θ lies conventionally in the range $-\pi < \theta \le \pi$, but, since rotation by θ is the same as rotation by $2n\pi + \theta$, where n is any integer,

$$re^{i\theta} \equiv re^{i(\theta+2n\pi)}.$$

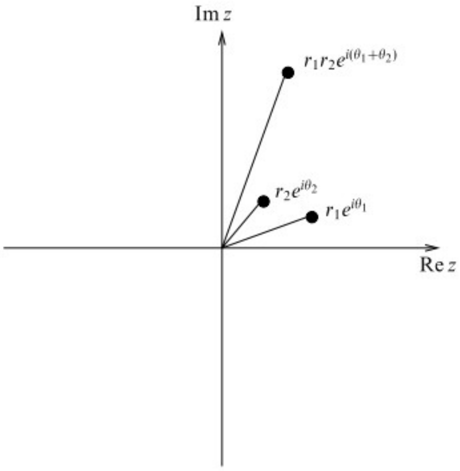

Figure 3.8 The multiplication of two complex numbers. In this case r_1 and r_2 are both greater than unity.

The algebra of the polar representation is different from that of the real and imaginary component representation, though, of course, the results are identical. Some operations prove much easier in the polar representation, others much more complicated. The best representation for a particular problem must be determined by the manipulation required.

3.3.1 Multiplication and division in polar form

Multiplication and division in polar form are particularly simple. The product of $z_1 = r_1 e^{i\theta_1}$ and $z_2 = r_2 e^{i\theta_2}$ is given by

$$\begin{aligned} z_1 z_2 &= r_1 e^{i\theta_1} r_2 e^{i\theta_2} \\ &= r_1 r_2 e^{i(\theta_1+\theta_2)}. \end{aligned} \tag{3.25}$$

The relations $|z_1 z_2| = |z_1||z_2|$ and $\arg(z_1 z_2) = \arg z_1 + \arg z_2$ follow immediately. An example of the multiplication of two complex numbers is shown in figure 3.8.

Division is equally simple in polar form; the quotient of z_1 and z_2 is given by

$$\frac{z_1}{z_2} = \frac{r_1 e^{i\theta_1}}{r_2 e^{i\theta_2}} = \frac{r_1}{r_2} e^{i(\theta_1-\theta_2)}. \tag{3.26}$$

The relations $|z_1/z_2| = |z_1|/|z_2|$ and $\arg(z_1/z_2) = \arg z_1 - \arg z_2$ are again

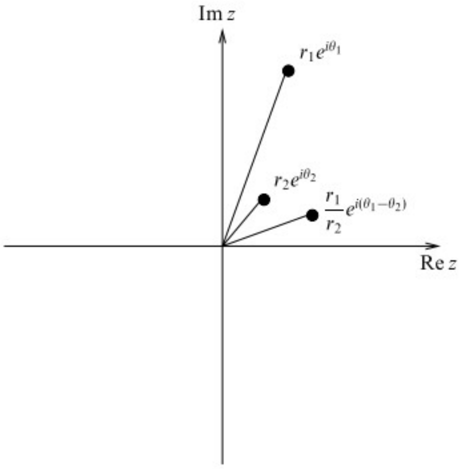

Figure 3.9 The division of two complex numbers. As in the previous figure, r_1 and r_2 are both greater than unity.

immediately apparent. The division of two complex numbers in polar form is shown in figure 3.9.

3.4 de Moivre's theorem

We now derive an extremely important theorem. Since $\left(e^{i\theta}\right)^n = e^{in\theta}$, we have

$$(\cos\theta + i\sin\theta)^n = \cos n\theta + i\sin n\theta, \tag{3.27}$$

where the identity $e^{in\theta} = \cos n\theta + i\sin n\theta$ follows from the series definition of $e^{in\theta}$ (see (3.21)). This result is called *de Moivre's theorem* and is often used in the manipulation of complex numbers. The theorem is valid for all n whether real, imaginary or complex.

There are numerous applications of de Moivre's theorem but this section examines just three: proofs of trigonometric identities; finding the nth roots of unity; and solving polynomial equations with complex roots.

3.4.1 Trigonometric identities

The use of de Moivre's theorem in finding trigonometric identities is best illustrated by example. We consider the expression of a multiple-angle function in terms of a polynomial in the single-angle function, and its converse.

►*Express* $\sin 3\theta$ *and* $\cos 3\theta$ *in terms of powers of* $\cos\theta$ *and* $\sin\theta$.

Using de Moivre's theorem,

$$\begin{aligned}\cos 3\theta + i\sin 3\theta &= (\cos\theta + i\sin\theta)^3\\ &= (\cos^3\theta - 3\cos\theta\sin^2\theta) + i(3\sin\theta\cos^2\theta - \sin^3\theta).\end{aligned} \tag{3.28}$$

We can equate the real and imaginary coefficients separately, i.e.

$$\begin{aligned}\cos 3\theta &= \cos^3\theta - 3\cos\theta\sin^2\theta\\ &= 4\cos^3\theta - 3\cos\theta\end{aligned} \tag{3.29}$$

and

$$\begin{aligned}\sin 3\theta &= 3\sin\theta\cos^2\theta - \sin^3\theta\\ &= 3\sin\theta - 4\sin^3\theta. \blacktriangleleft\end{aligned}$$

This method can clearly be applied to finding power expansions of $\cos n\theta$ and $\sin n\theta$ for any positive integer n.

The converse process uses the following properties of $z = e^{i\theta}$,

$$z^n + \frac{1}{z^n} = 2\cos n\theta, \tag{3.30}$$

$$z^n - \frac{1}{z^n} = 2i\sin n\theta. \tag{3.31}$$

These equalities follow from simple applications of de Moivre's theorem, i.e.

$$\begin{aligned}z^n + \frac{1}{z^n} &= (\cos\theta + i\sin\theta)^n + (\cos\theta + i\sin\theta)^{-n}\\ &= \cos n\theta + i\sin n\theta + \cos(-n\theta) + i\sin(-n\theta)\\ &= \cos n\theta + i\sin n\theta + \cos n\theta - i\sin n\theta\\ &= 2\cos n\theta\end{aligned}$$

and

$$\begin{aligned}z^n - \frac{1}{z^n} &= (\cos\theta + i\sin\theta)^n - (\cos\theta + i\sin\theta)^{-n}\\ &= \cos n\theta + i\sin n\theta - \cos n\theta + i\sin n\theta\\ &= 2i\sin n\theta.\end{aligned}$$

In the particular case where $n = 1$,

$$z + \frac{1}{z} = e^{i\theta} + e^{-i\theta} = 2\cos\theta, \tag{3.32}$$

$$z - \frac{1}{z} = e^{i\theta} - e^{-i\theta} = 2i\sin\theta. \tag{3.33}$$

►*Find an expression for* $\cos^3\theta$ *in terms of* $\cos 3\theta$ *and* $\cos\theta$.

Using (3.32),

$$\begin{aligned}\cos^3\theta &= \frac{1}{2^3}\left(z+\frac{1}{z}\right)^3\\ &= \frac{1}{8}\left(z^3+3z+\frac{3}{z}+\frac{1}{z^3}\right)\\ &= \frac{1}{8}\left(z^3+\frac{1}{z^3}\right)+\frac{3}{8}\left(z+\frac{1}{z}\right).\end{aligned}$$

Now using (3.30) and (3.32), we find

$$\cos^3\theta = \tfrac{1}{4}\cos 3\theta + \tfrac{3}{4}\cos\theta. \blacktriangleleft$$

This result happens to be a simple rearrangement of (3.29), but cases involving larger values of n are better handled using this direct method than by rearranging polynomial expansions of multiple-angle functions.

3.4.2 Finding the nth roots of unity

The equation $z^2 = 1$ has the familiar solutions $z = \pm 1$. However, now that we have introduced the concept of complex numbers we can solve the general equation $z^n = 1$. Recalling the fundamental theorem of algebra, we know that the equation has n solutions. In order to proceed we rewrite the equation as

$$z^n = e^{2ik\pi},$$

where k is any integer. Now taking the nth root of each side of the equation we find

$$z = e^{2ik\pi/n}.$$

Hence, the solutions of $z^n = 1$ are

$$z_{1,2,\ldots,n} = 1,\ \ e^{2i\pi/n},\ \ \ldots,\ \ e^{2i(n-1)\pi/n},$$

corresponding to the values $0, 1, 2, \ldots, n-1$ for k. Larger integer values of k do not give new solutions, since the roots already listed are simply cyclically repeated for $k = n, n+1, n+2$, etc.

►*Find the solutions to the equation* $z^3 = 1$.

By applying the above method we find

$$z = e^{2ik\pi/3}.$$

Hence the three solutions are $z_1 = e^{0i} = 1$, $z_2 = e^{2i\pi/3}$, $z_3 = e^{4i\pi/3}$. We note that, as expected, the next solution, for which $k = 3$, gives $z_4 = e^{6i\pi/3} = 1 = z_1$, so that there are only three separate solutions. ◄

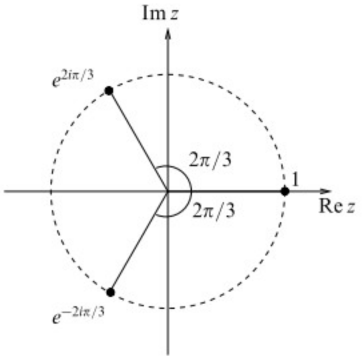

Figure 3.10 The solutions of $z^3 = 1$.

Not surprisingly, given that $|z^3| = |z|^3$ from (3.10), all the roots of unity have unit modulus, i.e. they all lie on a circle in the Argand diagram of unit radius. The three roots are shown in figure 3.10.

The cube roots of unity are often written 1, ω and ω^2. The properties $\omega^3 = 1$ and $1 + \omega + \omega^2 = 0$ are easily proved.

3.4.3 Solving polynomial equations

A third application of de Moivre's theorem is to the solution of polynomial equations. Complex equations in the form of a polynomial relationship must first be solved for z in a similar fashion to the method for finding the roots of real polynomial equations. Then the complex roots of z may be found.

►*Solve the equation* $z^6 - z^5 + 4z^4 - 6z^3 + 2z^2 - 8z + 8 = 0$.

We first factorise to give

$$(z^3 - 2)(z^2 + 4)(z - 1) = 0.$$

Hence $z^3 = 2$ or $z^2 = -4$ or $z = 1$. The solutions to the quadratic equation are $z = \pm 2i$; to find the complex cube roots, we first write the equation in the form

$$z^3 = 2 = 2e^{2ik\pi},$$

where k is any integer. If we now take the cube root, we get

$$z = 2^{1/3}e^{2ik\pi/3}.$$

To avoid the duplication of solutions, we use the fact that $-\pi < \arg z \leq \pi$ and find

$$
\begin{aligned}
z_1 &= 2^{1/3}, \\
z_2 &= 2^{1/3}e^{2\pi i/3} = 2^{1/3}\left(-\frac{1}{2} + \frac{\sqrt{3}}{2}i\right), \\
z_3 &= 2^{1/3}e^{-2\pi i/3} = 2^{1/3}\left(-\frac{1}{2} - \frac{\sqrt{3}}{2}i\right).
\end{aligned}
$$

The complex numbers z_1, z_2 and z_3, together with $z_4 = 2i$, $z_5 = -2i$ and $z_6 = 1$ are the solutions to the original polynomial equation.

As expected from the fundamental theorem of algebra, we find that the total number of complex roots (six, in this case) is equal to the largest power of z in the polynomial. ◀

A useful result is that the roots of a polynomial with real coefficients occur in conjugate pairs (i.e. if z_1 is a root, then z_1^* is a second distinct root, unless z_1 is real). This may be proved as follows. Let the polynomial equation of which z is a root be

$$a_n z^n + a_{n-1}z^{n-1} + \cdots + a_1 z + a_0 = 0.$$

Taking the complex conjugate of this equation,

$$a_n^*(z^*)^n + a_{n-1}^*(z^*)^{n-1} + \cdots + a_1^* z^* + a_0^* = 0.$$

But the a_n are real, and so z^* satisfies

$$a_n(z^*)^n + a_{n-1}(z^*)^{n-1} + \cdots + a_1 z^* + a_0 = 0,$$

and is also a root of the original equation.

3.5 Complex logarithms and complex powers

The concept of a complex exponential has already been introduced in section 3.3, where it was assumed that the definition of an exponential as a series was valid for complex numbers as well as for real numbers. Similarly we can define the logarithm of a complex number and we can use complex numbers as exponents.

Let us denote the natural logarithm of a complex number z by $w = \mathrm{Ln}\, z$, where the notation Ln will be explained shortly. Thus, w must satisfy

$$z = e^w.$$

Using (3.20), we see that

$$z_1 z_2 = e^{w_1}e^{w_2} = e^{w_1+w_2},$$

and taking logarithms of both sides we find

$$\mathrm{Ln}\,(z_1 z_2) = w_1 + w_2 = \mathrm{Ln}\, z_1 + \mathrm{Ln}\, z_2, \tag{3.34}$$

which shows that the familiar rule for the logarithm of the product of two real numbers also holds for complex numbers.

We may use (3.34) to investigate further the properties of $\mathrm{Ln}\, z$. We have already noted that the argument of a complex number is multivalued, i.e. $\arg z = \theta + 2n\pi$, where n is any integer. Thus, in polar form, the complex number z should strictly be written as

$$z = re^{i(\theta+2n\pi)}.$$

Taking the logarithm of both sides, and using (3.34), we find

$$\mathrm{Ln}\, z = \ln r + i(\theta + 2n\pi), \tag{3.35}$$

where $\ln r$ is the natural logarithm of the real positive quantity r and so is written normally. Thus from (3.35) we see that $\mathrm{Ln}\, z$ is itself multivalued. To avoid this multivalued behaviour it is conventional to define another function $\ln z$, the *principal value* of $\mathrm{Ln}\, z$, which is obtained from $\mathrm{Ln}\, z$ by restricting the argument of z to lie in the range $-\pi < \theta \leq \pi$.

►*Evaluate* $\mathrm{Ln}\,(-i)$.

By rewriting $-i$ as a complex exponential, we find

$$\mathrm{Ln}\,(-i) = \mathrm{Ln}\,\left[e^{i(-\pi/2+2n\pi)}\right] = i(-\pi/2 + 2n\pi),$$

where n is any integer. Hence $\mathrm{Ln}\,(-i) = -i\pi/2,\ 3i\pi/2,\ \ldots$. We note that $\ln(-i)$, the principal value of $\mathrm{Ln}\,(-i)$, is given by $\ln(-i) = -i\pi/2$. ◄

If z and t are both complex numbers then the zth power of t is defined by

$$t^z = e^{z\,\mathrm{Ln}\, t}.$$

Since $\mathrm{Ln}\, t$ is multivalued, so too is this definition.

►*Simplify the expression* $z = i^{-2i}$.

Firstly we take the logarithm of both sides of the equation to give

$$\mathrm{Ln}\, z = -2i\,\mathrm{Ln}\, i.$$

Now inverting the process we find

$$e^{\mathrm{Ln}\, z} = z = e^{-2i\,\mathrm{Ln}\, i}.$$

We can write $i = e^{i(\pi/2+2n\pi)}$, where n is any integer, and hence

$$\begin{aligned} \mathrm{Ln}\, i &= \mathrm{Ln}\,\left[e^{i\left(\pi/2+2n\pi\right)}\right] \\ &= i\left(\pi/2 + 2n\pi\right). \end{aligned}$$

We can now simplify z to give

$$\begin{aligned} i^{-2i} &= e^{-2i\times i\left(\pi/2+2n\pi\right)} \\ &= e^{(\pi+4n\pi)}, \end{aligned}$$

which, perhaps surprisingly, is a real quantity rather than a complex one. ◄

Complex powers and the logarithms of complex numbers are discussed further in chapter 24.

3.6 Applications to differentiation and integration

We can use the exponential form of a complex number together with de Moivre's theorem (see section 3.4) to simplify the differentiation of trigonometric functions.

►*Find the derivative with respect to x of* $e^{3x}\cos 4x$.

We could differentiate this function straightforwardly using the product rule (see subsection 2.1.2). However, an alternative method in this case is to use a complex exponential. Let us consider the complex number

$$z = e^{3x}(\cos 4x + i\sin 4x) = e^{3x}e^{4ix} = e^{(3+4i)x},$$

where we have used de Moivre's theorem to rewrite the trigonometric functions as a complex exponential. This complex number has $e^{3x}\cos 4x$ as its real part. Now, differentiating z with respect to x we obtain

$$\frac{dz}{dx} = (3+4i)e^{(3+4i)x} = (3+4i)e^{3x}(\cos 4x + i\sin 4x), \qquad (3.36)$$

where we have again used de Moivre's theorem. Equating real parts we then find

$$\frac{d}{dx}\left(e^{3x}\cos 4x\right) = e^{3x}(3\cos 4x - 4\sin 4x).$$

By equating the imaginary parts of (3.36), we also obtain, as a bonus,

$$\frac{d}{dx}\left(e^{3x}\sin 4x\right) = e^{3x}(4\cos 4x + 3\sin 4x). \blacktriangleleft$$

In a similar way the complex exponential can be used to evaluate integrals containing trigonometric and exponential functions.

►*Evaluate the integral* $I = \int e^{ax}\cos bx\, dx$.

Let us consider the integrand as the real part of the complex number

$$e^{ax}(\cos bx + i\sin bx) = e^{ax}e^{ibx} = e^{(a+ib)x},$$

where we use de Moivre's theorem to rewrite the trigonometric functions as a complex exponential. Integrating we find

$$\begin{aligned}\int e^{(a+ib)x}\,dx &= \frac{e^{(a+ib)x}}{a+ib} + c\\ &= \frac{(a-ib)e^{(a+ib)x}}{(a-ib)(a+ib)} + c\\ &= \frac{e^{ax}}{a^2+b^2}\left(ae^{ibx} - ibe^{ibx}\right) + c, \qquad (3.37)\end{aligned}$$

where the constant of integration c is in general complex. Denoting this constant by $c = c_1 + ic_2$ and equating real parts in (3.37) we obtain

$$I = \int e^{ax}\cos bx\,dx = \frac{e^{ax}}{a^2+b^2}(a\cos bx + b\sin bx) + c_1,$$

which agrees with result (2.37) found using integration by parts. Equating imaginary parts in (3.37) we obtain, as a bonus,

$$J = \int e^{ax}\sin bx\,dx = \frac{e^{ax}}{a^2+b^2}(a\sin bx - b\cos bx) + c_2. \blacktriangleleft$$

3.7 Hyperbolic functions

The *hyperbolic functions* are the complex analogues of the trigonometric functions. The analogy may not be immediately apparent and their definitions may appear at first to be somewhat arbitrary. However, careful examination of their properties reveals the purpose of the definitions. For instance, their close relationship with the trigonometric functions, both in their identities and in their calculus, means that many of the familiar properties of trigonometric functions can also be applied to the hyperbolic functions. Further, hyperbolic functions occur regularly, and so giving them special names is a notational convenience.

3.7.1 Definitions

The two fundamental hyperbolic functions are $\cosh x$ and $\sinh x$, which, as their names suggest, are the hyperbolic equivalents of $\cos x$ and $\sin x$. They are defined by the following relations:

$$\cosh x = \tfrac{1}{2}(e^x + e^{-x}), \tag{3.38}$$

$$\sinh x = \tfrac{1}{2}(e^x - e^{-x}). \tag{3.39}$$

Note that $\cosh x$ is an even function and $\sinh x$ is an odd function. By analogy with the trigonometric functions, the remaining hyperbolic functions are

$$\tanh x = \frac{\sinh x}{\cosh x} = \frac{e^x - e^{-x}}{e^x + e^{-x}}, \tag{3.40}$$

$$\operatorname{sech} x = \frac{1}{\cosh x} = \frac{2}{e^x + e^{-x}}, \tag{3.41}$$

$$\operatorname{cosech} x = \frac{1}{\sinh x} = \frac{2}{e^x - e^{-x}}, \tag{3.42}$$

$$\coth x = \frac{1}{\tanh x} = \frac{e^x + e^{-x}}{e^x - e^{-x}}. \tag{3.43}$$

All the hyperbolic functions above have been defined in terms of the real variable x. However, this was simply so that they may be plotted (see figures 3.11–3.13); the definitions are equally valid for any complex number z.

3.7.2 Hyperbolic–trigonometric analogies

In the previous subsections we have alluded to the analogy between trigonometric and hyperbolic functions. Here, we discuss the close relationship between the two groups of functions.

Recalling (3.32) and (3.33) we find

$$\cos ix = \tfrac{1}{2}(e^x + e^{-x}),$$

$$\sin ix = \tfrac{1}{2}i(e^x - e^{-x}).$$

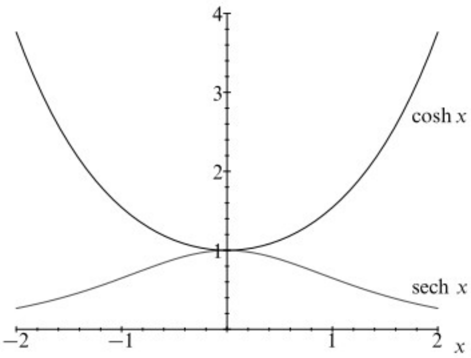

Figure 3.11 Graphs of cosh x and sech$x$.

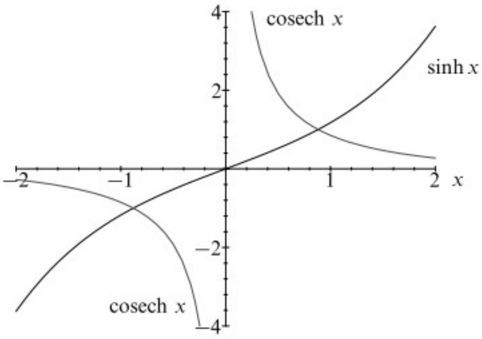

Figure 3.12 Graphs of sinh x and cosech$x$.

Hence, by the definitions given in the previous subsection,

$$\cosh x = \cos ix, \tag{3.44}$$

$$i \sinh x = \sin ix, \tag{3.45}$$

$$\cos x = \cosh ix, \tag{3.46}$$

$$i \sin x = \sinh ix. \tag{3.47}$$

These useful equations make the relationship between hyperbolic and trigono-

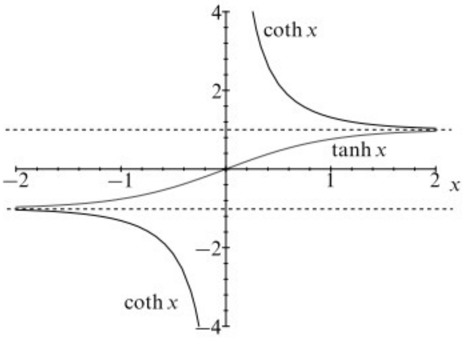

Figure 3.13 Graphs of tanh x and coth x.

metric functions transparent. The similarity in their calculus is discussed further in subsection 3.7.6.

3.7.3 Identities of hyperbolic functions

The analogies between trigonometric functions and hyperbolic functions having been established, we should not be surprised that all the trigonometric identities also hold for hyperbolic functions, with the following modification. Wherever $\sin^2 x$ occurs it must be replaced by $-\sinh^2 x$, and vice versa. Note that this replacement is necessary even if the $\sin^2 x$ is hidden, e.g. $\tan^2 x = \sin^2 x/\cos^2 x$ and so must be replaced by $(-\sinh^2 x/\cosh^2 x) = -\tanh^2 x$.

►*Find the hyperbolic identity analogous to* $\cos^2 x + \sin^2 x = 1$.

Using the rules stated above $\cos^2 x$ is replaced by $\cosh^2 x$, and $\sin^2 x$ by $-\sinh^2 x$, and so the identity becomes

$$\cosh^2 x - \sinh^2 x = 1.$$

This can be verified by direct substitution, using the definitions of $\cosh x$ and $\sinh x$; see (3.38) and (3.39). ◄

Some other identities that can be proved in a similar way are

$$\text{sech}^2 x = 1 - \tanh^2 x, \tag{3.48}$$

$$\text{cosech}^2 x = \coth^2 x - 1, \tag{3.49}$$

$$\sinh 2x = 2 \sinh x \cosh x, \tag{3.50}$$

$$\cosh 2x = \cosh^2 x + \sinh^2 x. \tag{3.51}$$

3.7.4 Solving hyperbolic equations

When we are presented with a hyperbolic equation to solve, we may proceed by analogy with the solution of trigonometric equations. However, it is almost always easier to express the equation directly in terms of exponentials.

►*Solve the hyperbolic equation* $\cosh x - 5\sinh x - 5 = 0$.

Substituting the definitions of the hyperbolic functions we obtain

$$\tfrac{1}{2}(e^x + e^{-x}) - \tfrac{5}{2}(e^x - e^{-x}) - 5 = 0.$$

Rearranging, and then multiplying through by $-e^x$, gives in turn

$$-2e^x + 3e^{-x} - 5 = 0$$

and

$$2e^{2x} + 5e^x - 3 = 0.$$

Now we can factorise and solve:

$$(2e^x - 1)(e^x + 3) = 0.$$

Thus $e^x = 1/2$ or $e^x = -3$. Hence $x = -\ln 2$ or $x = \ln(-3)$. The interpretation of the logarithm of a negative number has been discussed in section 3.5. ◄

3.7.5 Inverses of hyperbolic functions

Just like trigonometric functions, hyperbolic functions have inverses. If $y = \cosh x$ then $x = \cosh^{-1} y$, which serves as a definition of the inverse. By using the fundamental definitions of hyperbolic functions, we can find closed-form expressions for their inverses. This is best illustrated by example.

►*Find a closed-form expression for the inverse hyperbolic function* $y = \sinh^{-1} x$.

First we write x as a function of y, i.e.

$$y = \sinh^{-1} x \quad \Rightarrow \quad x = \sinh y.$$

Now, since $\cosh y = \frac{1}{2}(e^y + e^{-y})$ and $\sinh y = \frac{1}{2}(e^y - e^{-y})$,

$$\begin{aligned} e^y &= \cosh y + \sinh y \\ &= \sqrt{1 + \sinh^2 y} + \sinh y \\ e^y &= \sqrt{1 + x^2} + x, \end{aligned}$$

and hence

$$y = \ln(\sqrt{1 + x^2} + x). \text{ ◄}$$

In a similar fashion it can be shown that

$$\cosh^{-1} x = \ln(\sqrt{x^2 - 1} + x).$$

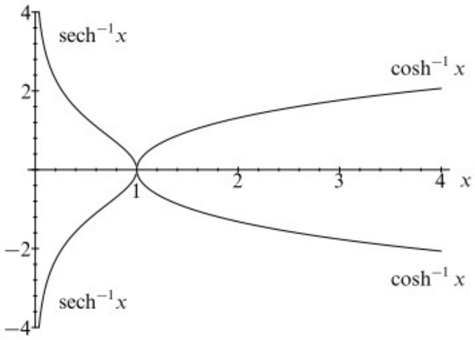

Figure 3.14 Graphs of $\cosh^{-1}x$ and $\mathrm{sech}^{-1}x$.

►*Find a closed-form expression for the inverse hyperbolic function* $y = \tanh^{-1}x$.

First we write x as a function of y, i.e.

$$y = \tanh^{-1}x \qquad \Rightarrow \qquad x = \tanh y.$$

Now, using the definition of $\tanh y$ and rearranging, we find

$$x = \frac{e^y - e^{-y}}{e^y + e^{-y}} \qquad \Rightarrow \qquad (x+1)e^{-y} = (1-x)e^y.$$

Thus, it follows that

$$\begin{aligned} e^{2y} = \frac{1+x}{1-x} \quad \Rightarrow \quad e^y &= \sqrt{\frac{1+x}{1-x}}, \\ y &= \ln\sqrt{\frac{1+x}{1-x}}, \\ \tanh^{-1}x &= \frac{1}{2}\ln\left(\frac{1+x}{1-x}\right). \end{aligned}$$ ◄

Graphs of the inverse hyperbolic functions are given in figures 3.14–3.16.

3.7.6 Calculus of hyperbolic functions

Just as the identities of hyperbolic functions closely follow those of their trigonometric counterparts, so their calculus is similar. The derivatives of the two basic

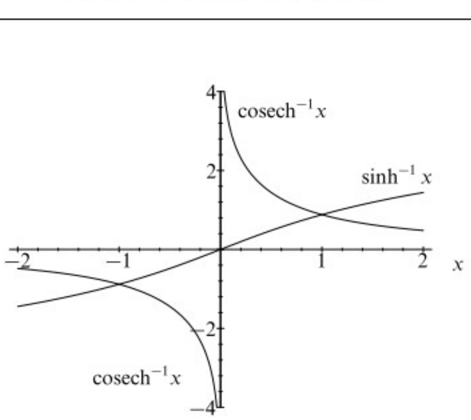

Figure 3.15 Graphs of $\sinh^{-1} x$ and $\operatorname{cosech}^{-1} x$.

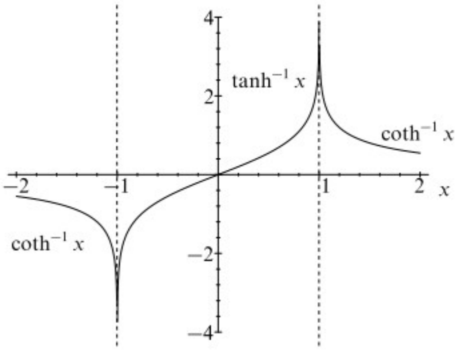

Figure 3.16 Graphs of $\tanh^{-1} x$ and $\coth^{-1} x$.

hyperbolic functions are given by

$$\frac{d}{dx}(\cosh x) = \sinh x, \tag{3.52}$$

$$\frac{d}{dx}(\sinh x) = \cosh x. \tag{3.53}$$

They may be deduced by considering the definitions (3.38), (3.39) as follows.

►*Verify the relation* $(d/dx)\cosh x = \sinh x$.

Using the definition of $\cosh x$,

$$\cosh x = \tfrac{1}{2}(e^x + e^{-x}),$$

and differentiating directly, we find

$$\begin{aligned}\frac{d}{dx}(\cosh x) &= \tfrac{1}{2}(e^x - e^{-x})\\ &= \sinh x. \blacktriangleleft\end{aligned}$$

Clearly the integrals of the fundamental hyperbolic functions are also defined by these relations. The derivatives of the remaining hyperbolic functions can be derived by product differentiation and are presented below only for completeness.

$$\frac{d}{dx}(\tanh x) = \text{sech}^2 x, \tag{3.54}$$

$$\frac{d}{dx}(\text{sech } x) = -\text{sech } x \tanh x, \tag{3.55}$$

$$\frac{d}{dx}(\text{cosech } x) = -\text{cosech } x \coth x, \tag{3.56}$$

$$\frac{d}{dx}(\coth x) = -\text{cosech}^2 x. \tag{3.57}$$

The inverse hyperbolic functions also have derivatives, which are given by the following:

$$\frac{d}{dx}\left(\cosh^{-1}\frac{x}{a}\right) = \frac{1}{\sqrt{x^2 - a^2}}, \tag{3.58}$$

$$\frac{d}{dx}\left(\sinh^{-1}\frac{x}{a}\right) = \frac{1}{\sqrt{x^2 + a^2}}, \tag{3.59}$$

$$\frac{d}{dx}\left(\tanh^{-1}\frac{x}{a}\right) = \frac{a}{a^2 - x^2}, \quad \text{for } x^2 < a^2, \tag{3.60}$$

$$\frac{d}{dx}\left(\coth^{-1}\frac{x}{a}\right) = \frac{-a}{x^2 - a^2}, \quad \text{for } x^2 > a^2. \tag{3.61}$$

These may be derived from the logarithmic form of the inverse (see subsection 3.7.5).

►*Evaluate* $(d/dx)\sinh^{-1}x$ *using the logarithmic form of the inverse.*

From the results of section 3.7.5,

$$\begin{aligned}\frac{d}{dx}\left(\sinh^{-1}x\right) &= \frac{d}{dx}\left[\ln\left(x+\sqrt{x^2+1}\right)\right]\\ &= \frac{1}{x+\sqrt{x^2+1}}\left(1+\frac{x}{\sqrt{x^2+1}}\right)\\ &= \frac{1}{x+\sqrt{x^2+1}}\left(\frac{\sqrt{x^2+1}+x}{\sqrt{x^2+1}}\right)\\ &= \frac{1}{\sqrt{x^2+1}}.\end{aligned}$$ ◄

3.8 Exercises

3.1 Two complex numbers z and w are given by $z = 3+4i$ and $w = 2-i$. On an Argand diagram, plot

(a) $z+w$, (b) $w-z$, (c) wz, (d) z/w,
(e) z^*w+w^*z, (f) w^2, (g) $\ln z$, (h) $(1+z+w)^{1/2}$.

3.2 By considering the real and imaginary parts of the product $e^{i\theta}e^{i\phi}$ prove the standard formulae for $\cos(\theta+\phi)$ and $\sin(\theta+\phi)$.

3.3 By writing $\pi/12 = (\pi/3)-(\pi/4)$ and considering $e^{i\pi/12}$, evaluate $\cot(\pi/12)$.

3.4 Find the locus in the complex z-plane of points that satisfy the following equations.

(a) $z-c=\rho\left(\dfrac{1+it}{1-it}\right)$, where c is complex, ρ is real and t is a real parameter that varies in the range $-\infty<t<\infty$.
(b) $z=a+bt+ct^2$, in which t is a real parameter and a, b, and c are complex numbers with b/c real.

3.5 Evaluate

(a) $\mathrm{Re}(\exp 2iz)$, (b) $\mathrm{Im}(\cosh^2 z)$, (c) $(-1+\sqrt{3}i)^{1/2}$,
(d) $|\exp(i^{1/2})|$, (e) $\exp(i^3)$, (f) $\mathrm{Im}(2^{i+3})$, (g) i^i, (h) $\ln[(\sqrt{3}+i)^3]$.

3.6 Find the equations in terms of x and y of the sets of points in the Argand diagram that satisfy the following:

(a) $\mathrm{Re}\,z^2=\mathrm{Im}\,z^2$;
(b) $(\mathrm{Im}\,z^2)/z^2=-i$;
(c) $\arg[z/(z-1)]=\pi/2$.

3.7 Show that the locus of all points $z=x+iy$ in the complex plane that satisfy

$$|z-ia|=\lambda|z+ia|,\quad \lambda>0,$$

is a circle of radius $|2\lambda a/(1-\lambda^2)|$ centred on the point $z=ia[(1+\lambda^2)/(1-\lambda^2)]$. Sketch the circles for a few typical values of λ, including $\lambda<1$, $\lambda>1$ and $\lambda=1$.

3.8 The two sets of points $z=a$, $z=b$, $z=c$, and $z=A$, $z=B$, $z=C$ are the corners of two similar triangles in the Argand diagram. Express in terms of $a,b,\ldots,C$

11

Line, surface and volume integrals

In the previous chapter we encountered continuously varying scalar and vector fields and discussed the action of various differential operators on them. In addition to these differential operations, the need often arises to consider the integration of field quantities along lines, over surfaces and throughout volumes. In general the integrand may be scalar or vector in nature, but the evaluation of such integrals involves their reduction to one or more scalar integrals, which are then evaluated. In the case of surface and volume integrals this requires the evaluation of double and triple integrals (see chapter 6).

11.1 Line integrals

In this section we discuss *line* or *path integrals*, in which some quantity related to the field is integrated between two given points in space, A and B, along a prescribed curve C that joins them. In general, we may encounter line integrals of the forms

$$\int_C \phi \, d\mathbf{r}, \qquad \int_C \mathbf{a} \cdot d\mathbf{r}, \qquad \int_C \mathbf{a} \times d\mathbf{r}, \tag{11.1}$$

where ϕ is a scalar field and $\mathbf{a}$ is a vector field. The three integrals themselves are respectively vector, scalar and vector in nature. As we will see below, in physical applications line integrals of the second type are by far the most common.

The formal definition of a line integral closely follows that of ordinary integrals and can be considered as the limit of a sum. We may divide the path C joining the points A and B into N small line elements $\Delta\mathbf{r}_p$, $p = 1, \ldots, N$. If (x_p, y_p, z_p) is any point on the line element $\Delta\mathbf{r}_p$ then the second type of line integral in (11.1), for example, is defined as

$$\int_C \mathbf{a} \cdot d\mathbf{r} = \lim_{N\to\infty} \sum_{p=1}^{N} \mathbf{a}(x_p, y_p, z_p) \cdot \Delta\mathbf{r}_p,$$

where it is assumed that all $|\Delta\mathbf{r}_p| \to 0$ as $N \to \infty$.

Each of the line integrals in (11.1) is evaluated over some curve C that may be either open (A and B being distinct points) or closed (the curve C forms a loop, so that A and B are coincident). In the case where C is closed, the line integral is written $\oint_C$ to indicate this. The curve may be given either parametrically by $\mathbf{r}(u) = x(u)\mathbf{i} + y(u)\mathbf{j} + z(u)\mathbf{k}$ or by means of simultaneous equations relating x, y, z for the given path (in Cartesian coordinates). A full discussion of the different representations of space curves was given in section 10.3.

In general, the value of the line integral depends not only on the end-points A and B but also on the path C joining them. For a closed curve we must also specify the direction around the loop in which the integral is taken. It is usually taken to be such that a person walking around the loop C in this direction always has the region R on his/her left; this is equivalent to traversing C in the anticlockwise direction (as viewed from above).

11.1.1 Evaluating line integrals

The method of evaluating a line integral is to reduce it to a set of scalar integrals. It is usual to work in Cartesian coordinates, in which case $d\mathbf{r} = dx\,\mathbf{i} + dy\,\mathbf{j} + dz\,\mathbf{k}$. The first type of line integral in (11.1) then becomes simply

$$\int_C \phi\, d\mathbf{r} = \mathbf{i}\int_C \phi(x,y,z)\,dx + \mathbf{j}\int_C \phi(x,y,z)\,dy + \mathbf{k}\int_C \phi(x,y,z)\,dz.$$

The three integrals on the RHS are ordinary scalar integrals that can be evaluated in the usual way once the path of integration C has been specified. Note that in the above we have used relations of the form

$$\int \phi\,\mathbf{i}\,dx = \mathbf{i}\int \phi\,dx,$$

which is allowable since the Cartesian unit vectors are of constant magnitude and direction and hence may be taken out of the integral. If we had been using a different coordinate system, such as spherical polars, then, as we saw in the previous chapter, the unit basis vectors would not be constant. In that case the basis vectors could not be factorised out of the integral.

The second and third line integrals in (11.1) can also be reduced to a set of scalar integrals by writing the vector field $\mathbf{a}$ in terms of its Cartesian components as $\mathbf{a} = a_x\mathbf{i} + a_y\mathbf{j} + a_z\mathbf{k}$, where a_x, a_y, a_z are each (in general) functions of x, y, z. The second line integral in (11.1), for example, can then be written as

$$\begin{aligned}\int_C \mathbf{a}\cdot d\mathbf{r} &= \int_C (a_x\mathbf{i} + a_y\mathbf{j} + a_z\mathbf{k})\cdot(dx\,\mathbf{i} + dy\,\mathbf{j} + dz\,\mathbf{k})\\ &= \int_C (a_x\,dx + a_y\,dy + a_z\,dz)\\ &= \int_C a_x\,dx + \int_C a_y\,dy + \int_C a_z\,dz. \qquad (11.2)\end{aligned}$$

A similar procedure may be followed for the third type of line integral in (11.1), which involves a cross product.

Line integrals have properties that are analogous to those of ordinary integrals. In particular, the following are useful properties (which we illustrate using the second form of line integral in (11.1) but which are valid for all three types).

(i) Reversing the path of integration changes the sign of the integral. If the path C along which the line integrals are evaluated has A and B as its end-points then

$$\int_A^B \mathbf{a}\cdot d\mathbf{r} = -\int_B^A \mathbf{a}\cdot d\mathbf{r}.$$

This implies that if the path C is a loop then integrating around the loop in the opposite direction changes the sign of the integral.

(ii) If the path of integration is subdivided into smaller segments then the sum of the separate line integrals along each segment is equal to the line integral along the whole path. So, if P is any point on the path of integration that lies between the path's end-points A and B then

$$\int_A^B \mathbf{a}\cdot d\mathbf{r} = \int_A^P \mathbf{a}\cdot d\mathbf{r} + \int_P^B \mathbf{a}\cdot d\mathbf{r}.$$

►*Evaluate the line integral* $I = \int_C \mathbf{a}\cdot d\mathbf{r}$, *where* $\mathbf{a} = (x+y)\mathbf{i} + (y-x)\mathbf{j}$, *along each of the paths in the xy-plane shown in figure 11.1, namely*

(i) *the parabola* $y^2 = x$ *from* $(1,1)$ *to* $(4,2)$,
(ii) *the curve* $x = 2u^2 + u + 1$, $y = 1 + u^2$ *from* $(1,1)$ *to* $(4,2)$,
(iii) *the line* $y = 1$ *from* $(1,1)$ *to* $(4,1)$, *followed by the line* $x = 4$ *from* $(4,1)$ *to* $(4,2)$.

Since each of the paths lies entirely in the xy-plane, we have $d\mathbf{r} = dx\,\mathbf{i} + dy\,\mathbf{j}$. We can therefore write the line integral as

$$I = \int_C \mathbf{a}\cdot d\mathbf{r} = \int_C [(x+y)\,dx + (y-x)\,dy]. \tag{11.3}$$

We must now evaluate this line integral along each of the prescribed paths.

Case (i). Along the parabola $y^2 = x$ we have $2y\,dy = dx$. Substituting for x in (11.3) and using just the limits on y, we obtain

$$I = \int_{(1,1)}^{(4,2)} [(x+y)\,dx + (y-x)\,dy] = \int_1^2 [(y^2+y)2y + (y-y^2)]\,dy = 11\tfrac{1}{3}.$$

Note that we could just as easily have substituted for y and obtained an integral in x, which would have given the same result.

Case (ii). The second path is given in terms of a parameter u. We could eliminate u between the two equations to obtain a relationship between x and y directly and proceed as above, but it is usually quicker to write the line integral in terms of the parameter u. Along the curve $x = 2u^2 + u + 1$, $y = 1 + u^2$ we have $dx = (4u+1)\,du$ and $dy = 2u\,du$.

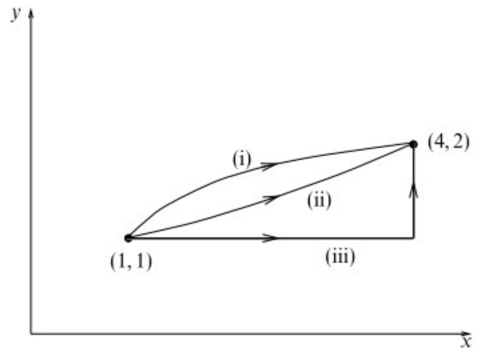

Figure 11.1 Different possible paths between the points (1, 1) and (4, 2).

Substituting for x and y in (11.3) and writing the correct limits on u, we obtain

$$\begin{aligned} I &= \int_{(1,1)}^{(4,2)} [(x+y)\,dx + (y-x)\,dy] \\ &= \int_0^1 [(3u^2+u+2)(4u+1) - (u^2+u)2u]\,du = 10\tfrac{2}{3}. \end{aligned}$$

Case (iii). For the third path the line integral must be evaluated along the two line segments separately and the results added together. First, along the line $y = 1$ we have $dy = 0$. Substituting this into (11.3) and using just the limits on x for this segment, we obtain

$$\int_{(1,1)}^{(4,1)} [(x+y)\,dx + (y-x)\,dy] = \int_1^4 (x+1)\,dx = 10\tfrac{1}{2}.$$

Next, along the line $x = 4$ we have $dx = 0$. Substituting this into (11.3) and using just the limits on y for this segment, we obtain

$$\int_{(4,1)}^{(4,2)} [(x+y)\,dx + (y-x)\,dy] = \int_1^2 (y-4)\,dy = -2\tfrac{1}{2}.$$

The value of the line integral along the whole path is just the sum of the values of the line integrals along each segment, and is given by $I = 10\frac{1}{2} - 2\frac{1}{2} = 8$. ◄

When calculating a line integral along some curve C, which is given in terms of x, y and z, we are sometimes faced with the problem that the curve C is such that x, y and z are not single-valued functions of one another over the entire length of the curve. This is a particular problem for closed loops in the xy-plane (and also for some open curves). In such cases the path may be subdivided into shorter line segments along which one coordinate is a single-valued function of the other two. The sum of the line integrals along these segments is then equal to the line integral along the entire curve C. A better solution, however, is to represent the curve in a parametric form $\mathbf{r}(u)$ that is valid for its entire length.

►*Evaluate the line integral $I = \oint_C x\,dy$, where C is the circle in the xy-plane defined by $x^2 + y^2 = a^2$, $z = 0$.*

Adopting the usual convention mentioned above, the circle C is to be traversed in the anticlockwise direction. Taking the circle as a whole means x is not a single-valued function of y. We must therefore divide the path into two parts with $x = +\sqrt{a^2 - y^2}$ for the semicircle lying to the right of $x = 0$, and $x = -\sqrt{a^2 - y^2}$ for the semicircle lying to the left of $x = 0$. The required line integral is then the sum of the integrals along the two semicircles. Substituting for x, it is given by

$$\begin{aligned} I = \oint_C x\,dy &= \int_{-a}^{a} \sqrt{a^2 - y^2}\,dy + \int_{a}^{-a} \left(-\sqrt{a^2 - y^2}\right)\,dy \\ &= 4\int_0^a \sqrt{a^2 - y^2}\,dy = \pi a^2. \end{aligned}$$

Alternatively, we can represent the entire circle parametrically, in terms of the azimuthal angle ϕ, so that $x = a\cos\phi$ and $y = a\sin\phi$ with ϕ running from 0 to 2π. The integral can therefore be evaluated over the whole circle at once. Noting that $dy = a\cos\phi\,d\phi$, we can rewrite the line integral completely in terms of the parameter ϕ and obtain

$$I = \oint_C x\,dy = a^2 \int_0^{2\pi} \cos^2\phi\,d\phi = \pi a^2. \blacktriangleleft$$

11.1.2 Physical examples of line integrals

There are many physical examples of line integrals, but perhaps the most common is the expression for the total work done by a force $\mathbf{F}$ when it moves its point of application from a point A to a point B along a given curve C. We allow the magnitude and direction of $\mathbf{F}$ to vary along the curve. Let the force act at a point $\mathbf{r}$ and consider a small displacement $d\mathbf{r}$ along the curve; then the small amount of work done is $dW = \mathbf{F}\cdot d\mathbf{r}$, as discussed in subsection 7.6.1 (note that dW can be either positive or negative). Therefore, the total work done in traversing the path C is

$$W_C = \int_C \mathbf{F}\cdot d\mathbf{r}.$$

Naturally, other physical quantities can be expressed in such a way. For example, the electrostatic potential energy gained by moving a charge q along a path C in an electric field $\mathbf{E}$ is $-q\int_C \mathbf{E}\cdot d\mathbf{r}$. We may also note that Ampère's law concerning the magnetic field $\mathbf{B}$ associated with a current-carrying wire can be written as

$$\oint_C \mathbf{B}\cdot d\mathbf{r} = \mu_0 I,$$

where I is the current enclosed by a closed path C traversed in a right-handed sense with respect to the current direction.

Magnetostatics also provides a physical example of the third type of line integral in (11.1). If a loop of wire C carrying a current I is placed in a magnetic field $\mathbf{B}$ then the force $d\mathbf{F}$ on a small length $d\mathbf{r}$ of the wire is given by $d\mathbf{F} = I\, d\mathbf{r} \times \mathbf{B}$, and so the total (vector) force on the loop is

$$\mathbf{F} = I \oint_C d\mathbf{r} \times \mathbf{B}.$$

11.1.3 Line integrals with respect to a scalar

In addition to those listed in (11.1), we can form other types of line integral, which depend on a particular curve C but for which we integrate with respect to a scalar du, rather than the vector differential $d\mathbf{r}$. This distinction is somewhat arbitrary, however, since we can always rewrite line integrals containing the vector differential $d\mathbf{r}$ as a line integral with respect to some scalar parameter. If the path C along which the integral is taken is described parametrically by $\mathbf{r}(u)$ then

$$d\mathbf{r} = \frac{d\mathbf{r}}{du}\, du,$$

and the second type of line integral in (11.1), for example, can be written as

$$\int_C \mathbf{a} \cdot d\mathbf{r} = \int_C \mathbf{a} \cdot \frac{d\mathbf{r}}{du}\, du.$$

A similar procedure can be followed for the other types of line integral in (11.1).

Commonly occurring special cases of line integrals with respect to a scalar are

$$\int_C \phi\, ds, \qquad \int_C \mathbf{a}\, ds,$$

where s is the arc length along the curve C. We can always represent C parametrically by $\mathbf{r}(u)$, and from section 10.3 we have

$$ds = \sqrt{\frac{d\mathbf{r}}{du} \cdot \frac{d\mathbf{r}}{du}}\, du.$$

The line integrals can therefore be expressed entirely in terms of the parameter u and thence evaluated.

►*Evaluate the line integral $I = \int_C (x-y)^2\, ds$, where C is the semicircle of radius a running from $A = (a, 0)$ to $B = (-a, 0)$ and for which $y \geq 0$.*

The semicircular path from A to B can be described in terms of the azimuthal angle ϕ (measured from the x-axis) by

$$\mathbf{r}(\phi) = a\cos\phi\, \mathbf{i} + a\sin\phi\, \mathbf{j},$$

where ϕ runs from 0 to π. Therefore the element of arc length is given, from section 10.3, by

$$ds = \sqrt{\frac{d\mathbf{r}}{d\phi} \cdot \frac{d\mathbf{r}}{d\phi}}\, d\phi = a(\cos^2\phi + \sin^2\phi)\, d\phi = a\, d\phi.$$

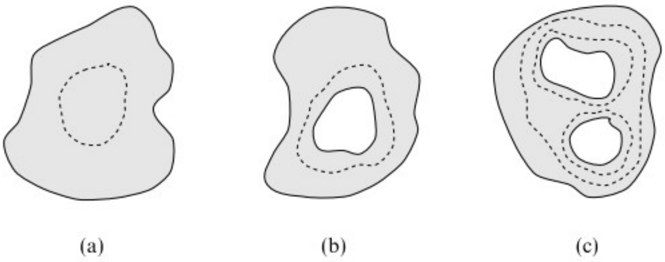

Figure 11.2 (a) A simply connected region; (b) a doubly connected region; (c) a triply connected region.

Since $(x-y)^2 = a^2(1-\sin 2\phi)$, the line integral becomes

$$I = \int_C (x-y)^2\,ds = \int_0^{\pi} a^3(1-\sin 2\phi)\,d\phi = \pi a^3. \blacktriangleleft$$

As discussed in the previous chapter, the expression (10.58) for the square of the element of arc length in three-dimensional orthogonal curvilinear coordinates u_1, u_2, u_3 is

$$(ds)^2 = h_1^2\,(du_1)^2 + h_2^2\,(du_2)^2 + h_3^2\,(du_3)^2,$$

where h_1, h_2, h_3 are the scale factors of the coordinate system. If a curve C in three dimensions is given parametrically by the equations $u_i = u_i(\lambda)$ for $i = 1, 2, 3$ then the element of arc length along the curve is

$$ds = \sqrt{h_1^2\left(\frac{du_1}{d\lambda}\right)^2 + h_2^2\left(\frac{du_2}{d\lambda}\right)^2 + h_3^2\left(\frac{du_3}{d\lambda}\right)^2}\,d\lambda.$$

11.2 Connectivity of regions

In physical systems it is usual to define a scalar or vector field in some region R. In the next and some later sections we will need the concept of the *connectivity* of such a region in both two and three dimensions.

We begin by discussing planar regions. A plane region R is said to be *simply connected* if every simple closed curve within R can be continuously shrunk to a point without leaving the region (see figure 11.2(a)). If, however, the region R contains a hole then there exist simple closed curves that cannot be shrunk to a point without leaving R (see figure 11.2(b)). Such a region is said to be doubly connected, since its boundary has two distinct parts. Similarly, a region with $n-1$ holes is said to be *n-fold connected*, or *multiply connected* (the region in figure 11.2(c) is triply connected).

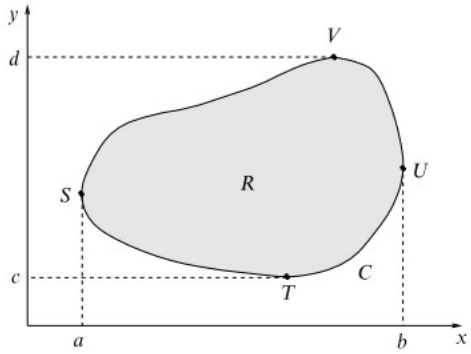

Figure 11.3 A simply connected region R bounded by the curve C.

These ideas can be extended to regions that are not planar, such as general three-dimensional surfaces and volumes. The same criteria concerning the shrinking of closed curves to a point also apply when deciding the connectivity of such regions. In these cases, however, the curves must lie in the surface or volume in question. For example, the interior of a torus is not simply connected, since there exist closed curves in the interior that cannot be shrunk to a point without leaving the torus. The region between two concentric spheres of different radii is simply connected.

11.3 Green's theorem in a plane

In subsection 11.1.1 we considered (amongst other things) the evaluation of line integrals for which the path C is closed and lies entirely in the xy-plane. Since the path is closed it will enclose a region R of the plane. We now discuss how to express the line integral around the loop as a double integral over the enclosed region R.

Suppose the functions $P(x,y)$, $Q(x,y)$ and their partial derivatives are single-valued, finite and continuous inside and on the boundary C of some simply connected region R in the xy-plane. *Green's theorem in a plane* (sometimes called the divergence theorem in two dimensions) then states

$$\oint_C (P\,dx + Q\,dy) = \iint_R \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) dx\,dy, \tag{11.4}$$

and so relates the line integral around C to a double integral over the enclosed region R. This theorem may be proved straightforwardly in the following way. Consider the simply connected region R in figure 11.3, and let $y = y_1(x)$ and

$y = y_2(x)$ be the equations of the curves STU and SVU respectively. We then write

$$\begin{aligned}\iint_R \frac{\partial P}{\partial y}\,dx\,dy &= \int_a^b dx \int_{y_1(x)}^{y_2(x)} dy\,\frac{\partial P}{\partial y} = \int_a^b dx\Big[P(x,y)\Big]_{y=y_1(x)}^{y=y_2(x)} \\ &= \int_a^b \Big[P(x,y_2(x)) - P(x,y_1(x))\Big]\,dx \\ &= -\int_a^b P(x,y_1(x))\,dx - \int_b^a P(x,y_2(x))\,dx = -\oint_C P\,dx.\end{aligned}$$

If we now let $x = x_1(y)$ and $x = x_2(y)$ be the equations of the curves TSV and TUV respectively, we can similarly show that

$$\begin{aligned}\iint_R \frac{\partial Q}{\partial x}\,dx\,dy &= \int_c^d dy \int_{x_1(y)}^{x_2(y)} dx\,\frac{\partial Q}{\partial x} = \int_c^d dy\Big[Q(x,y)\Big]_{x=x_1(y)}^{x=x_2(y)} \\ &= \int_c^d \Big[Q(x_2(y),y) - Q(x_1(y),y)\Big]\,dy \\ &= \int_d^c Q(x_1,y)\,dy + \int_c^d Q(x_2,y)\,dy = \oint_C Q\,dy.\end{aligned}$$

Subtracting these two results gives Green's theorem in a plane.

►*Show that the area of a region R enclosed by a simple closed curve C is given by* $A = \frac{1}{2}\oint_C(x\,dy - y\,dx) = \oint_C x\,dy = -\oint_C y\,dx$. *Hence calculate the area of the ellipse* $x = a\cos\phi$, $y = b\sin\phi$.

In Green's theorem (11.4) put $P = -y$ and $Q = x$; then

$$\oint_C (x\,dy - y\,dx) = \iint_R (1+1)\,dx\,dy = 2\iint_R dx\,dy = 2A.$$

Therefore the area of the region is $A = \frac{1}{2}\oint_C(x\,dy - y\,dx)$. Alternatively, we could put $P = 0$ and $Q = x$ and obtain $A = \oint_C x\,dy$, or put $P = -y$ and $Q = 0$, which gives $A = -\oint_C y\,dx$.

The area of the ellipse $x = a\cos\phi$, $y = b\sin\phi$ is given by

$$\begin{aligned}A = \frac{1}{2}\oint_C (x\,dy - y\,dx) &= \frac{1}{2}\int_0^{2\pi} ab(\cos^2\phi + \sin^2\phi)\,d\phi \\ &= \frac{ab}{2}\int_0^{2\pi} d\phi = \pi ab. \blacktriangleleft\end{aligned}$$

It may further be shown that Green's theorem in a plane is also valid for multiply connected regions. In this case, the line integral must be taken over all the distinct boundaries of the region. Furthermore, each boundary must be traversed in the positive direction, so that a person travelling along it in this direction always has the region R on their left. In order to apply Green's theorem

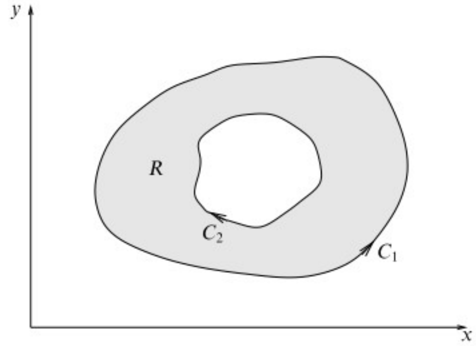

Figure 11.4 A doubly connected region R bounded by the curves C_1 and C_2.

to the region R shown in figure 11.4, the line integrals must be taken over both boundaries, C_1 and C_2, in the directions indicated, and the results added together.

We may also use Green's theorem in a plane to investigate the path independence (or not) of line integrals when the paths lie in the xy-plane. Let us consider the line integral

$$I = \int_A^B (P\,dx + Q\,dy).$$

For the line integral from A to B to be independent of the path taken, it must have the same value along any two arbitrary paths C_1 and C_2 joining the points. Moreover, if we consider as the path the closed loop C formed by $C_1 - C_2$ then the line integral around this loop must be zero. From Green's theorem in a plane, (11.4), we see that a *sufficient* condition for $I = 0$ is that

$$\frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x}, \tag{11.5}$$

throughout some simply connected region R containing the loop, where we assume that these partial derivatives are continuous in R.

It may be shown that (11.5) is also a *necessary* condition for $I = 0$ and is equivalent to requiring $P\,dx + Q\,dy$ to be an exact differential of some function $\phi(x, y)$ such that $P\,dx + Q\,dy = d\phi$. It follows that $\int_A^B (P\,dx + Q\,dy) = \phi(B) - \phi(A)$ and that $\oint_C (P\,dx + Q\,dy)$ around any closed loop C in the region R is identically zero. These results are special cases of the general results for paths in three dimensions, which are discussed in the next section.

►*Evaluate the line integral*

$$I = \oint_C \left[(e^x y + \cos x \sin y)\, dx + (e^x + \sin x \cos y)\, dy\right],$$

around the ellipse $x^2/a^2 + y^2/b^2 = 1$.

Clearly, it is not straightforward to calculate this line integral directly. However, if we let

$$P = e^x y + \cos x \sin y \qquad \text{and} \qquad Q = e^x + \sin x \cos y,$$

then $\partial P/\partial y = e^x + \cos x \cos y = \partial Q/\partial x$, and so $P\,dx + Q\,dy$ is an exact differential (it is actually the differential of the function $f(x, y) = e^x y + \sin x \sin y$). From the above discussion, we can conclude immediately that $I = 0$. ◄

11.4 Conservative fields and potentials

So far we have made the point that, in general, the value of a line integral between two points A and B depends on the path C taken from A to B. In the previous section, however, we saw that, for paths in the xy-plane, line integrals whose integrands have certain properties are independent of the path taken. We now extend that discussion to the full three-dimensional case.

For line integrals of the form $\int_C \mathbf{a} \cdot d\mathbf{r}$, there exists a class of vector fields for which the line integral between two points is *independent* of the path taken. Such vector fields are called *conservative*. A vector field $\mathbf{a}$ that has continuous partial derivatives in a simply connected region R is conservative if, and only if, any of the following is true.

- (i) The integral $\int_A^B \mathbf{a} \cdot d\mathbf{r}$, where A and B lie in the region R, is independent of the path from A to B. Hence the integral $\oint_C \mathbf{a} \cdot d\mathbf{r}$ around any closed loop in R is zero.
- (ii) There exists a single-valued function ϕ of position such that $\mathbf{a} = \nabla\phi$.
- (iii) $\nabla \times \mathbf{a} = \mathbf{0}$.
- (iv) $\mathbf{a} \cdot d\mathbf{r}$ is an exact differential.

The validity or otherwise of any of these statements implies the same for the other three, as we will now show.

First, let us assume that (i) above is true. If the line integral from A to B is independent of the path taken between the points then its value must be a function only of the positions of A and B. We may therefore write

$$\int_A^B \mathbf{a} \cdot d\mathbf{r} = \phi(B) - \phi(A), \tag{11.6}$$

which defines a single-valued scalar function of position ϕ. If the points A and B are separated by an infinitesimal displacement $d\mathbf{r}$ then (11.6) becomes

$$\mathbf{a} \cdot d\mathbf{r} = d\phi,$$

which shows that we require $\mathbf{a}\cdot d\mathbf{r}$ to be an exact differential: condition (iv). From (10.27) we can write $d\phi = \nabla\phi \cdot d\mathbf{r}$, and so we have

$$(\mathbf{a} - \nabla\phi) \cdot d\mathbf{r} = 0.$$

Since $d\mathbf{r}$ is arbitrary, we find that $\mathbf{a} = \nabla\phi$; this immediately implies $\nabla \times \mathbf{a} = \mathbf{0}$, condition (iii) (see (10.37)).

Alternatively, if we suppose that there exists a single-valued function of position ϕ such that $\mathbf{a} = \nabla\phi$ then $\nabla \times \mathbf{a} = \mathbf{0}$ follows as before. The line integral around a closed loop then becomes

$$\oint_C \mathbf{a} \cdot d\mathbf{r} = \oint_C \nabla\phi \cdot d\mathbf{r} = \oint d\phi.$$

Since we defined ϕ to be single-valued, this integral is zero as required.

Now suppose $\nabla \times \mathbf{a} = \mathbf{0}$. From Stoke's theorem, which is discussed in section 11.9, we immediately obtain $\oint_C \mathbf{a}\cdot d\mathbf{r} = 0$; then $\mathbf{a} = \nabla\phi$ and $\mathbf{a}\cdot d\mathbf{r} = d\phi$ follow as above.

Finally, let us suppose $\mathbf{a} \cdot d\mathbf{r} = d\phi$. Then immediately we have $\mathbf{a} = \nabla\phi$, and the other results follow as above.

►*Evaluate the line integral* $I = \int_A^B \mathbf{a} \cdot d\mathbf{r}$, *where* $\mathbf{a} = (xy^2 + z)\mathbf{i} + (x^2y + 2)\mathbf{j} + x\mathbf{k}$, *A is the point* (c, c, h) *and B is the point* $(2c, c/2, h)$, *along the different paths*

(i) *C_1, given by* $x = cu$, $y = c/u$, $z = h$,
(ii) *C_2, given by* $2y = 3c - x$, $z = h$.

Show that the vector field $\mathbf{a}$ *is in fact conservative, and find* ϕ *such that* $\mathbf{a} = \nabla\phi$.

Expanding out the integrand, we have

$$I = \int_{(c,c,h)}^{(2c,c/2,h)} \left[(xy^2 + z)\,dx + (x^2y + 2)\,dy + x\,dz\right], \tag{11.7}$$

which we must evaluate along each of the paths C_1 and C_2.

(i) Along C_1 we have $dx = c\,du$, $dy = -(c/u^2)\,du$, $dz = 0$, and on substituting in (11.7) and finding the limits on u, we obtain

$$I = \int_1^2 c\left(h - \frac{2}{u^2}\right)\,du = c(h-1).$$

(ii) Along C_2 we have $2\,dy = -dx$, $dz = 0$ and, on substituting in (11.7) and using the limits on x, we obtain

$$I = \int_c^{2c} \left(\tfrac{1}{2}x^3 - \tfrac{9}{4}cx^2 + \tfrac{9}{4}c^2x + h - 1\right)\,dx = c(h-1).$$

Hence the line integral has the same value along paths C_1 and C_2. Taking the curl of $\mathbf{a}$, we have

$$\nabla \times \mathbf{a} = (0-0)\mathbf{i} + (1-1)\mathbf{j} + (2xy - 2xy)\mathbf{k} = \mathbf{0},$$

so $\mathbf{a}$ is a conservative vector field, and the line integral between two points must be independent of the path taken. Since **a** is conservative, we can write $\mathbf{a} = \nabla\phi$. Therefore, ϕ must satisfy

$$\frac{\partial \phi}{\partial x} = xy^2 + z,$$

which implies that $\phi = \frac{1}{2}x^2y^2 + zx + f(y, z)$ for some function f. Secondly, we require

$$\frac{\partial \phi}{\partial y} = x^2y + \frac{\partial f}{\partial y} = x^2y + 2,$$

which implies $f = 2y + g(z)$. Finally, since

$$\frac{\partial \phi}{\partial z} = x + \frac{\partial g}{\partial z} = x,$$

we have g = constant = k. It can be seen that we have explicitly constructed the function $\phi = \frac{1}{2}x^2y^2 + zx + 2y + k$. ◄

The quantity ϕ that figures so prominently in this section is called the *scalar potential function* of the conservative vector field **a** (which satisfies $\nabla \times \mathbf{a} = \mathbf{0}$), and is unique up to an arbitrary additive constant. Scalar potentials that are multivalued functions of position (but in simple ways) are also of value in describing some physical situations, the most obvious example being the scalar magnetic potential associated with a current-carrying wire. When the integral of a field quantity around a closed loop is considered, provided the loop does not enclose a net current, the potential is single-valued and all the above results still hold. If the loop does enclose a net current, however, our analysis is no longer valid and extra care must be taken.

If, instead of being conservative, a vector field **b** satisfies $\nabla \cdot \mathbf{b} = 0$ (i.e. **b** is solenoidal) then it is both possible and useful, for example in the theory of electromagnetism, to define a *vector field* **a** such that $\mathbf{b} = \nabla \times \mathbf{a}$. It may be shown that such a vector field **a** always exists. Further, if **a** is one such vector field then $\mathbf{a}' = \mathbf{a} + \nabla\psi + \mathbf{c}$, where ψ is any scalar function and **c** is any constant vector, also satisfies the above relationship, i.e. $\mathbf{b} = \nabla \times \mathbf{a}'$. This was discussed more fully in subsection 10.8.2.

11.5 Surface integrals

As with line integrals, integrals over surfaces can involve vector and scalar fields and, equally, can result in either a vector or a scalar. The simplest case involves entirely scalars and is of the form

$$\int_S \phi \, dS. \tag{11.8}$$

As analogues of the line integrals listed in (11.1), we may also encounter surface integrals involving vectors, namely

$$\int_S \phi \, d\mathbf{S}, \qquad \int_S \mathbf{a} \cdot d\mathbf{S}, \qquad \int_S \mathbf{a} \times d\mathbf{S}. \tag{11.9}$$

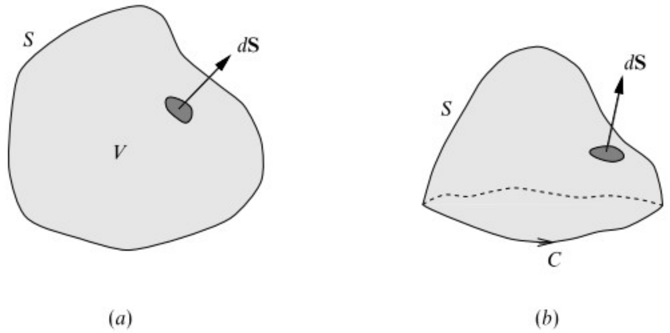

Figure 11.5 (a) A closed surface and (b) an open surface. In each case a normal to the surface is shown: $d\mathbf{S} = \hat{\mathbf{n}}\, dS$.

All the above integrals are taken over some surface S, which may be either open or closed, and are therefore, in general, double integrals. Following the notation for line integrals, for surface integrals over a closed surface $\int_S$ is replaced by $\oint_S$.

The vector differential $d\mathbf{S}$ in (11.9) represents a vector area element of the surface S. It may also be written $d\mathbf{S} = \hat{\mathbf{n}}\, dS$, where $\hat{\mathbf{n}}$ is a unit normal to the surface at the position of the element and dS is the scalar area of the element used in (11.8). The convention for the direction of the normal $\hat{\mathbf{n}}$ to a surface depends on whether the surface is open or closed. A closed surface, see figure 11.5(a), does not have to be simply connected (for example, the surface of a torus is not), but it does have to enclose a volume V, which may be of infinite extent. The direction of $\hat{\mathbf{n}}$ is taken to point outwards from the enclosed volume as shown. An open surface, see figure 11.5(b), spans some perimeter curve C. The direction of $\hat{\mathbf{n}}$ is then given by the right-hand sense with respect to the direction in which the perimeter is traversed, i.e. follows the right-hand screw rule discussed in subsection 7.6.2. An open surface does not have to be simply connected but for our purposes it must be two-sided (a Möbius strip is an example of a one-sided surface).

The formal definition of a surface integral is very similar to that of a line integral. We divide the surface S into N elements of area ΔS_p, $p = 1, 2, \ldots, N$, each with a unit normal $\hat{\mathbf{n}}_p$. If (x_p, y_p, z_p) is any point in ΔS_p then the second type of surface integral in (11.9), for example, is defined as

$$\int_S \mathbf{a} \cdot d\mathbf{S} = \lim_{N\to\infty} \sum_{p=1}^{N} \mathbf{a}(x_p, y_p, z_p) \cdot \hat{\mathbf{n}}_p \Delta S_p,$$

where it is required that all $\Delta S_p \to 0$ as $N \to \infty$.

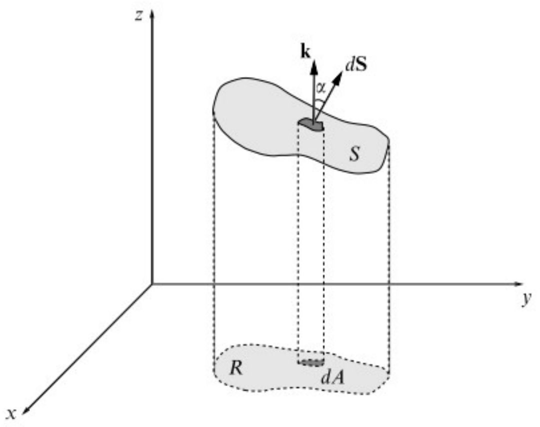

Figure 11.6 A surface S (or part thereof) projected onto a region R in the xy-plane; $d\mathbf{S}$ is a surface element.

11.5.1 Evaluating surface integrals

We now consider how to evaluate surface integrals over some general surface. This involves writing the scalar area element dS in terms of the coordinate differentials of our chosen coordinate system. In some particularly simple cases this is very straightforward. For example, if S is the surface of a sphere of radius a (or some part thereof) then using spherical polar coordinates θ, ϕ on the sphere we have $dS = a^2 \sin\theta \, d\theta \, d\phi$. For a general surface, however, it is not usually possible to represent the surface in a simple way in any particular coordinate system. In such cases, it is usual to work in Cartesian coordinates and consider the projections of the surface onto the coordinate planes.

Consider a surface (or part of a surface) S as in figure 11.6. The surface S is projected onto a region R of the xy-plane, so that an element of surface area dS projects onto the area element dA. From the figure, we see that $dA = |\cos\alpha| \, dS$, where α is the angle between the unit vector $\mathbf{k}$ in the z-direction and the unit normal $\hat{\mathbf{n}}$ to the surface at P. So, at any given point of S, we have simply

$$dS = \frac{dA}{|\cos\alpha|} = \frac{dA}{|\hat{\mathbf{n}} \cdot \mathbf{k}|}.$$

Now, if the surface S is given by the equation $f(x, y, z) = 0$ then, as shown in subsection 10.7.1, the unit normal at any point of the surface is given by $\hat{\mathbf{n}} = \nabla f / |\nabla f|$ evaluated at that point, cf. (10.32). The scalar element of surface area then becomes

$$dS = \frac{dA}{|\hat{\mathbf{n}} \cdot \mathbf{k}|} = \frac{|\nabla f| \, dA}{\nabla f \cdot \mathbf{k}} = \frac{|\nabla f| \, dA}{\partial f / \partial z}, \tag{11.10}$$

where $|\nabla f|$ and $\partial f/\partial z$ are evaluated on the surface S. We can therefore express any surface integral over S as a double integral over the region R in the xy-plane.

►*Evaluate the surface integral* $I = \int_S \mathbf{a}\cdot d\mathbf{S}$, *where* $\mathbf{a} = x\mathbf{i}$ *and* S *is the surface of the hemisphere* $x^2+y^2+z^2=a^2$ *with* $z\geq 0$.

The surface of the hemisphere is shown in figure 11.7. In this case dS may be easily expressed in spherical polar coordinates as $dS = a^2\sin\theta\, d\theta\, d\phi$, and the unit normal to the surface at any point is simply $\hat{\mathbf{r}}$. On the surface of the hemisphere we have $x = a\sin\theta\cos\phi$ and so

$$\mathbf{a}\cdot d\mathbf{S} = x\,(\mathbf{i}\cdot\hat{\mathbf{r}})\,dS = (a\sin\theta\cos\phi)(\sin\theta\cos\phi)(a^2\sin\theta\,d\theta\,d\phi).$$

Therefore, inserting the correct limits on θ and ϕ, we have

$$I = \int_S \mathbf{a}\cdot d\mathbf{S} = a^3\int_0^{\pi/2} d\theta\,\sin^3\theta\int_0^{2\pi} d\phi\,\cos^2\phi = \frac{2\pi a^3}{3}.$$

We could, however, follow the general prescription above and project the hemisphere S onto the region R in the xy-plane that is a circle of radius a centred at the origin. Writing the equation of the surface of the hemisphere as $f(x,y) = x^2+y^2+z^2-a^2 = 0$ and using (11.10), we have

$$I = \int_S \mathbf{a}\cdot d\mathbf{S} = \int_S x\,(\mathbf{i}\cdot\hat{\mathbf{r}})\,dS = \int_R x\,(\mathbf{i}\cdot\hat{\mathbf{r}})\,\frac{|\nabla f|\,dA}{\partial f/\partial z}.$$

Now $\nabla f = 2x\mathbf{i}+2y\mathbf{j}+2z\mathbf{k} = 2\mathbf{r}$, so on the surface S we have $|\nabla f| = 2|\mathbf{r}| = 2a$. On S we also have $\partial f/\partial z = 2z = 2\sqrt{a^2-x^2-y^2}$ and $\mathbf{i}\cdot\hat{\mathbf{r}} = x/a$. Therefore, the integral becomes

$$I = \iint_R \frac{x^2}{\sqrt{a^2-x^2-y^2}}\,dx\,dy.$$

Although this integral may be evaluated directly, it is quicker to transform to plane polar coordinates:

$$\begin{aligned} I &= \iint_{R'} \frac{\rho^2\cos^2\phi}{\sqrt{a^2-\rho^2}}\,\rho\,d\rho\,d\phi \\ &= \int_0^{2\pi}\cos^2\phi\,d\phi\int_0^a \frac{\rho^3\,d\rho}{\sqrt{a^2-\rho^2}}. \end{aligned}$$

Making the substitution $\rho = a\sin u$, we finally obtain

$$I = \int_0^{2\pi}\cos^2\phi\,d\phi\int_0^{\pi/2} a^3\sin^3 u\,du = \frac{2\pi a^3}{3}. \blacktriangleleft$$

In the above discussion we assumed that any line parallel to the z-axis intersects S only once. If this is not the case, we must split up the surface into smaller surfaces S_1, S_2 etc. that are of this type. The surface integral over S is then the sum of the surface integrals over S_1, S_2 and so on. This is always necessary for closed surfaces.

Sometimes we may need to project a surface S (or some part of it) onto the zx- or yz-plane, rather than the xy-plane; for such cases, the above analysis is easily modified.

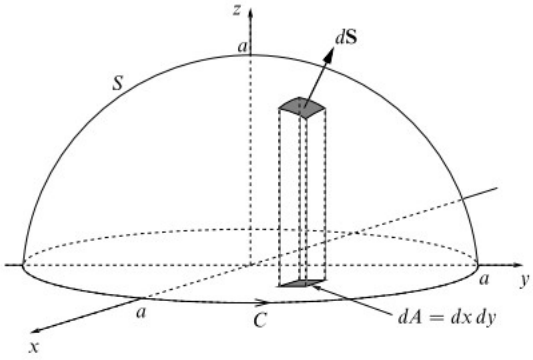

Figure 11.7 The surface of the hemisphere $x^2 + y^2 + z^2 = a^2$, $z \geq 0$.

11.5.2 Vector areas of surfaces

The vector area of a surface S is defined as

$$\mathbf{S} = \int_S d\mathbf{S},$$

where the surface integral may be evaluated as above.

►*Find the vector area of the surface of the hemisphere* $x^2 + y^2 + z^2 = a^2$ *with* $z \geq 0$.

As in the previous example, $d\mathbf{S} = a^2 \sin\theta \, d\theta \, d\phi \, \hat{\mathbf{r}}$ in spherical polar coordinates. Therefore the vector area is given by

$$\mathbf{S} = \iint_S a^2 \sin\theta \; \hat{\mathbf{r}} \, d\theta \, d\phi.$$

Now, since $\hat{\mathbf{r}}$ varies over the surface S, it also must be integrated. This is most easily achieved by writing $\hat{\mathbf{r}}$ in terms of the constant Cartesian basis vectors. On S we have

$$\hat{\mathbf{r}} = \sin\theta\cos\phi\,\mathbf{i} + \sin\theta\sin\phi\,\mathbf{j} + \cos\theta\,\mathbf{k},$$

so the expression for the vector area becomes

$$\begin{aligned}\mathbf{S} &= \mathbf{i}\left(a^2\int_0^{2\pi}\cos\phi\,d\phi\int_0^{\pi/2}\sin^2\theta\,d\theta\right) + \mathbf{j}\left(a^2\int_0^{2\pi}\sin\phi\,d\phi\int_0^{\pi/2}\sin^2\theta\,d\theta\right)\\ &\quad + \mathbf{k}\left(a^2\int_0^{2\pi}d\phi\int_0^{\pi/2}\sin\theta\cos\theta\,d\theta\right)\\ &= \mathbf{0} + \mathbf{0} + \pi a^2\mathbf{k} = \pi a^2\mathbf{k}.\end{aligned}$$

Note that the magnitude of $\mathbf{S}$ is the projected area, of the hemisphere onto the xy-plane, and not the surface area of the hemisphere. ◄

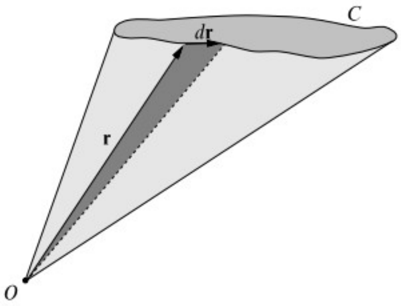

Figure 11.8 The conical surface spanning the perimeter C and having its vertex at the origin.

The hemispherical shell discussed above is an example of an open surface. For a closed surface, however, the vector area is always zero. This may be seen by projecting the surface down onto each Cartesian coordinate plane in turn. For each projection, every positive element of area on the upper surface is cancelled by the corresponding negative element on the lower surface. Therefore, each component of $\mathbf{S} = \oint_S d\mathbf{S}$ vanishes.

An important corollary of this result is that the vector area of an open surface depends only on its perimeter, or boundary curve, C. This may be proved as follows. If surfaces S_1 and S_2 have the same perimeter then $S_1 - S_2$ is a closed surface, for which

$$\oint d\mathbf{S} = \int_{S_1} d\mathbf{S} - \int_{S_2} d\mathbf{S} = \mathbf{0}.$$

Hence $\mathbf{S}_1 = \mathbf{S}_2$. Moreover, we may derive an expression for the vector area of an open surface S solely in terms of a line integral around its perimeter C. Since we may choose any surface with perimeter C, we will consider a cone with its vertex at the origin (see figure 11.8). The vector area of the elementary triangular region shown in the figure is $d\mathbf{S} = \frac{1}{2}\mathbf{r} \times d\mathbf{r}$. Therefore, the vector area of the cone, and hence of *any* open surface with perimeter C, is given by the line integral

$$\mathbf{S} = \frac{1}{2}\oint_C \mathbf{r} \times d\mathbf{r}.$$

For a surface confined to the xy-plane, $\mathbf{r} = x\mathbf{i} + y\mathbf{j}$ and $d\mathbf{r} = dx\,\mathbf{i} + dy\,\mathbf{j}$, and we obtain for this special case that the area of the surface is given by $A = \frac{1}{2}\oint_C (x\,dy - y\,dx)$, as we found in section 11.3.

►*Find the vector area of the surface of the hemisphere* $x^2 + y^2 + z^2 = a^2$, $z \geq 0$, *by evaluating the line integral* $\mathbf{S} = \frac{1}{2}\oint_C \mathbf{r} \times d\mathbf{r}$ *around its perimeter.*

The perimeter C of the hemisphere is the circle $x^2 + y^2 = a^2$, on which we have

$$\mathbf{r} = a\cos\phi\,\mathbf{i} + a\sin\phi\,\mathbf{j}, \qquad d\mathbf{r} = -a\sin\phi\,d\phi\,\mathbf{i} + a\cos\phi\,d\phi\,\mathbf{j}.$$

Therefore the cross product $\mathbf{r} \times d\mathbf{r}$ is given by

$$\mathbf{r} \times d\mathbf{r} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ a\cos\phi & a\sin\phi & 0 \\ -a\sin\phi\,d\phi & a\cos\phi\,d\phi & 0 \end{vmatrix} = a^2(\cos^2\phi + \sin^2\phi)\,d\phi\,\mathbf{k} = a^2\,d\phi\,\mathbf{k},$$

and the vector area becomes

$$\mathbf{S} = \tfrac{1}{2}a^2\mathbf{k}\int_0^{2\pi} d\phi = \pi a^2\,\mathbf{k}. ◄$$

11.5.3 Physical examples of surface integrals

There are many examples of surface integrals in the physical sciences. Surface integrals of the form (11.8) occur in computing the total electric charge on a surface or the mass of a shell, $\int_S \rho(\mathbf{r})\,dS$, given the charge or mass density $\rho(\mathbf{r})$. For surface integrals involving vectors, the second form in (11.9) is the most common. For a vector field $\mathbf{a}$, the surface integral $\int_S \mathbf{a}\cdot d\mathbf{S}$ is called the *flux* of $\mathbf{a}$ through S. Examples of physically important flux integrals are numerous. For example, let us consider a surface S in a fluid with density $\rho(\mathbf{r})$ that has a velocity field $\mathbf{v}(\mathbf{r})$. The mass of fluid crossing an element of surface area $d\mathbf{S}$ in time dt is $dM = \rho\mathbf{v}\cdot d\mathbf{S}\,dt$. Therefore the *net* total mass flux of fluid crossing S is $M = \int_S \rho(\mathbf{r})\mathbf{v}(\mathbf{r})\cdot d\mathbf{S}$. As a another example, the electromagnetic flux of energy out of a given volume V bounded by a surface S is $\oint_S(\mathbf{E}\times\mathbf{H})\cdot d\mathbf{S}$.

The solid angle, to be defined below, subtended at a point O by a surface (closed or otherwise) can also be represented by an integral of this form, although it is not strictly a flux integral (unless we imagine isotropic rays radiating from O). The integral

$$\Omega = \int_S \frac{\mathbf{r}\cdot d\mathbf{S}}{r^3} = \int_S \frac{\hat{\mathbf{r}}\cdot d\mathbf{S}}{r^2}, \tag{11.11}$$

gives the *solid angle* Ω *subtended at* O *by a surface* S if $\mathbf{r}$ is the position vector measured from O of an element of the surface. A little thought will show that (11.11) takes account of all three relevant factors: the size of the element of surface, its inclination to the line joining the element to O and the distance from O. Such a general expression is often useful for computing solid angles when the three-dimensional geometry is complicated. Note that (11.11) remains valid when the surface S is not convex and when a single ray from O in certain directions would cut S in more than one place (but we exclude multiply connected regions).

In particular, when the surface is closed $\Omega = 0$ if O is outside S and $\Omega = 4\pi$ if O is an interior point.

Surface integrals resulting in vectors occur less frequently. An example is afforded, however, by the total resultant force experienced by a body immersed in a stationary fluid in which the hydrostatic pressure is given by $p(\mathbf{r})$. The pressure is everywhere inwardly directed and the resultant force is $\mathbf{F} = -\oint_S p\,d\mathbf{S}$, taken over the whole surface.

11.6 Volume integrals

Volume integrals are defined in an obvious way and are generally simpler than line or surface integrals since the element of volume dV is a scalar quantity. We may encounter volume integrals of the forms

$$\int_V \phi\,dV, \qquad \int_V \mathbf{a}\,dV. \tag{11.12}$$

Clearly, the first form results in a scalar, whereas the second form yields a vector. Two closely related physical examples, one of each kind, are provided by the total mass of a fluid contained in a volume V, given by $\int_V \rho(\mathbf{r})\,dV$, and the total linear momentum of that same fluid, given by $\int_V \rho(\mathbf{r})\mathbf{v}(\mathbf{r})\,dV$ where $\mathbf{v}(\mathbf{r})$ is the velocity field in the fluid. As a slightly more complicated example of a volume integral we may consider the following.

►*Find an expression for the angular momentum of a solid body rotating with angular velocity* $\boldsymbol{\omega}$ *about an axis through the origin.*

Consider a small volume element dV situated at position $\mathbf{r}$; its linear momentum is $\rho\,dV\dot{\mathbf{r}}$, where $\rho = \rho(\mathbf{r})$ is the density distribution, and its angular momentum about O is $\mathbf{r}\times\rho\dot{\mathbf{r}}\,dV$. Thus for the whole body the angular momentum $\mathbf{L}$ is

$$\mathbf{L} = \int_V (\mathbf{r}\times\dot{\mathbf{r}})\rho\,dV.$$

Putting $\dot{\mathbf{r}} = \boldsymbol{\omega}\times\mathbf{r}$ yields

$$\mathbf{L} = \int_V [\mathbf{r}\times(\boldsymbol{\omega}\times\mathbf{r})]\,\rho\,dV = \int_V \boldsymbol{\omega} r^2\rho\,dV - \int_V (\mathbf{r}\cdot\boldsymbol{\omega})\mathbf{r}\rho\,dV. \blacktriangleleft$$

The evaluation of the first type of volume integral in (11.12) has already been considered in our discussion of multiple integrals in chapter 6. The evaluation of the second type of volume integral follows directly since we can write

$$\int_V \mathbf{a}\,dV = \mathbf{i}\int_V a_x\,dV + \mathbf{j}\int_V a_y\,dV + \mathbf{k}\int_V a_z\,dV, \tag{11.13}$$

where a_x, a_y, a_z are the Cartesian components of $\mathbf{a}$. Of course, we could have written $\mathbf{a}$ in terms of the basis vectors of some other coordinate system (e.g. spherical polars) but, since such basis vectors are not, in general, constant, they

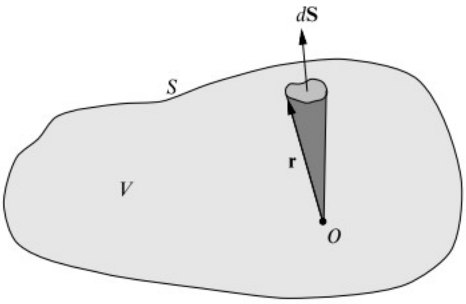

Figure 11.9 A general volume V containing the origin and bounded by the closed surface S.

cannot be taken out of the integral sign as in (11.13) and must be included as part of the integrand.

11.6.1 Volumes of three-dimensional regions

As discussed in chapter 6, the volume of a three-dimensional region V is simply $V = \int_V dV$, which may be evaluated directly once the limits of integration have been found. However, the volume of the region obviously depends only on the surface S that bounds it. We should therefore be able to express the volume V in terms of a surface integral over S. This is indeed possible, and the appropriate expression may derived as follows. Referring to figure 11.9, let us suppose that the origin O is contained within V. The volume of the small shaded cone is $dV = \frac{1}{3}\mathbf{r} \cdot d\mathbf{S}$; the total volume of the region is thus given by

$$V = \frac{1}{3} \oint_S \mathbf{r} \cdot d\mathbf{S}.$$

It may be shown that this expression is valid even when O is not contained in V. Although this surface integral form is available, in practice it is usually simpler to evaluate the volume integral directly.

►*Find the volume enclosed between a sphere of radius a centred on the origin and a circular cone of half-angle α with its vertex at the origin.*

The element of vector area $d\mathbf{S}$ on the surface of the sphere is given in spherical polar coordinates by $a^2 \sin\theta \, d\theta \, d\phi \, \hat{\mathbf{r}}$. Now taking the axis of the cone to lie along the z-axis (from which θ is measured) the required volume is given by

$$\begin{aligned} V = \frac{1}{3} \oint_S \mathbf{r} \cdot d\mathbf{S} &= \frac{1}{3} \int_0^{2\pi} d\phi \int_0^{\alpha} a^2 \sin\theta \, \mathbf{r} \cdot \hat{\mathbf{r}} \, d\theta \\ &= \frac{1}{3} \int_0^{2\pi} d\phi \int_0^{\alpha} a^3 \sin\theta \, d\theta = \frac{2\pi a^3}{3}(1 - \cos\alpha). \end{aligned}$$ ◄

11.7 Integral forms for grad, div and curl

In the previous chapter we defined the vector operators grad, div and curl in purely mathematical terms, which depended on the coordinate system in which they were expressed. An interesting application of line, surface and volume integrals is the expression of grad, div and curl in coordinate-free, geometrical terms. If ϕ is a scalar field and $\mathbf{a}$ is a vector field then it may be shown that at any point P

$$\nabla\phi = \lim_{V\to 0}\left(\frac{1}{V}\oint_S \phi\, d\mathbf{S}\right) \tag{11.14}$$

$$\nabla\cdot\mathbf{a} = \lim_{V\to 0}\left(\frac{1}{V}\oint_S \mathbf{a}\cdot d\mathbf{S}\right) \tag{11.15}$$

$$\nabla\times\mathbf{a} = \lim_{V\to 0}\left(\frac{1}{V}\oint_S d\mathbf{S}\times\mathbf{a}\right) \tag{11.16}$$

where V is a small volume enclosing P and S is its bounding surface. Indeed, we may consider these equations as the (geometrical) *definitions* of grad, div and curl. An alternative, but equivalent, geometrical definition of $\nabla\times\mathbf{a}$ at a point P, which is often easier to use than (11.16), is given by

$$(\nabla\times\mathbf{a})\cdot\hat{\mathbf{n}} = \lim_{A\to 0}\left(\frac{1}{A}\oint_C \mathbf{a}\cdot d\mathbf{r}\right), \tag{11.17}$$

where C is a plane contour of area A enclosing the point P and $\hat{\mathbf{n}}$ is the unit normal to the enclosed planar area.

It may be shown, *in any coordinate system*, that all the above equations are consistent with our definitions in the previous chapter, although the difficulty of proof depends on the chosen coordinate system. The most general coordinate system encountered in that chapter was one with orthogonal curvilinear coordinates u_1, u_2, u_3, of which Cartesians, cylindrical polars and spherical polars are all special cases. Although it may be shown that (11.14) leads to the usual expression for grad in curvilinear coordinates, the proof requires complicated manipulations of the derivatives of the basis vectors with respect to the coordinates and is not presented here. In Cartesian coordinates, however, the proof is quite simple.

►*Show that the geometrical definition of* grad *leads to the usual expression for* $\nabla\phi$ *in Cartesian coordinates.*

Consider the surface S of a small rectangular volume element $\Delta V = \Delta x\,\Delta y\,\Delta z$ that has its faces parallel to the x, y, and z coordinate surfaces; the point P (see above) is at one corner. We must calculate the surface integral (11.14) over each of its six faces. Remembering that the normal to the surface points outwards from the volume on each face, the two faces with $x =$ constant have areas $\Delta\mathbf{S} = -\mathbf{i}\,\Delta y\,\Delta z$ and $\Delta\mathbf{S} = \mathbf{i}\,\Delta y\,\Delta z$ respectively. Furthermore, over each small surface element, we may take ϕ to be constant, so that the net contribution to the surface integral from these two faces is then

$$[(\phi + \Delta\phi) - \phi]\,\Delta y\,\Delta z\,\mathbf{i} = \left(\phi + \frac{\partial \phi}{\partial x}\,\Delta x - \phi\right)\,\Delta y\,\Delta z\,\mathbf{i}$$
$$= \frac{\partial \phi}{\partial x}\,\Delta x\,\Delta y\,\Delta z\,\mathbf{i}.$$

The surface integral over the pairs of faces with $y =$ constant and $z =$ constant respectively may be found in a similar way, and we obtain

$$\oint_S \phi\, d\mathbf{S} = \left(\frac{\partial \phi}{\partial x}\,\mathbf{i} + \frac{\partial \phi}{\partial y}\,\mathbf{j} + \frac{\partial \phi}{\partial z}\,\mathbf{k}\right)\,\Delta x\,\Delta y\,\Delta z.$$

Therefore $\nabla\phi$ at the point P is given by

$$\nabla\phi = \lim_{\Delta x, \Delta y, \Delta z \to 0}\left[\frac{1}{\Delta x\,\Delta y\,\Delta z}\left(\frac{\partial \phi}{\partial x}\,\mathbf{i} + \frac{\partial \phi}{\partial y}\,\mathbf{j} + \frac{\partial \phi}{\partial z}\,\mathbf{k}\right)\,\Delta x\,\Delta y\,\Delta z\right]$$
$$= \frac{\partial \phi}{\partial x}\,\mathbf{i} + \frac{\partial \phi}{\partial y}\,\mathbf{j} + \frac{\partial \phi}{\partial z}\,\mathbf{k}. \blacktriangleleft$$

We now turn to (11.15) and (11.17). These geometrical definitions may be shown straightforwardly to lead to the usual expressions for div and curl in orthogonal curvilinear coordinates.

►*By considering the infinitesimal volume element $dV = h_1h_2h_3\,\Delta u_1\,\Delta u_2\,\Delta u_3$ shown in figure 11.10, show that (11.15) leads to the usual expression for $\nabla\cdot\mathbf{a}$ in orthogonal curvilinear coordinates.*

Let us write the vector field in terms of its components with respect to the basis vectors of the curvilinear coordinate system as $\mathbf{a} = a_1\hat{\mathbf{e}}_1 + a_2\hat{\mathbf{e}}_2 + a_3\hat{\mathbf{e}}_3$. We consider first the contribution to the RHS of (11.15) from the two faces with $u_1 =$ constant, i.e. $PQRS$ and the face opposite it (see figure 11.10). Now, the volume element is formed from the orthogonal vectors $h_1\,\Delta u_1\,\hat{\mathbf{e}}_1$, $h_2\,\Delta u_2\,\hat{\mathbf{e}}_2$ and $h_3\,\Delta u_3\,\hat{\mathbf{e}}_3$ at the point P and so for $PQRS$ we have

$$\Delta\mathbf{S} = h_2h_3\,\Delta u_2\,\Delta u_3\,\hat{\mathbf{e}}_3\times\hat{\mathbf{e}}_2 = -h_2h_3\,\Delta u_2\,\Delta u_3\,\hat{\mathbf{e}}_1.$$

Reasoning along the same lines as in the previous example, we conclude that the contribution to the surface integral of $\mathbf{a}\cdot d\mathbf{S}$ over $PQRS$ and its opposite face taken together is given by

$$\frac{\partial}{\partial u_1}(\mathbf{a}\cdot\Delta\mathbf{S})\,\Delta u_1 = \frac{\partial}{\partial u_1}(a_1h_2h_3)\,\Delta u_1\,\Delta u_2\,\Delta u_3.$$

The surface integrals over the pairs of faces with $u_2 =$ constant and $u_3 =$ constant respectively may be found in a similar way, and we obtain

$$\oint_S \mathbf{a}\cdot d\mathbf{S} = \left[\frac{\partial}{\partial u_1}(a_1h_2h_3) + \frac{\partial}{\partial u_2}(a_2h_3h_1) + \frac{\partial}{\partial u_3}(a_3h_1h_2)\right]\,\Delta u_1\,\Delta u_2\,\Delta u_3.$$

Therefore $\nabla\cdot\mathbf{a}$ at the point P is given by

$$\nabla\cdot\mathbf{a} = \lim_{\Delta u_1, \Delta u_2, \Delta u_3 \to 0}\left[\frac{1}{h_1h_2h_3\,\Delta u_1\,\Delta u_2\,\Delta u_3}\oint_S \mathbf{a}\cdot d\mathbf{S}\right]$$
$$= \frac{1}{h_1h_2h_3}\left[\frac{\partial}{\partial u_1}(a_1h_2h_3) + \frac{\partial}{\partial u_2}(a_2h_3h_1) + \frac{\partial}{\partial u_3}(a_3h_1h_2)\right]. \blacktriangleleft$$

Figure 11.10 A general volume ΔV in orthogonal curvilinear coordinates u_1, u_2, u_3. PT gives the vector $h_1\,\Delta u_1\,\hat{\mathbf{e}}_1$, PS gives $h_2\,\Delta u_2\,\hat{\mathbf{e}}_2$ and PQ gives $h_3\,\Delta u_3\,\hat{\mathbf{e}}_3$.

►*By considering the infinitesimal planar surface element $PQRS$ in figure 11.10, show that (11.17) leads to the usual expression for $\nabla\times\mathbf{a}$ in orthogonal curvilinear coordinates.*

The planar surface $PQRS$ is defined by the orthogonal vectors $h_2\,\Delta u_2\,\hat{\mathbf{e}}_2$ and $h_3\,\Delta u_3\,\hat{\mathbf{e}}_3$ at the point P. If we traverse the loop in the direction $PSRQ$ then, by the right-hand convention, the unit normal to the plane is $\hat{\mathbf{e}}_1$. Writing $\mathbf{a} = a_1\hat{\mathbf{e}}_1 + a_2\hat{\mathbf{e}}_2 + a_3\hat{\mathbf{e}}_3$, the line integral around the loop in this direction is given by
